It is apparent to every one who is familiar with intrapelvic surgery that there is a great difference, in both immediate and remote results, between abdominal and vaginal section. Experience shows that the latter is borne far better than the former. There are less pain and discomfort, there are less likelihood of shock and less danger of septic infection, and the future well-being of the patient is less frequently threatened with uncomfortable sequelæ. Our later statistics show how greatly the death rate has been reduced by the resort to the vaginal route for the performance of operations that were formerly done through the abdomen alone. The reason for this is not far to seek. The peritoneum is a highly absorptive, delicate, and sensitive membrane. It belongs to the lymphatic system, with a most exquisite nerve supply derived from the sympathetic. It is, in fact, a large lymphatic sac, and, covering as it does the intestines and pelvic organs, presents a vast serous surface. Its careful protection, therefore, from infection and injury is of the first importance. It is said, and said truly, that with our modern cleanliness and care the mere opening of the peritoneum is attended with but slight danger. Still it is the initial step of a capital operation, and no man undertakes it without some slight fear. There is danger then, and that danger is increased in proportion to the amount of exposure and disturbance the peritoneal surfaces are subjected to.

By the abdominal route, even with the advantages of the Trendelenburg posture, and even though the greatest care is exercised, there necessarily must be more exposure and more handling of the intestines and other peritoneal surfaces than there could possibly be in the vaginal operation in the same class of cases.

With the greater amount of peritoneal surface exposed, and the lack of immediate and efficient drainage, there must be greater liability to infection and greater possibility of shock. With every source of danger from infection removed, the vaginal operation is borne far better than the abdominal. I have frequently seen a delicate and enfeebled woman go through a severe operation by the vagina that would probably have killed her from shock had it been done by the upper route. There is comparatively very little disturbance of sympathetic-nerve centres by the vaginal operation. It seems to be the more toilsome, though less dangerous route.

Besides the above-named objections to abdominal sections, there may be mentioned a number of other, though in comparison minor ones. The undesirable scar and the danger of ventral hernia should be named first. Then the discomfort and pain of the abdominal incision are no small items. They are in marked contrast, as I have before said, to those of vaginal section. These are the chief terrors to the woman who needs operation. I have often said to a patient: "It will not be necessary to cut open the abdomen. Your operation can be done from below." In nearly every instance this statement has made a marked impression and has been the deciding point in favor of an operation, even when life depended upon it.

I should not omit to mention here adhesions to intestines and omentum which usually follow the abdominal incision. They do sometimes follow vaginal section and may be of serious import. I have twice been obliged to break up adhesions several days after vaginal hysterectomy, in order to save my patient, but this is of the rarest occurrence and is probably due to faulty gauze packing.

To vaginal section the only positive objection that can be urged is that the surgeon must depend to a great extent on the sense of touch, while in abdominal section he has complete control of the whole operative field for both sight and touch. But the answer may be made that to the man skilled in this kind of work sight is not so necessary. The route possesses the great advantage of natural and perfect drainage, which the law of gravity gives to it. To my mind, in all operations in pelvic disease thorough drainage is one of the most important factors.

In regard to the wound in the vagina, it heals rapidly and most kindly and is not attended with the danger of hernia; or I should say, to be accurate, the danger is practically none.

In consequence of these facts, old theories and practices are giving way to new ideas and methods. Many are doing more work by the vagina than ever. There are, however, many others, and excellent operators too, who, with fixed habits of thought and action, uninfluenced by these ideas, are still doing most of these operations by the abdomen. They have learned to do their work well, and, having perfected their technique, are slow to change to methods they are not entirely familiar with. I speak of it here because they are the ones who are retarding the general acceptance of these ideas. They will be carried along, however, by a tendency which no individuality can long resist or greatly modify.

It is impossible to lay down any positive rule and say that such and such work should all be done in one particular way. Each case must be studied and judged according to its indications and merits. Each route will always have its uses.

To every man who has had an extensive experience with the diseases of women, and is skilled in both ways of operating, the question is ever uppermost in his mind: "Can this operation be done per vaginam; and, if so, can it best be done in this way?" The consideration of the upper route is always secondary in his thoughts, for the preponderance of reasons seems to favor the other.

There are but few operations in the pelvis that cannot be done per vaginam. It must be admitted, however, that there are many cases in which this route is not feasible, though naturally indicated.

It is my purpose to take up here, separately, the consideration of the different diseases for which these procedures are resorted to, and to present the histories of a few illustrative cases.

For ovarian and parovarian cysts the abdomen is almost invariably opened. It is my belief that for unilocular and broad-ligament cysts this is not necessary; that they can easily and with less danger to the patient be removed per vaginam. It must, of course, be always kept in mind that the presence of adhesions may interfere with the work, and this route may have to be abandoned for the other. But this can usually be done without hindrance or drawback. The following is an instructive case of the kind:

Case I.—Miss N——, twenty-five years of age. Menstruation regular, coming on every four weeks and lasting three days, and attended with no pain. At the age of twenty she first discovered an enlargement in the lower right side of the abdomen, which has grown steadily up to the present time, reaching several inches above the umbilicus, and filling and distending the whole lower portion of the abdomen. She has very little pain and complains merely of frequent micturition. This is her condition on entering the hospital, February 8th of this year:

Diagnosis, unilocular cyst, ovarian or intraligamentous.

Operation: Posterior vaginal section, uterus to the left and backward. The tumor could be reached with difficulty with the tip of the index finger. The cyst was then grasped with Jacob traction forceps, and a small opening made with blunt-pointed scissors. (I mention all these steps, because they are important.) It was found that an external sac was cut through, and the true cyst could be felt beyond. The external sac could, of course, be nothing but the lower surface of the broad ligament, and the cyst was therefore intraligamentous, either parovarian or intraligamentous ovarian. The contents of the cyst, a pale watery fluid, the true parovarian-cyst fluid, to the amount of about three gallons, were then evacuated. The cyst wall, with its covering, was then secured in the grasp of a forceps and drawn out. With very little difficulty the entire cyst was enucleated, it proving to be a true parovarian cyst. The broad-ligament covering, containing the ovary of the right side, was then clamped with the Skene electric clamp, beyond the ovary and as near to the uterus as possible. Six amperes of electricity were then applied, for a period of three and one-half minutes, and the external portion of the ligament was then cut away. Before the clamp was unlocked care was taken to grasp the stump just above with forceps. As there was no bleeding, after the clamp was cautiously removed the stump was allowed to slip back into the abdomen. Gauze was then packed in the opening. She recovered without incident.

From the experience gained in this case I have formed the belief that intraligamentous cysts can be more easily enucleated by beginning the process from below, where the ligamentous envelope is usually the thickest.

I would say here that I am making a thorough test of Dr. Skene's electric clamps, and, though they have not been entirely successful in every instance in sealing the arteries, still I feel encouraged to continue their use. I am confident that after I have learned thoroughly how to use them, how exactly to regulate the electricity, I shall be entirely satisfied with them. They possess many advantages over every other appliance for hæmostasis. As Dr. Skene says, they are not only hæmostatic—they are antiseptic and aseptic, as they close the lymphatics and by devitalizing the nerves prevent much of the pain caused by the ligatures upon the stumps.

The objection to vaginal ovariotomy, from the possible presence of adhesions, is not of much moment. Ovarian cysts, as we see them to-day, are not large and have not had time, as a rule, to acquire adhesions. Multilocular cysts of small size have been removed through the vagina. It is, however, a different matter with the larger variety, those which have been growing a number of years. Their walls are usually hypertrophic in many places and usually adherent to the abdominal wall, intestines, or omentum. Their removal through the vagina might be accomplished, but it would be a Herculean task and it would be better not to attempt it.

As a marked contrast to the one presented above, I will next relate a case of an immense multilocular cyst.

Case II.—Mrs. H——, aged fifty-six. Admitted to the Woman's Hospital, February 7, 1898. Her menstruation has continued without incident to the time of the menopause, three years ago. She has had one child, born twenty-seven years ago, and one miscarriage at the sixth month a year later. Since the menopause she has flowed at irregular intervals. Two years ago she observed a small tumor in the right inguinal region. This has continuously grown, and has reached its present enormous dimensions, greatly distending the abdomen and interfering with respiration. She has constant pain in the right side, where the tumor first appeared, which is somewhat relieved by lying upon the left side.

Diagnosis, multilocular ovarian cyst.

Operation, on the same afternoon as in the previous case. An abdominal incision large enough to admit the hand, was made and the cyst exposed. The patient was turned upon the left side and the cyst opened with a scalpel. About five gallons of dark grumous fluid was evacuated. The growth could not be removed till the cysts lining its wall had been evacuated by the hand, passed inside the main cyst. The greatest care was taken to prevent any of the fluid contents reaching the abdominal cavity. The cyst wall was hypertrophic at a number of points and adherent extensively to the omentum and intestines. These latter required time and patience in dissecting away and in ligating bleeding points. To the pedicle, which was twisted upon itself several times, the electric clamp was applied. This did not work well, even after two applications, and ligatures had to be resorted to. The patient made a rapid recovery.

This tumor it would have been hazardous and difficult to attempt to remove by way of the vagina. I present it as a type of those cysts for which the abdominal incision is required.

The dermoid cyst of the ovary is usually small, and contains a fluid which is highly dangerous. The rupture of a dermoid will produce fatal peritonitis, and death has followed even the aspiration of one. These cysts can and should be, whenever suspected, removed per vaginam. The following is a report of a case of the kind:

Case III.—Mrs. J——, aged thirty-five. Married ten years; had one abortion at the third month soon after marriage, but has had no children. She consulted me for pain in the pelvis and pressure symptoms. I found, on examination, what appeared to be a retroflexed uterus, the size of a pregnant uterus at three and one-half months. As she had passed over three menstrual periods, I felt sure I had to deal with a retrodisplaced pregnant uterus. It was impossible to replace the mass, even with the patient in the knee-chest position. I then decided to make the attempt under ether. This I proceeded later to do, and it shows what a difference an examination with ether and an examination without makes. With the muscles entirely relaxed, a somewhat enlarged uterus could be made out in front, distinct from a larger mass behind. The diagnosis of extra-uterine pregnancy was made, and later confirmed in consultation, and removal decided upon. Under ether posterior section was made.

The tumor proved to be a dermoid, the size of a cocoanut, which I evacuated and removed without difficulty. The pedicle was clamped. The patient recovered.

Fortunately this proved not to be extra-uterine pregnancy. I have operated many times for that condition through the abdominal incision, but believe it should not be attempted through the vagina. I have seen the attempt made, and the bleeding was so excessive that the patient nearly lost her life before the operator could successfully deal with the case from above. The danger of hemorrhage is so great by the vagina that the question no longer is one for argument.

Large myofibromata can be removed by the vagina. It requires great patience and persistence, and is very exhausting, moreover, to the operator. It is a very long process, and by the quickest operators can rarely be accomplished under two hours. It is of questionable advantage in the light of the perfected technique of abdominal hysterectomy. I have operated in both ways many times, and the result of my experience is that large fibroids, reaching above the umbilicus, are better removed through the abdominal incision; and the smaller ones, when advisable to operate at all, by morcellation from below. It rarely takes more than an hour and a half to remove even the largest fibroids through the abdomen, and that is the limit of time, as a rule, that a patient should be under ether. In cases in which it is possible to do myomectomy, the work should naturally be done from above. In removal of intraligamentous fibroids, the work should be done from above. The danger of hemorrhage is generally too great to admit of the attempt from below.

Case IV.—Miss S——, aged twenty-five. Admitted to the Woman's Hospital, February 25th. Menstruation of the twenty-eight days type, lasting two days and without marked pain. She complains of pain in the left side and left inguinal region, aggravated by exertion in walking or standing for any length of time. She complains also of pain and soreness low down in the pelvis. She has felt for some time a small mass in this locality. She has also had a discharge of blood and mucus from the rectum, and complains of weight, soreness, and pressure there.

Examination disclosed a hard tumor, the size of a large-sized orange, to the left and backward of the uterus, crowding the uterus forward and to the right. Above this and a little to the right of the median line was what appeared to be an oblong cyst. The tumor and uterus were bound firmly together and fixed in the pelvis; the cyst above was slightly movable.

Diagnosis, intraligamentous fibroid of the uterus, with possible hydrosalpinx.

Operation, February 28th. After thorough curettage the abdomen was opened; the omentum was found adherent to the parietal peritoneum and greatly thickened. A large, dense, fibrous band was encountered, firmly binding the parietal peritoneum to an oblong fluid tumor beneath and to the right. This tumor proved to be an ovarian cyst. Such a dense mass of organized exudates so covered the solid tumor, bladder, and uterus that it was impossible to make out at first just where the bladder and uterus were. A sound was first introduced into the bladder to indicate its position, and then into the uterus. By great care the bladder was stripped up from its attachment to the uterus. The internal junction of the broad ligament near to the uterus, on the right side, was then tied with catgut, and next the external extremity of the broad ligament. This was done to cut off the blood supply of the ovarian artery of that side. The upper border of this densely thickened broad ligament was then cut through, and, after an inch and a half of thickened cellular tissue was worked through the capsule of the tumor was reached. This was cut through and the fibroid enucleated as far as possible, then grasped with a volsellum and drawn out. It was found attached so thoroughly to the whole posterior surface of the uterus and so firmly that it would have been impossible to remove it without removing the uterus also. This was decided upon and with difficulty performed, but successfully. I think I have never met a case more difficult to deal with. The patient recovered.

Very small fibroids attached low down it is possible to remove through the vagina. I have removed successfully a small-sized fibroid, larger than an English walnut, that was attached to the anterior wall of the uterus, at about the level of the internal os. By anterior section, the bladder being separated from the uterus, it was readily reached and removed after ligation.

As regards cancer of the uterus, I can conceive of no circumstances which should favor abdominal hysterectomy. If a cancerous uterus cannot be removed per vaginam, it has reached a stage where operative interference is not justifiable. For operable cases fully as thorough and complete work can be done by the lower route. It is, I might say, inconceivable for a vagina to be found too small or too contracted to admit of the operation being done through that channel. When it is very small it is not a difficult or an objectionable practice to enlarge it by incision. The so-called sacral method, devised by Kraske, and the approach through a transverse incision of the perineum, the recto-vaginal septum being divided, are ingenious, but are rarely practised at the present day and are better relegated to oblivion.

With tuberculous conditions of the ovaries and tubes I have had too little experience to come to positive conclusions, but as far as it goes it is in favor of the abdominal route in dealing with them.

Cystic ovaries and small solid tumors of the ovary can easily be dealt with through the vagina.

We next come to the consideration of the treatment of suppurative diseases of the pelvic organs, which form the largest proportion of the diseases of women. It is in this field that the greatest advances have been made, and which began with our emancipation from the long-cherished theories regarding pelvic inflammation. It is my purpose here to trace a short outline of the predominant idea, which asserted itself successfully and shaped for years the study and treatment of pelvic diseases. It is hardly necessary for me to use the term cellulitis. It is understood before being spoken. It dominated every thought upon the subject. As I look back upon all the years during which we were in a state of stupor over the matter, our density seems inconceivable, when, with the light of the present, we can with such ease trace step by step, from beginning to end, all gradations in the advancement of pelvic inflammation. Many of us can remember case after case in which little or nothing was done, simply because we knew nothing to do for cellulitis.

As house surgeon to the Woman's Hospital in 1872, I was directed not to admit cases of the kind. Now they fill at least half our beds. The possibility of cure was rarely entertained. The hot-water douche was advised more as a palliative than from any hope of its permanent effectiveness. As a rule, when we had such a case, attempts were made by local treatment to cause absorption, but little was accomplished. Local treatment was kept up as a routine, in an aimless way, merely for the sake of doing something. The situation was puzzling and hopeless.

The solution of the problem came with the revelation of the fact that infection, beginning in a tube, passes through the fimbriated extremity to the peritoneum, and from there spreads to all the pelvic structures, and that the extent of the disease depends upon the progress and virulence of the poison. This reve-

lation at once opened a vista of grand possibilities, of which the end is not yet. The idea was taken up and acted upon with enthusiasm, and involved a recession along the whole line of surgical thought and procedure. The removal of tubes and ovaries became the popular fad of the day. Naturally surgical abuses would and did follow. But, in spite of the harm that has been done by unnecessary operations and the sacrifice of ovaries and tubes, great good has resulted. Great and permanent advances have been made both in knowledge and in treatment, great technical difficulties and perplexities have been overcome, and knotty questions have been settled. This could not have resulted except through the work of the vast army of operators. In passing judgment, therefore, we must not forget that it was an entirely new field, and that in the establishment of a new country the pioneer must precede the settler. Our knowledge of pelvic pathology is entirely from the work of the gynæcologist. Candid justice on the part of the general surgeon would grant a cordial recognition of this fact. The gynæcologist as such has not yet finished his work. He is still a necessity. The general surgeon, as a rule, is not at home with the vaginal management of pelvic disease, and it is by this route that the great bulk of pelvic surgery is being done to-day. That the general surgeon will become skilled in the vaginal method is to be expected and wished. Were I beginning my professional life now, I should strive to fit myself for the whole scope of surgical work, and this, I think, should be the aim of every young surgeon to-day. The time is likely to come when gynæcology and other surgical specialties are likely to be unknown as such. There are no new fields to conquer. Nothing but the perfecting of technique remains, with the sundering of fetters that bind to fixed methods, and the qualifying one's self to choose that which promises the greatest immediate and permanent good of each individual patient.

After our awakening from the long and restless night of pelvic cellulitis, when it was discovered that many cases of pelvic inflammation were cured by the removal of diseased ovaries and tubes, it was hoped that the problem had been solved. Experience, however, soon taught that there were many patients, with ovaries and tubes alone affected, who would be entirely cured; that others continued to suffer and were relieved only by removal of the uterus; that other cases were even made worse by operation, from leaving behind in the stump a portion of the septic tube or tubes which set up around them a secondary peritonitis. All who have been interested in pelvic surgery will remember such experiences.

Through the abdominal incision it is an easy matter to remove diseased ovaries and tubes that contain no pus. It is different when one has to deal with pyosalpinx, knowing that the spilling of a drop of pus may cost the patient her life. We have all had patients survive and patients die under such conditions. The pus may be sterile or it may not. It is a treacherous thing to enter the peritoneal cavity. I remember many cases in which pus was spilt, and after thorough washing out with decinormal salt solution the patients recovered. I remember others that died, even after thorough irrigation. I remember a case in which pus was spilt and several inches of the sigmoid removed on account of injury, and yet this patient recovered and is well to-day. I have records of cases in which primary operations were performed for the removal of ovaries and tubes, and secondary operations had to be performed at a later period for removal of the uterus. I also have lists of cases in which the abdomen has been opened for the removal of pus tubes, and, there being large abscesses on one or both sides, with all the pelvic organs thoroughly agglutinated and intestines firmly attached by dense adhesions, the abdomen was immediately closed and the abscess cavities were perforated and drained from below. All these add to our experience and teach the dangers of abdominal and the advantages of vaginal section. A short history of one or two here may be of some interest.

Case V.—Mrs. T——, married first at the age of twenty. Her menstrual life was uneventful up to this time. Several years after marriage she suffered from specific infection. She never had been pregnant. She lost her husband after four years of married life, and had been married for the second time a few months before I first saw her. She gave a history of pelvic abscess rupturing into the rectum several times. She was emaciated and a physical wreck. Examination disclosed a uterus somewhat enlarged, with masses on both sides fixed and firmly adherent in all directions. Her temperature was 104° F., and pulse above 100. I decided upon operation as soon as possible. The abdomen was opened and disclosed large tubo-ovarian abscesses on both sides, with the intestines bound to them with dense adhesions. I felt it would be death to attempt to enucleate these abscesses and break up the adhesions. I therefore closed the abdomen and drained both abscesses from below. This woman recovered after several months, and is now, five years after operation, apparently perfectly well. She menstruates regularly without pain, and the uterus is perfectly movable, all the exudates having apparently been absorbed.

I could repeat this picture many times, as I have had a large number of cases almost identically like it.

I have one still under my care now in which I attempted to remove an ovarian abscess by posterior vaginal section, and, finding the tumor high up and above the broad ligament, opened the abdomen to see what I could do in that direction. I found quite a large ovarian abscess with adherent intestines. I felt that I might possibly enucleate this tumor, but its walls seemed too thin for the attempt. Therefore the abdomen was closed, the sac perforated from below, and drained with a double drainage tube. About eight ounces of pus was evacuated. A culture was made, and a staphylococcus and a diplococcus which responded to the Gram stain were discovered. It is now four weeks since the operation, and the patient is continuing to do well. If possible to do so I keep in drainage tubes, as a rule, about six weeks, or as long as pus continues to flow in appreciable quantities. I feel that if I had not treated this patient in this way I should have lost her. I should have ruptured the cyst had I attempted its removal, and peritonitis would have undoubtedly followed.

Case VI.—Mrs. S——, aged twenty-eight. Married three and one-half years. Normal menstrual periods up to that time. One miscarriage at third month, several months after marriage. One year after marriage she had pelvic peritonitis, probably from specific infection, and was confined to bed for six weeks. Examination disclosed a large globular mass on the left, displacing the uterus to the right, and another smaller mass low down in the pelvis and to the right.

Diagnosis, double tubo-ovarian abscess.

Operation, February 23, 1898. The patient was placed under complete anæsthesia by Dr. Bennett in three minutes, beginning with nitrous oxide, followed by ether, with a Clover inhaler. Posterior section was made, and examination showed that both sides were hopelessly diseased and that total extirpation was the proper operation to perform. The bladder was separated from the cervix, the circular incision was made complete about the cervix, the uterine arteries were clamped, the cervix was cut away from the clamps and amputated high up, and the body of the uterus then drawn down with Jacob traction forceps. The large

pus sac on the left side was evacuated and its cavity thoroughly washed out with peroxide of hydrogen and salt solution. The body of the uterus was then bisected, to facilitate removal of the pus sac from the left side. This was treated with the Skene electric clamp, together with the left half of the uterus. The right tubo-ovarian abscess was removed entire, with the right half of the body of the uterus. It is now the ninth day since the operation, and the patient is recovering without incident.

Case VII.—Mrs. G——, aged twenty-six. Admitted to the Woman's Hospital, January 15th. Married one year and four months. Normal menstrual life up to that time. One child, born five months ago. Labor tedious and difficult. Instruments were applied under chloroform, and she has never been well since the birth of the child; she was in bed six weeks, and has lost about twenty-five pounds. The last eight weeks she has been having a temperature running from 102 to 103° F. She is thin, anæmic, and complains of constant pain in the left side and groin. Menstruation is at present regular and normal in amount. The sphincter ani was torn at the birth of the child, and she has no control over the movements of the bowels. Examination disclosed laceration of the cervix and complete laceration of the perineum. In the pelvis to the left of the uterus was a large globular mass, which was diagnosed as ovarian abscess.

Operation, January 17th. Posterior section was made after thorough curettage and packing of the uterus with gauze. An ovarian cyst was found upon the right side, thoroughly fixed by adhesions. The right ovary and tube were found to be healthy. Gauze was packed in the cavity backward and to the right; the cyst wall was then drawn down with a large hook as far as it was possible to do so, which was a very slight distance, and opened with a scalpel. About one pint of foul-smelling pus was evacuated. The cavity of the cyst was washed out with hydrogen peroxide and then with salt solution. The cyst wall was then grasped with forceps, the adhesions being broken away as the cyst was drawn out. The entire cyst wall was removed, together with an apparently perfectly healthy tube. A Jacob clamp was then applied and the tumor cut away. The pelvic cavity was then washed out with peroxide of hydrogen and salt solution, the cavity packed with iodoform gauze, and the patient put to bed in fair condition. She made a rapid recovery and left the hospital three weeks after operation, to return later for the necessary plastic work on the cervix and perineum. I was somewhat concerned for the other tube and ovary, fearing secondary infection. There was no evidence of trouble at the last accounts.

There is a class of cases which are frequently met with, that it is most puzzling to know just how to manage. I refer to tubal or tubo-ovarian abscess, that has opened into the rectum or some other portion of the intestine and is constantly discharging. There is great danger in performing hysterectomy by either route. I prefer to make posterior vaginal section and attempt to reach the abscess cavity, and in this way divert the drainage channel into the vagina, hoping either to cure the case by drainage alone or to prepare the way for a subsequent hysterectomy. The following case is a typical one of the kind. I give but a brief outline of the salient points.

Case VIII.—Mrs. H——, thirty-five years old, gave the history of about five years of pelvic disease, evidently from specific infection. An abscess opened into the rectum, and discharged at short intervals for more than a year. She was emaciated and in a wretched state of physical and mental ill health.

Examination disclosed a uterus fixed in the pelvis, with somewhat hardened globular masses in each broad ligament; there was a small fibroid in the right horn of the uterus, and all were enveloped in dense masses of exudate. There was an evening elevation of temperature, though not great, each day. She was losing ground rapidly, and it was evident that something must be done. I therefore decided to operate without delay. As it was a case in which I did not wish to take responsibility alone, I sought the counsel of a friend whose experience is large and for whose opinion I entertain the highest respect. Yielding to his advice, I opened the abdomen, with great misgiving, feeling satisfied in my own mind that it would not be the wisest plan to operate in that direction. I found just the condition I had expected—the whole pelvic contents fixed as in a vice, with intestines and omentum firmly adherent to them and shutting them off completely from the general peritoneal cavity. The opening of the abdomen served a good purpose in disclosing the fact that the abscess had undoubtedly opened into the rectum. I never under any circumstances disturb such a condition from the abdominal side. I therefore closed the incision at once, then placed the patient in the lithotomy position, and made posterior vaginal section, reaching and draining two pus cavities, one on either side, with a double rubber drainage tube. The patient recovered from the operation without any bad symptoms, and three months later had gained twenty-five pounds. For several weeks there was discharge of fæcal matter through the drainage tube, which gradually diminished till it ceased entirely. The drainage tube was removed at the end of six weeks. The vaginal opening was kept patulous by dilatation every few weeks, as long as there was any discharge of pus. The rectal fistula was opened twice by the dilatation, but closed immediately. At the end of six months the vaginal opening was closed and the patient was in apparently perfect health. It is ten months since the operation, and on examination very lately I found great changes in the pelvic condition. The uterus was still a little fixed. There had been a gradual absorption of the exudates, the masses on either side had entirely disappeared, and the infiltration in the broad ligaments was almost entirely gone. All the sensitiveness to pressure had disappeared. Moreover, she menstruated regularly and without pain, something she had not done for years. It is as complete a recovery as could have been expected from total ablation, and certainly more satisfactory to the patient.

In this connection I will mention another case with a similar history and a pelvic condition almost identical. It was treated in exactly the same manner, except that a secondary operation was subsequently required.

Case IX.—Mrs. M——. Every atom of pus was drained from the pelvis. She recovered from the operation, but did not improve so rapidly as the previous patient. She continued to suffer with pain in the pelvis and with pressure symptoms. At the end of a year examination showed marked absorption of exudates and disappearance of the mass upon the left side where the abscess cavity had been. The right broad ligament was still thickened and sensitive to the touch. It was decided that hysterectomy would be necessary to give her relief. Vaginal hysterectomy was therefore performed. The uterus, which was more or less fixed, was removed by morcellation, together with a large thickened tube from the right, which, however, contained no pus. There was no distinguishable trace of abscess cavity on the left. Complete relief and recovery followed.

I have selected the above cases as illustrations of types constantly met with and for the lessons they teach. True conservatism should certainly be our guide, and its principles should always be applied, when practicable, in the treatment of disease. Certainly no treatment could be simpler or more conser-

vative than the drainage of pelvic abscess of whatever kind, and no one will deny that, in several of the cases related above, the cure, when this method was employed, was as complete and as satisfactory as if the severest radical operation had been performed.

I would say here, by way of parenthesis, that in pelvic abscess, when it has been decided to perforate and drain through the vagina, it is safer to perforate directly through the vaginal vault, rather than first to make posterior section. This is specially advisable when there is disease on one side only. There is less danger of the spreading of infection to other parts of the pelvis.

If I were to lay down any fundamental rule, I am fully persuaded that in regard to pus tubes I should say: "Never open the abdomen for their removal." There are, of course, occasions when it may be advisable to open the abdomen, in cases of pyosalpinx, for the purpose of exploration; for example, when the complication with appendicitis is suspected, or when it is feared that a pus tube has opened into the intestine high up. Then, the abdomen having been opened, the question of "Which route?" assumes an entirely different aspect. Even then I would avoid every possible risk of spilling a drop of pus in the abdominal cavity, and would close the abdomen and operate through the vagina rather than run that risk. I have done so a number of times, and have never regretted it. I have very little faith in so-called conservative surgery, as applied to the removal of portions of ovaries and tubes, when there has been pus disease. I have known of many cases of secondary infection after abdominal section, due to this application of conservatism. This does not apply with the same force in posterior vaginal section, which has the advantage of perfect drainage.

In most of these pelvic diseases I believe the principles of conservatism can be applied with nearly as little difficulty by the vagina as by the abdomen. It can be decided by this route whether a tube is in a condition to be left or to be removed with almost as little difficulty. When it is decided to remove one and leave the other, it is safer to remove it per vaginam, and it lessens the risk of secondary infection.

In the large majority of cases there is no liquid pus. The tubes are enlarged and thickened by infiltration, and often firmly adherent to adjacent parts. These tubes are far more easily freed from their attachments through the vagina, even from their adhesions to intestines, and with less risk of injury to them. It may seem paradoxical, but I am satisfied by many trials that it is easier and safer to separate these adhesions by enucleation and traction from below, rather than by enucleation and traction upon intestines from above. And I have seldom failed to remove all of the diseased tubes and ovaries.

When a tube has opened into the rectum and is still discharging, it would not be advisable to remove it entire. When it cannot be reached and drained, it is best to do a hysterectomy and clamp off this tube as near as possible to its attachment to the gut, and leave the rest to nature. This I have lately done successfully. It could not have been done without too great a risk through the abdominal incision.

I think it is a mistake to say that as clean and thorough surgery cannot be done through the vagina. I do not think it necessary or wise to be indifferent as to leaving pus tubes to break down and come away after hysterectomy. I think that no portion should be left, but that the extirpation should be made as complete as possible; that when the vaginal vault closes there should be nothing left in the pelvis to produce future trouble. When it is possible to do so, I believe the uterus should always be saved. It is idle to say that as its function has ceased it is no longer necessary. Experience is teaching us that there are vasomotor disturbances that are prevented by its retention. I believe that often what appears to be a hopelessly diseased uterus can be cured by curettage and drainage, and even when the infection has been from gonorrhœa. Many are reporting such cases, and to substantiate the statement I need but to recall the history of the severe cases mentioned above, of double pelvic abscess with diseased uterus, that were cured by curettage and drainage.

My experience warrants me in asserting that for the surgical treatment of diseases of the pelvis due to infection it is rarely necessary to open the abdomen.

APPENDICITIS.[1]

By EDMUND M. POND, M.D.,

RUTLAND, VT.,

SURGEON TO THE RUTLAND HOSPITAL; CONSULTING SURGEON TO THE PROCTOR HOSPITAL.

It is not my intention to-day to review the history and all the details concerning appendicitis, but to come at once to the important parts, *i.e.*, pathology, symptoms, diagnosis, and treatment.

For convenience we will divide appendicitis into:

1st. Simple inflammation of the mucous membrane of the appendix, resulting in resolution—so-called catarrhal appendicitis.

2d. The same with or without the formation of calculi, either resulting in resolution or going on to gangrene and perforation.

3d. A class of cases which rapidly within twelve or twenty-four hours goes on to gangrene and perforation, with peritonitis or septicæmia.

4th. A type characterized by rapid lymphatic poisoning, in which neither gangrene, nor perforation, nor peritonitis is present.

5th. Appendicitis abscesses.

6th. Chronic appendicitis.

In the first class of cases we have an inflammation of the mucous membrane with a proliferation of cells and leucocytes. The organ is swollen and congested, and its calibre, reduced in size, soon becomes filled with the products of inflammation. If the microbic infection is not severe and the position of the organ is favorable for producing drainage, the attack may result in resolution; if not, it passes into the second form.

In this the appendix, attempting to expel its contents, rolls up fæcal matter. The calculi as they increase in size produce pressure and gangrene, or the inflammation may subside and leave the appendix with the calculi in position to start up a second attack. Even if calculi are not present, the disease may go on to gangrene and perforation.

The third class of cases is very rapid in its course. The rapidity may be due to the microbic infection, to rapid gangrene and perforation resulting from previously formed calculi, to the twisting of the appendix, or to embolism of its only artery. As perforation occurs we have protective peritonitis, which walls off the septic appendix; but the infection may be so rapid and so virulent that adhesions are unable to form, when general septic peritonitis results. To illustrate:

Willie, aged ten years, fell while skating. The following day he had severe pain in the abdomen, and in the evening his physician was summoned. The following day I saw the case and confirmed the diagnosis of appendicitis. An operation was performed that afternoon. When the abdomen was opened pus and sero-pus welled up in large amount. The intestines were as red as beefsteak and were covered in places with lymph, white and glistening. Only one

[1] Read before the Rutland County Medical Society, July, 1897.

adhesion was present, where the appendix, resting against the omentum, had formed a little groove for itself. This adhesion was not strong enough, for the appendix had perforated itself and had emptied its contents into the abdominal cavity. The abdomen was full of sero-pus. After a thorough flushing and the removal of the appendix, a tube was carried into the pelvis and gauze was inserted in various directions. On

FIG. 1.—*a*, Perforation; *b*, position of calculus just below; *c*, calculus.

the second day these were removed. The external and deep wound granulated, and a slow recovery followed.

A case following a previously formed calculus is well illustrated by the following:

Mrs. W——, aged thirty-eight years, one year ago had a very mild attack of catarrhal appendicitis. When she was seen by me at that time I had some doubt regarding the diagnosis, but after hearing the history of the case I agreed with the attending physician, though I decided to defer the operation. She made a rapid recovery. One year later, while on a visit, she was seized with agonizing pain in the right iliac region, with other symptoms of appendicitis. Returning home by train, she summoned her physician, who called me the following day. An immediate operation was performed. Pus was everywhere in the pelvis—the abdomen and the intestines were bathed in it. In the search for the appendix, which was postcæcal and pointed upward, an abscess partly protected by adhesions was opened. The appendix was gangrenous in places and a large perforation was present. At the opening a large calculus was found (see Fig. 1). The abdomen was drained with gauze, most of which was removed after twenty-four hours. At the end of two weeks the patient was doing well. In the third week fever came on, associated with increasing swelling in the right side, which swelling corresponded in position to the outer and under surface of the ascending colon. The temperature rose to 105° F., the pulse to 110, where they remained for some ten days. At its height the swelling was the size of a kidney. Exploration failed to reveal pus. Finally the swelling subsided and the patient made a good recovery.

The next class, those in which rapid lymphatic poisoning follows, without perforation, gangrene, or peritonitis, is illustrated by the following. In considering this case let us remember that the lymphatics of the appendix empty directly into those of the mesentery of the small intestines.

Lizzie, aged seven years, was taken with severe pain in the abdomen, which soon became localized in the right iliac fossa. The temperature and pulse were accelerated, the face was anxious, the eyes were sunken; tenderness and pain were well marked over McBurney's point; there was tension of the right rectus muscle; the bowels were constipated and there was some vomiting. The bowels were moved by a laxative. An operation was advised after twenty-four hours, but was refused; finally consent was granted after forty-eight hours, on account of increasing symptoms. The appendix was found inflamed, tense, and congested. The lymphatics all through the mesentery of the small intestines were enlarged. No peritonitis, pus, or gangrene was present. After the removal of the appendix a small piece of gauze was carried over its stump. This was removed at the end of twenty-four hours. The patient seemed comfortable and appeared well, except for the facial expression, *i.e.*, sunken eyes, pinched nose and face. The pulse was good, from 90 to 100, and the temperature was normal. The patient rapidly failed and died that night.

Here there was acute lymphatic septicæmia. It was beyond the appendix and in all the lymphatic system. She died with apparently normal pulse and temperature. Examination of the appendix showed inflammation of its mucous membrane. The organ was distended and very tense. (Fig. 2 illustrates the appendix and a mesenteric gland.)

It is very important that we bear in mind the position of the appendix in the majority of cases. It is situated either postcæcal or below the cæcum; it may also be anterior to or to the right of the cæcum, sometimes occupying the pelvis or pointing to the opposite side. If it were always anterior to or to the outer side of the cæcum, we could delay operation until adhesions formed and pus gathered; but, since in the greater number of cases it is deeply seated, we are not safe in taking this stand. In a large number of cases McBurney's point is a reliable guide, but we do sometimes have cases when the pain is localized upon the left side. In these the appendix is long and its apex occupies the posterior cul-de-sac or opposite side.

John, aged twelve years, received a blow in the abdomen over the appendix. For two weeks after he had stomach disturbances and pain in the right side. While at a circus he was taken with severe abdominal pain and vomiting. Two days later I saw the boy, with his physician, and found the symptoms as follows: slight rigidity of the right rectus muscle, more in its upper half; iliac region free from swelling; and the usual symptoms of appendicitis, with but slight pain upon deep pressure. Occupying the posterior and outer part of the abdomen, just below the right kidney, was a swelling, with extreme rigidity of the posterior muscles. At a point two inches below the kidney a spot was present which was as sore as a boil. Diagnosis of appendicitis, with appendix pointing backward and upward, was made. Operation was performed at once, an anterior abdominal incision being made. The appendix was deep seated, surrounded by pus and by thickened tissue. The apex of the appendix corresponded exactly to the sensitive spot below the kidney. The appendix was split transversely and was gangrenous; at the opening a bean-shaped fæcal calculus was found. The tissues around were also gangrenous. After the removal of the appendix a gauze drain was carried down to the abscess cavity and to the stump of

FIG. 2.—*a*, Appendix; *b*, mesenteric lymphatic gland.

the appendix. The gauze was removed the third day. The following day a small fæcal fistula occurred. It was surprising to note the rapid improvement which followed the opening, with free intestinal drainage. The opening discharged for some weeks and finally closed. The patient made a good recovery. (Fig. 3 shows appendix and contents.)

The form of microbic infection also plays an impor-

tant part: the bacillus coli communis, which is found in the mucus of the colon, the streptococcus, and the staphylococcus seem to be the important agents. Why it is that we have in one case a mild infection, and in others a severe one resulting in death in a few days, we are unable to say. Even in mild cases, when recovery follows, we may have cicatricial contraction,

Fig. 3.—*a*, Position of calculus; *b*, perforation; *c*, calculus.

producing strictures, which favor the formation of calculi; or we may have calculi already formed. When these conditions are present, other attacks are almost sure to follow.

The three cardinal symptoms of appendicitis are pain, localized tenderness, and muscular rigidity. The pain, lancinating, colicky, and paroxysmal, is at first located in the umbilical or epigastric region, but soon becomes fixed in the right iliac reigon. Localized tenderness is always present and follows localization of pain. In the majority of cases it is located at McBurney's point, but occasionally it is over the under surface of the liver, posteriorly below the kidney, or in the left side. If the organ is seated deep, it may require deep palpation: and if pointing inward or toward the pelvis, it may require rectal examination.

Rigidity of the abdominal muscles follows localization of pain. As a rule, it is confined to the right rectus muscle, but also may affect others. Other symptoms of less importance are acceleration of pulse and rise of temperature. To illustrate what severe lesions may be present without these symptoms, I will state the following:

William, aged fifty-five years, had for a week attacks of colicky pain, mostly localized at the umbilicus. During this time he was working. At last the attacks became so severe that he went to bed. Tenderness was most marked over McBurney's point, and the pulse and temperature were normal. On the sixth day a swelling occurred, which disappeared on the eighth. I saw him on the eighth, when his symptoms were as follows: pulse and temperature normal; tenderness and rigidity on the right side; no tumor; stupor, with slight delirium. When the abdomen was opened there was a gush of pus and fæcal matter, the abdomen being filled. The appendix, located at the lower and inner side of the cæcum, looked like an angleworm after having been chewed by fish. Above in the cæcum was an opening nearly two inches in diameter. An abscess sac with adhesions was below the cæcum, and a second one was postcæcal. The abdomen was washed out and gauze drainage was carried to the pelvis, to each abscess, and to the free abdominal cavity. The opening in the cæcum was stitched to the external wound to form an artificial anus. The gauze was gradually removed, some remaining for a week. The wound granulated, and all that remained unhealed was the artificial opening. This opening was directly opposite the ileo-cæcal valve, and the valve pouted out through the folds of the cæcal mucous membrane. Several attempts were made soon afterward to close the opening, but so much cicatricial tissue was present and the current from the ileum came so directly against it that failure resulted. It is now two years since the operation, and the fæcal opening has contracted until it is now about three-fourths of an inch in diameter, and the tissues around it are soft. The patient refuses to have it closed, because he enjoys such good health.

In this case, just before the operation an enema was ordered to unload the intestines, but none of it returned. As was seen afterward, it passed through the opening in the cæcum into the general peritoneal cavity.

We may have perforation, gangrene, and even septicæmia, with but little acceleration of pulse or rise of temperature.

S——, aged thirty-four years, a bookkeeper, was taken with severe pain in the abdomen while at work. I saw the patient the same evening, and with his physician and other counsel advised an immediate operation. The symptoms were mild: temperature and pulse but little above normal, slight muscular rigidity, and little localized pain. It was thought advisable to defer an operation, and that it probably would not be needed. The family physician the following morning advised an operation, although the patient was no worse. When the abdomen was opened the appendix was found gangrenous and surrounded by pus; a perforation the size of the finger was present at the base, and a gangrenous area of one and one-half inches in diameter in the cæcum. This was excised and the opening in the intestine closed by three rows of fine silk suture (Lembert). A gauze drain was carried to the abscess sac and cæcum, and was removed in forty-eight hours. Rapid recovery followed. Fig. 4 shows the appendix.

D——, aged thirty-five years, was taken with severe abdominal pains. For thirty-six hours he walked the floor, thinking he had colic. At the end of that time his physician saw him and diagnosed appendicitis. The patient was ordered to bed and given large doses of morphine, which, after a while, controlled the pain. The following day I saw the case. The symptoms were: pulse, 130; temperature, 103° F.; respiration rapid; abdomen enormously distended, marked rigidity and localized tenderness. Upon opening the abdomen pus was found everywhere. The pelvis contained a quart or more, and the intestines were bathed in it. Below and posterior to the cæcum were circumscribed abscesses partly shut off. The appendix was gangrenous and perforated, and contained two calculi. The omentum and intestines in contact with the appendix were also gangrenous. The abdomen was flushed and packed with gauze. As soon as possible after the operation cathartics were given, but no action was obtained. The pulse was full and gradually fell in twenty-four hours to 80; the temperature was normal. This condition was followed in twelve hours by collapse and death.

This illustrates postoperative septicæmia with normal pulse and temperature. Acceleration of pulse and rise of temperature often indicate the severity of the attack, but too much security must not be placed upon their absence. Vomiting may or may not be present with the first symptoms. If it is present it generally subsides after localization of tenderness. If vomiting continues and becomes stercoraceous in character and is

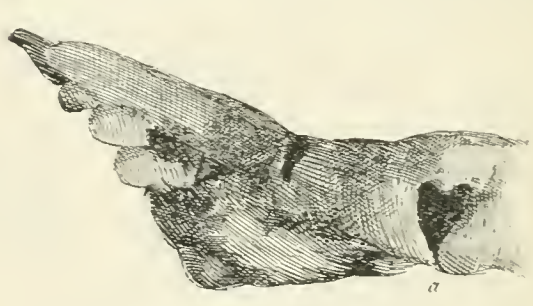

Fig. 4.—*a*, Perforation.

thrown off by regurgitation, such a state indicates a fatal termination. As a rule constipation is present, but diarrhœa may supervene. The abdomen may be distended, due to the retention of gas from constipation or paralysis of the intestines; or it may be flat, as in some septic cases. A tumor, if present, is of importance, but it is absent in a large proportion of the cases and should not be waited for. The tongue is furred and often red and coated; the respiration is hurried, and the face is anxious. The latter symptom is often of importance in septic cases, the eyes being sunken and the nose and mouth pinched.

Chronic appendicitis presents, as a rule, a clear history, and I will not enter upon its discussion.

Diagnosis.—The diagnosis of appendicitis, as a rule, is easy; still, mistakes may be made. In the female, tubal and ovarian trouble should be excluded, which can generally be determined by careful bimanual examination. To illustrate:

Miss N——, aged thirty-five years, had just finished her menstrual period. After taking a cool douche she was seized with severe pain in the abdomen. This was followed by a rise of temperature and an acceleration of the pulse. The pain and tenderness soon became localized. Her physician made the diagnosis of appendicitis and advised an operation, which was refused. Soon after the patient entered the hospital. She seemed to do well for four or five days, when the

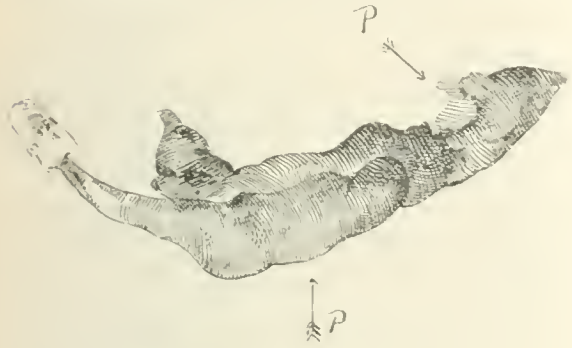

Fig. 5. Arrows indicate points of perforation.

temperature and pulse again increased. The question arose whether it could be pelvic trouble. The muscular rigidity was marked: localized tenderness was present: and induration could be made out above and about McBurney's point. A careful bimanual vaginal and rectal examination demonstrated an absence of pelvic disease. The uterus was retroflected and the tubes and ovaries were low down. An operation was performed that night. The appendix was postcæcal, pointing upward, and was surrounded by about three ounces of thick pus. The whole was matted together, and it was necessary to dig the appendix from the mass. The tissues around were thickened in places, forming masses as large as the hand. It appeared almost like a malignant disease, but after careful examination proved to be inflammatory. The pus was removed by dry sponging, and drainage was secured by gauze carried in different directions. While convalescence followed slowly, a good recovery was eventually made. Fig. 5 shows the appendix.

Other acute diseases may be mistaken for appendicitis; such as typhoid fever, articular rheumatism, extra-uterine pregnancy, ruptured gall bladder, tumors of various kinds, and cancer of the cæcum.

To illustrate ruptured gall bladder simulating appendicitis, I will state the following:

B——, aged forty-five years, while lifting a heavy weight, was taken with severe epigastric pain and collapse. His physician saw him soon after and made the diagnosis of appendicitis, which I confirmed the following day. He had but slight rise of temperature: pulse, 120: face anxious: pain was localized over McBurney's point, and tenderness was well marked. The right rectus muscle was rigid. When the abdomen was opened, a quart or more of bile gushed out. No adhesions were present and the appendix was soon exposed and removed. The abdominal cavity was flushed with a saline solution. A second incision was then made over the gall bladder, which was situated deep and near the spine, and was enlarged and distended. Search was made for gall stones, but none were found. Our patient now went into collapse, and it was expected that he would die before we could get him to bed. A column of gauze was carried down upon the gall bladder and the upper part of the wound sutured. The wound over the appendix was closed without drainage. The patient rallied with hypodermics and enemas. Large quantities of bile drained away during the next twenty-four hours. On the second day the gauze was removed, and the following day a fistula formed in the gall bladder. For several weeks this discharged large amounts of yellow and green ropy bile, and finally closed, and the patient made a good recovery.

To illustrate rheumatism simulating appendicitis:

X——, aged thirty-five years, was taken with all the symptoms of appendicitis. Pain, localized tenderness, and constipation were present. During the examination he spoke of his knee being sore, and upon inspection it was found to be filled with fluid. We decided to wait until morning before advising an operation, at which time the patient was found with acute inflammatory rheumatism.

Whenever we have a patient complaining of abdominal colic, we should not make light of it; that patient should be watched until no doubt remains as to its cause.

Prognosis.—If an operation is performed within the first twenty-four hours, the prognosis is good and recovery will follow in most cases. If opium is used the prognosis is bad, as it masks symptoms, delays operation, and constipates the bowels. From the patient's appearance we cannot give correct prognosis: for when all seems well the appendix may be about to perforate. Many recover without an operation. Many recover, and then die in the second or third attack. In a given case, how can we tell the lesion, the condition of the microbic infection, or the probable outcome? Until this question can be answered, no case of appendicitis, no matter how mild, is safe.

Treatment.—As soon as a diagnosis is made of appendicitis, no matter how mild the case may be, an immediate operation should be performed, unless a patient is in severe shock following sudden perforation. In such cases first overcome the shock. Any patient who will recover without an operation will recover with one, and many patients who subsequently die would get well if operated upon sufficiently early. If we were sure that our patient would get fully over the first attack, we could wait and operate during the interval. But how can we tell the lesion in the appendix, and at what moment it may start up rapid infection? I am well convinced that a large number of patients in the hands of the general country practitioner die during the first attack and are never recorded. I am also convinced that most of the so-called medical cures are subsequently followed by relapse. It is not safe for a country physician to defer an operation. He has not a large hospital and trained nurses at his elbow for an immediate operation, should it become necessary at any moment. I have seen a great many patients, sick from five to seven days, who either died or barely survived the operation, with the slow convalescence which will always accompany pus and gangrenous tissues. In some of these cases life could have been saved; and in others, months of suffering, had an early operation been performed.

The operation in an early stage of appendicitis, as a rule, is easy, and the danger from septicæmia is not great; while in advanced cases the operation is often difficult and the danger from septicæmia great, as is also that of subsequent hernia which often follows pus with necessary gauze packing.

The incision I have used a great deal has been

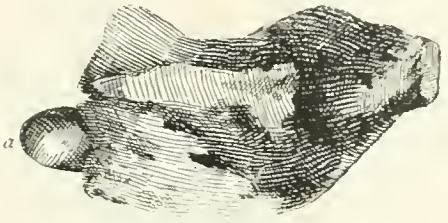

Fig. 6.—*a*, Calculus, perforated through whole circumference of appendix.

through the outer side of the right rectus muscle. After the fascia is divided, the rectus muscle is separated by the handle of the scalpel and then by the fingers to the length of the original incision. This exposes the peritoneum. In the majority of cases this gives us access to the appendix, even if it is deep seated; and in cases in which gauze packing is used hernia, as a rule, does not follow. I have not found that infection follows the exposure of the muscles in this situation; for the external wound has always healed kindly, and in pus cases has kept pace with the deeper wound.

While preparing for operation and in those cases in which an operation has been refused, the first thing to do is to give a dose of castor oil or calomel; an enema should also be given and the patient kept quiet. The diet should be liquid and an external application of ice used. Do not give opium in any form. It constipates the bowels, produces distention of the intestines, and masks the symptoms. The temptation to give a hypodermic of morphine to a patient suffering the agonizing pain of appendicitis is very great. Still, bear in mind that it is not safe. A cathartic to unload the intestines and to relieve the blood pressure will benefit your patient more than morphine.

Appendiceal abscesses often require great care in opening, to prevent general peritoneal infection. To illustrate:

B——, aged thirty-six years, had appendicitis of ten days' standing. A large abscess filled the right iliac region; an incision was made low, in the usual position, and the general abdominal cavity was opened about one-half inch to the inner side of the abscess sac, which was below and to the outer side. The peritoneum was closed with a few fine silk sutures, and the tissue pushed toward the right side until the abscess sac was found adherent to the parietal peritoneum. This was incised extraperitoneally. Had the abscess been opened at the first incision, pus would have escaped into the peritoneal cavity and peritonitis resulted. A rapid recovery followed and no sign of peritonitis was present.

Mac——, aged twenty-one years, strong and robust, was taken with abdominal pain, tenderness, etc. He was seen by me, on the seventh day, with the following conditions: pulse, 140; temperature, 104.5° F.; abdomen enormously distended and very sensitive, especially on the right side; bowels constipated; face anxious, eyes sunken; vomiting, delirious. The diagnosis was appendicitis, and little hope was offered from an operation. The family requesting surgical interference, the abdomen was opened. As soon as the peritoneum was incised pus welled out. Its odor was most offensive, having a peculiar sickening sweetness. The intestines were adherent throughout most of the abdomen. Pus filled the pelvis, and the intestines were bathed in it.

At this operation I had but one assistant, and the ether required most of his attention, which left me alone to handle instruments, etc. The appendix was dug out, found gangrenous to its base, and perforated. The cæcum was also gangrenous where the appendix joined. After removal and flushing with hot water, gauze was carried to the base of the appendix and also in other directions. The lower half of the wound was left open. During the operation the patient several times seemed dead. After he was got to bed enemas and hypodermics were used. He remained for the following twenty-four hours just alive and semiconscious; his pulse was very rapid, his temperature high, and he was delirious. At the end of thirty-six hours he was in about the same condition—bowels unable to move, abdomen enormously distended, sunken eyes, and pinched face. At this time I decided to remove the gauze and to make an artificial anus to relieve the distention. Upon removal of the gauze there was a gush of gas, followed by fæcal matter. During the next twenty-four hours a large amount of gas and fæcal matter passed, and the bowels also began to operate. From this time the patient gained and made a good recovery. The opening into the intestine, being postcæcal, closed in a few weeks. This illustrates that occasionally a patient whose case seems hopeless may recover.

A similar case was that of a boy, twenty-one years old, strong and robust. Several years before he had had a slight attack of appendicitis. While in good health he was taken suddenly with a second attack. When he was seen by me on the fifth day, his temperature was 104° F.; pulse, 140; skin moist; facial expression bad; abdomen enormously distended with constipation and opium; there was tenderness over most of the abdomen but it was most marked over the appendix. Little hope was offered, but the family desired an operation. When the abdomen was opened pus was found everywhere. The appendix was gangrenous and ruptured through out its entire circumference. At the side of the perforation a round fæcal calculus was found; the lumen of the appendix at its intestinal side was not one-tenth its normal calibre. For twenty-four hours the patient did well, after which paroxysmal vomiting occurred, and he died thirty-six hours after the operation. The bowels could not be moved. Fig. 6 shows the appendix.

Bessie, aged four and one-half years, was taken with abdominal pain and with other symptoms of appendicitis. When she was seen by me on the fourth day, her

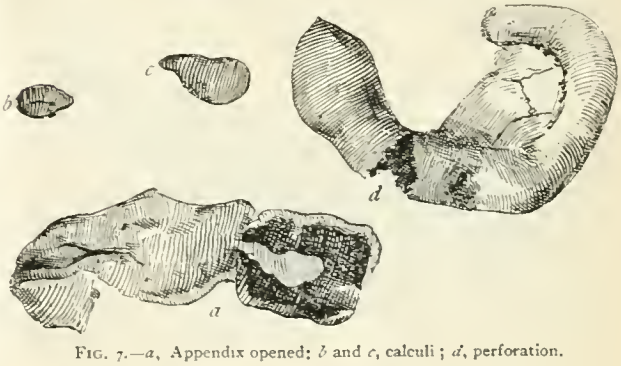

Fig. 7.—*a*, Appendix opened; *b* and *c*, calculi; *d*, perforation.

condition was as follows: temperature, 103.5° F.; pulse, 130; face anxious, eyes sunken; abdomen distended and tenderness well marked, especially over McBurney's point; rigidity of right rectus muscle. After the abdomen was opened a gush of pus followed, which was removed by dry sponging. The appendix, which was postcæcal, was found among adhesions with a pus.

sac around it. Pus was also free in the abdominal cavity. The appendix was gangrenous and perforated, and the opening extended nearly around its lumen. After irrigation of the abdomen gauze drains were used in the pelvis and around the cæcum. The upper half of the wound was closed: the patient reacted nicely and the bowels moved in twenty-four hours. Part of the gauze was removed on the second day, and the remainder on the third day. The abdomen was still enormously distended. During the third day a fæcal fistula formed, which discharged freely. The distention went down and the patient improved rapidly. After some weeks the fistula closed and the wound healed. Fig. 7 shows the appendix.

In each of the above cases a fistula was a benefit. It relieved distention and promoted drainage.

In bad cases of appendicitis, when the abdomen is filled with pus and the intestines are paralyzed by overdistention, morphine, and infection, an opening into the intestines to promote intestinal drainage will be a benefit. Four of the above-cited cases had fæcal openings and all showed marked improvement after its occurrence. I have cited these few cases simply to illustrate my stand in appendicitis.

MEGALONYCHOSIS.[1]

By E. L. KEYES, Jr., M.D.,

NEW YORK.

Gentlemen: The case which I present for your consideration this evening is of little importance except from the point of view of the diagnostician. To take the ordinary routine of the text-book—of its etiology I know nothing, of its pathology almost as little, and as for symptoms of a subjective nature there are none. Hence treatment is unnecessary, fortunately for the patient, for I cannot imagine a treatment that would be of the least value in checking a simple hypertrophy of the nail matrices, the condition in question, excepting only the surgical method of removing the offending members. But, coming now to the diagnosis, on this point, at least, I believe that

Fig. 1. Hands in Megalonychosis.

this nail hypertrophy merits attention, although not so much for what it is as for what it is not. I should not venture to make this sweeping statement from my own slight experience, had my opinion not been fortified by the inaccurate diagnoses of two eminent dermatologists to whom I have had the pleasure of showing

Fig. 2.—Left Foot in Megalonychosis.

this case. The one called it acromegaly, the other the so-called "Hippocratic finger," both of which diagnoses closer investigation seems to have refuted absolutely.

But what my case may lack in importance I trust it will make up in interest, for, as far as I have been able to ascertain, no such wide departure from the normal in the relative size of nail and finger has been reported, except perhaps in the condition named by Marie "hypertrophic pneumogenic osteo-arthropathy," a disease differing widely in its systemic character from the purely local condition of nail hypertrophy.

Yet the view of the case which is most prominent in my mind is the practical one—the importance of this very unusual condition of the nails as a third horn to the dilemma of differentiating the fingers of acromegaly from those of the pneumogenic osteo-arthropathy, or, again, the fingers of the scrofulous diathesis from those of chronic venous congestion of cardiac origin.

The more important data in the history of the case are as follows:

The patient is a Russian by birth. He is forty-eight years of age, married, and owner of a large wholesale tailoring establishment. He gives no history of hereditary disease in his parents, his nine brothers and sisters, or his six children.

His only serious illness occurred during his seventeenth year, when for six weeks he remained in bed with high fever, typhus he believes, although he recollects none of the circumstances. When convalescent and scarcely able to walk he was taken to a Russian bath about half a mile from his home. This was in the midst of winter, a Russian winter, with the thermometer many degrees below zero. The bath greatly weakened him and he had to be carried home, suffering intensely from the

[1] Read at a meeting of the Practitioners' Society, March 4, 1898.

cold. In fact, he believes that his finger tips were partially frozen, for he remembers that they remained blue and numb for some days, and when he resumed his work as a tailor a week later his fingers were exquisitely sensitive to the touch of the needle. Moreover, he says that since then his finger tips have always been rather large, although he noted no marked hypertrophy until seven years later, when at the age of twenty-four he came to this country and began work with the shears as a cutter in a tailoring-establishment of this city. Working with ceaseless energy, he frequently snatched only some three or four hours' sleep each night for months together. Then it

FIG. 3.—Skiagraph of Feet, showing Hypertrophied First Phalanx of Great Toes.

was that his finger tips attained within a few years their present dimensions (Fig. 1); his toes enlarged at the same time and with the same rapidity (Fig. 2). But although he attributes the condition of his fingers to the freezing and the use of the shears—to my mind most inadequate factors—he fails to offer any explanation for the hypertrophy of his toe nails. His present trouble is chronic dyspepsia and vesical spasm, which have been relieved in spite of his somewhat irregular observance of the details of treatment.

Physical examination reveals no departure from the normal excepting in the nails. These are normal in texture, thickness, and smoothness, but the matrices are so large as to curve around the ends of the digits on all sides, thus assuming an exaggerated convexity and giving rise to a seeming hypertrophy of the whole terminal phalanx. These (Fig. 3) skiagraphs,[1] however, show that the bones are absolutely normal, with the exception of those of the great toes, both of which show a distinct hypertrophy of the bones at the interphalangeal joint, and of the exostosis on the terminal phalanx, as compared with the normal foot.

The defect in the nail of the middle finger of the left hand is traumatic in origin. The patient affirms that none of his family have any deformities of the fingers or toes whatever.

Of the differential diagnosis between this nail hypertrophy and any of the onychiæ, onychauxes, onychogryphoses, little need be said. Hypertrophies heretofore described have all been in the development of thickenings or lengthenings, and invariably accompanied by such evidences of a pathological process as striations, brittleness, and a wide departure from the normal coloring and texture. Here on the contrary is what I might term a physiological overgrowth, chiefly lateral, and productive of no such structural change as would indicate a pathological process.

The perfect health and the lateral hypertrophy differ markedly enough from the friable, striated, elongated nails of the scrofulous subject, and equally from the talons produced by chronic congestion of cardiac origin, which talons are curved by a lumping up of the matrix *in situ*, rather than by its turning over the end of the finger from its very size. And the very extraordinary hypertrophy in my case, as well as the etiological factors, form very definite features of the diagnosis.

To the hands of an acromegalic, those of my patient present a marked contrast. He has no general enlargements of the hands and feet, nor are the bones hypertrophied—with the exception noted above; nor are the fingers "of even dimensions from tip to base"

[1] For the skiagraphs, taken at the House of Relief, I am indebted to the kindness of Dr. Lewis A. Stimson; for the photographs to Dr. George H. Fox.

—on the contrary, they are notably clubbed. But the most striking dissimilarity is in the nails themselves. In acromegaly "their development is not proportioned to that of the fingers; they are short and flattened and not in the least hypertrophied."[1] One could not ask for a greater contrast.

I know of but one other disease with which this nail hypertrophy might be confounded, namely, that described by Marie as hypertrophic pneumogenic osteo-arthropathy; for, although in this descriptive title the word hypertrophic is absolutely the only one wherein I can claim the slightest clew of resemblance, although my case be neither pneumogenic nor arthropathic, yet here alone are described nails of sufficiently generous proportions to be classed with those I have to show to-night. Here again, as in acromegaly, the appearance of the hands is distinctive enough, but it is interesting to note the description of the nails and fingers. Labadie-Lagrave[2] devotes a paragraph to them, as follows: "The fingers present the most marked lesions. They are especially enlarged at the tip of the last phalanx, assuming the shape of a bell clapper or a drumstick. The nails participate in the deformity, growing longer, broader, and more curved, with a tendency to hood the end of the finger. These organs tend to become circular, like a watch crystal; but the skin which limits their concavity, instead of prolonging approximately the posterior surface of the finger, turns sharply to form the anterior surface." Thus far the description exactly fits my patient; but the similarity vanishes when it goes on to speak of friability, striations, thinness, and abnormal flexibility, adding that there is hypertrophy of the finger pulp and of the bones, characteristics which my case does not possess. It is scarcely necessary to say that the joint and pulmonary lesions of themselves suffice to differentiate the arthropathy from the nail hypertrophy.

To sum up the characteristics of this case, apart from the bone hypertrophy of the great toes, which may be set aside as an indefinite element, we have a simple universal enlargement of the nails, physiological in character, as though a large man's nails had been transplanted to a small hand, with no accompanying constitutional or local change, and with no cause as yet discovered. It is a distinct condition and may be readily differentiated from any other. I have ventured to name it megalonychosis, meaning thereby to indicate its nature—a universal non-inflammatory enlargement of the nails.

129 East Thirty-Fourth Street.

Adenoid Vegetations at the Vault of the Pharynx, with Special Reference to Anæsthesia in Operating.—Lenzmann (*Therapeutische Monatshefte*, 1897, p. 9) is of the opinion that for a thorough, sure, and safe removal of the vegetations, narcosis is absolutely necessary. He operates on patients only in the sitting posture; children are held on the lap of a nurse. The operation is to be conducted in that stage of anæsthesia in which the sense of pain has disappeared but the reflexes are not abolished. A mouth gag is not recommended, since it renders swallowing difficult; to open the mouth an ordinary spatula is sufficient. First the tonsils are removed with the Mackenzie tonsillotome if necessary, then the adenoid vegetations are removed with Gottstein's curette. After the operation Lenzmann recommends rest in bed and fluid diet for a few days, nasal tampon, and finally swallowing of ice. Lenzmann has seen numerous cases of anorexia with hypertrophy of the pharyngeal tonsil; inasmuch as no cause for the anorexia could be found, he removed the adenoid growths with most excellent results.

Progress of Medical Science.

To Diagnosticate Gastroptosis.—Dr. Langerhans ("On Enteroptosis," *Archiv für Verdauungs-Krankheiten*, B. iii., Heft 3) employs an ordinary stomach tube, furnished at its end with a soft-rubber balloon; after introduction of the tube the balloon is distended with a measured quantity of air. In cases of true gastroptosis, at first a circumscribed portion of the abdominal wall arches forward, generally in the median line or to the left of the median line, at about the height of the umbilicus; this tumor soon takes the shape of a mass lying crosswise, from left to right, at the umbilical line, and from the left side a perpendicular portion arises and loses itself under the margin of the ribs. The important etiological factor of enteroptosis is the relaxation of the abdominal muscles (postpuerperal enteroptosis, "enteroptosis of Landau"), which physiologically hold the abdominal organs in their position in some unknown manner. Another cause of enteroptosis is a true chlorosis, which probably brings about the sinking of the hollow viscera by the dragging of the normal stomach and intestines upon the anæmic peritoneal ligaments, or by the overweighting of the anæmic stomach through stagnation of its contents, or in other unknown ways. This is the "enteroptosis of Meinert." Langerhans further believes that nervous dyspepsia may lead to gastroptosis; he acknowledges also a hereditary disposition to enteroptosis. The corset is not a factor in the above-described cases of gastroptosis. The enteroptosis of mild degree, caused by frequent parturition and consequent relaxation of the abdomen, when it is gradual is physiological and causes no symptoms. The "enteroptosis of Meinert" rarely runs its course without symptoms. The disease causes severe subjective and objective dyspeptic symptoms, with changes in secretion and motility of the stomach. The sinking *per se* of the hollow viscera produces a change in mechanical relations, causing "insults" by pressure on the unprotected kidneys, increased work in forcing out the stomach contents, and stretching of the mesenteric folds. The cumulative effect of these continued irritations is finally to affect the central nervous system; depending upon the individual, hysteria or neurasthenia will result, the abdominal symptoms being predominant. Enteroptosis is the most frequent cause of intestinal hysteria and neurasthenia. Abdominal bandages are of benefit only in the "enteroptosis of Landau;" in this form, abdominal massage with alcohol is also of advantage. Operative fixation of the kidney may be helpful in the few rare cases in which other organs are not at all or only slightly out of place. Massage of the lumbar muscles and faradization of the abdomen the writer considers of no use. He has had no results from the administration of beer yeast. Langerhans lays stress upon gymnastic exercises, particularly upon the bending backward and twisting of the lower portion of the body, both in sitting, standing, and lying-down postures. Careful observation and treatment of the nervous system are to be carried out.—*Centralblatt für innere Medicin*, No. 3, 1898.

Dyspeptic Asthma.—Boas (*Archiv für Verdauungs-Krankheiten*, 1896, B. ii., H. 4) says this is a condition in which the patients suffer from severe dyspnœa, sometimes almost to the point of suffocation, accompanied by symptoms of collapse, caused by disturbance of digestion, the symptoms disappearing after the irritation in the gastro-intestinal tract has been removed. He has observed eleven cases, four of which were mild, the remainder severe. Among the latter were three in which were also found changes in the lungs and heart, so that the gastro-intestinal irritation might be looked upon as the exciting cause of the

asthma; in the other cases gastric or intestinal symptoms alone were present. The attacks occurred at intervals of days or weeks. Several hours—rarely immediately—after meals, after the presence of mild dyspeptic symptoms (eructation, feeling of fulness of the stomach, etc.), there took place severe dyspnœa, accompanied by a feeling of fear, diffuse perspiration, and tympanitic distention of the abdomen; these symptoms lasted a few hours, sometimes all night, and usually disappeared after eructations of gas or vomiting. The examination of the stomach contents showed light secretory or motor disturbances in a few cases; in others the contents were normal. The writer believes that dyspeptic asthma is due to reflex irritation from the stomach causing insufficiency of the myocardium.

Neoplasms of the Brain and Insanity. — Among five hundred and eighty-eight cases of brain tumor occurring in a Roman institution for diseases of the mind and brain, Gianelli says (*Il Policlinico*, July, 1897) that two hundred and sixty-five had no mental disturbances; the remainder had. In those cases accompanied by mental disturbances, the site of the tumor was most often in the cerebrum, seventy-seven times in the frontal lobes, thirty-two times in the cerebellum and hypophysis. In those cases unaccompanied by mental disturbances the tumors, on the other hand, were found most frequently in the cerebellum, and next frequently in the pedunculus cerebri. Mental hallucinations cannot always be used as a basis in the localization of a new growth; they may result from a tumor remote from the zone of irritation. The most numerous tumors are the sarcomata, then the gliomata, next tubercle. Syphilitic new growths are much oftener accompanied by mental disturbances than are tuberculous. The nature and site of the tumor can influence the mental aberrations; yet it is often possible to have two cases of the same kind of tumor situated in the same locality, one of which may produce insanity while the other may not. The writer attributes this to the peculiar constitution of the individual and thus to the individual effect of a certain amount of cerebral irritation. Regarding the site of a tumor as determined by examination of the mental condition of the patient, the author has drawn the following inferences: 1, hallucinations point to irritation of the corresponding sensory cortical centre, though the tumor need not necessarily be in the immediate neighborhood of the latter; 2, the more often symptoms of torpor, slow intellection, and weakened memory occur in the beginning of the disease, the more probably is the tumor situated in the frontal lobe; 3, should the above-named symptoms occur late in the disease, the site of the tumor may be in other parts of the brain; 4, the psychical aberrations mentioned indicate simply a more or less marked morphological change of the cortex of the brain; 5, tumors of the corpus callosum appear always to be accompanied by mental aberrations; 6, a new growth, which runs its course like the classical picture of progressive paralysis, is very probably situated in the frontal lobes; 7, the tendency on the patient's part to spite and wittiness points to the frontal lobes as the site of the tumor, particularly to the right side; 8, again are the frontal lobes the probable sites when patients show change of character or tendency to become angry, to threaten, to insult, to become obscene. Attempts at tumor localization depending upon the above inferences have but a relative value, since the anatomical boundaries of cerebral functions cannot be sharply drawn.

Should We Drink at our Meals?—In an interesting and somewhat historical article, Dr. C. A. Ewald, of Berlin (*Zeitschrift für Krankenpflege*, January, 1898, No. 1), discusses this mooted question at some length. He considers soup, because of its small percentage of nourishing material, merely as fluid; he states that, aside from what is directly taken as drink, much fluid reaches the stomach during a meal, through the sauces and from the water percentage (both natural and by cooking) of the meats, vegetables, etc. Most persons feel the necessity of adding more fluid to the meal by drinking either ordinary water, carbonated waters, or alcoholic beverages. The more one eats, generally the more one drinks, and the greatest eaters are generally the greatest drinkers. If drink be prohibited, the amount eaten is less; indeed, on the above very greatly depends the secret of the "Schweininger cure" for obesity. It is a well-known fact that if the appetite is weak and the mind and nerves are somewhat relaxed, a drink of water will excite the appetite and stimulate both brain and nerves; and this is due directly to the fluid and not to alcohol contained, for we find these facts the same in abstainers. The more fluid in the way of drink is added to the gastric juice, the greater is the quantity secreted; hence the greater the tax upon the gastric glands. Under normal circumstances, however, the stomach, without detriment, accommodates itself to a range of large quantities of fluid. Ewald says that much of the fluid passes into the intestines, another portion is absorbed: hence there never is in the normal stomach a stagnation of large quantities of liquid. The widely accepted belief that alcoholic fluids (not taken to the point of toxicity) retard digestion does not seem to be borne out by the recent experiments of Chittenden. Not even whiskey and brandy seemed to retard digestion. The proteolytic power of the stomach and the power of the pancreatic juice are uninfluenced by small quantities of alcohol-containing fluids. The extraction of body warmth through cold drinks the writer considers as very much overrated. He attributes the bad effects of such drinks to irritation of the stomach mucosa, which becomes, therefore, a possible starting-point for acute or chronic inflammatory conditions. In the normal stomach, the author concludes that not only does drinking at meals, within certain limits, not interfere with digestion; it even aids this process. With patients suffering from stomach or other diseases, however, the case is different. Drinking *ad libitum* cannot be allowed. To the question, Shall patients drink nothing with their meals? Dr. Ewald answers that he sees no reason why small amounts of fluid should not be allowed, excepting to patients suffering from dilatation of the stomach. As above shown, fluids, and particularly alcoholic and carbonated fluids, will, even in limited amounts, aid digestion and increase the appetite, and will more than counterbalance the so-called ill effects of drinking at meals, viz., the possible slowing of digestion, the dilution of the solid constituents of the meal, the overburdening of the stomach, a very improbable lowering of body temperature, etc. Even admitting that such effects do occur, the question of drinking before, during, or after meals Dr. Ewald considers as belonging to the hokus-pokus of suggestion therapy: the physiological act is not influenced if fluid is taken one-half hour sooner or later. The fluid should not be very cold; further, we must follow the indications of the disease and, as far as possible, the wish of the patient. Naturally, alcoholic fluids that have a direct local irritating effect will be withheld, *e.g.*, in ulcer of the stomach, new inflammatory processes, necrosing neoplasms. Another question is, How far shall we allow abnormally increased thirst to be quenched, as in diabetes, fever, and some chronic diseases? The writer answers that the thirst should be quenched with as little liquid as possible. This is particularly true in cases of stomach dilatation, when the patients have the tendency to drink large quantities, partly because stomach absorption is very slow

and imperfect. Moreover, though this seems paradoxical, thirst may be lessened by forbidding water as a drink. Then, too, thirst very often depends upon dryness of the mouth and pharynx; hence frequent moistening of the mouth and gargling will often lessen thirst.

Syphilis and Yaws.—In discussing the question, "Is yaws syphilis?" in the October number of the *Indian Medical Gazette*, Arthur Powell brings forward many arguments and considerable evidence to combat Mr. Jonathan Hutchinson's belief in the identity of the two affections. There is a woodcut showing two cases—one with ringed lesions on the abdomen, but it is unfortunately too blurred to show the lesions so that a diagnosis could be ventured from its inspection. A long differential table closes the article, which will prove of interest to dermatologists and those practising in countries where "yaws" exists.

Meningeal Tuberculosis may so closely simulate opium coma that the former should be thought of in all doubtful cases, especially, as Belfield points out, if there be suspicious abdominal enlargement. Weber has recently written on the subject to *The Lancet*.

A Foreign Body in the Air Passages was reported by Dr. E. Peyrissac in the *Revue Hebdomadaire de Laryngologie, d'Otologie et de Rhinologie*, January 1, 1898, which was expelled without tracheotomy after intratracheal injection of cold water.

The Poison of Bees.—It is generally assumed that the poison of the sting of the bee is formic acid. Langer, however, finds that this is only partly true. The bee poison which he examined was a bitter-tasting liquid with an agreeable odor, which, although it contained formic acid, when diluted to a one-per-cent. solution, so that it no longer gave an acid reaction to litmus, still possessed appreciable physiological action. Moreover, when kept at a temperature of 100° F. for over six weeks, so that all the formic acid was entirely volatilized, the liquid still produced hyperæmia of the conjunctivæ when introduced into the sac. Langer has isolated the active principle, which he finds gives alkaloidal reactions and is unaffected by heat or cold or by acids. Injected into the veins of animals it produces effects similar to those of the venom of serpents.—*Public Health.*

The Limits of Nephrectomy. — P. Wagner (*Centralblatt fur Krankheiten der Harn- und Sexual-Organe*, 1897, Nos. 2 and 3) says that conservative surgery in other fields has finally narrowed the field of radical kidney operations. Though in cases of nephrectomy compensatory growth of the remaining kidney is the rule, yet in quite a respectable percentage of nephrectomies this compensation has not occurred and the one kidney has not been able properly to carry on the functions of both organs. Often such insufficiency of the remaining kidney comes on suddenly; in other cases, in which the disease is apt to be double-sided (*e.g.*, pyonephrosis, hydronephrosis, pyelitis calculosa, cystic degeneration of the kidney), the insufficiency is expected when the more diseased kidney is extirpated. Besides the danger of an insufficient compensation of the remaining organ, nephrectomy in itself is often a dangerous operation. Despite antiseptic and aseptic precautions and the careful observance of proper technique, the extirpation of a large adherent kidney tumor is at times one of the most dangerous and difficult of procedures, and may lead directly to a fatal termination. Moreover, because of the increased work thrown on the remaining kidney, this organ is more liable to become diseased; indeed, some authors claim that almost one-half of the patients on whom a nephrectomy has been done die from disease of the other kidney. All these observations have brought the writer to the conclusion that a kidney which is able to perform its healthy functions ought never to be extirpated; a kidney whose functions are diseased ought to be extirpated only when conservative measures fail. In operable cases, when nephrectomy might possibly have been indicated, less radical measures (nephrorrhaphy, nephrolithotomy, nephrotomy, kidney resection, resection of the ureter, ureter implantation) have often produced a cure. The indications for primary nephrectomy are: 1. Malignant tumors either of the kidney itself or of the kidney capsule. In recent years the above diagnosis has been made fairly early in the disease; hence the radical operation is followed by better results than formerly. Only those cases are to be considered cured in which there has been no recurrence for at least two years after the operation; the writer has found in the literature twenty-six such cured cases. 2. Tuberculosis of one kidney. In a number of cases of tuberculosis of the genito-urinary tract, the infection has been known to begin in the kidney, the disease spreading downward along the tract, but only after the kidney has been a long time tuberculous. In such cases nephrectomy is the only sure cure and proper operation, except in those who are in a very depressed condition and in whom there are tuberculous processes (particularly tuberculosis of the other kidney) in other parts of the body. In these latter patients a palliative operation (nephrotomy), with eventual secondary nephrectomy, is indicated. Cases are known in which extirpation of a tuberculous kidney has produced a cure for a number of years, even though symptoms of tuberculosis of the bladder or beginning tuberculosis of the other kidney were present; it seems that these latter processes come to a standstill, may perhaps even heal, when the chief source of infection is removed. 3. Primary nephrectomy is indicated in those cases in which the kidney is riddled with large and small abscesses, and in which the most radical nephrotomy cannot open all the pus cavities. Such patients may be saved by a timely nephrectomy; it is only when the functional ability of the remaining kidney is in doubt that a nephrotomy (with secondary nephrectomy) is indicated. 4. In certain cases of rupture of the kidney or of its hilus through injury, primary nephrectomy is indicated. Indications for secondary nephrectomy, besides those above mentioned under kidney tuberculosis, "pus kidney," and rupture of the kidney, may occur in cases of pyonephrosis and hydronephrosis.

Is New Splenic Tissue Formed after the Removal of the Spleen?—Tedeschi (*Gazzetta degli Ospedale*, No. 97) says that experiments upon animals favor an affirmative answer to the above question; in the case of man he again thinks the question can be answered affirmatively. He describes in full an autopsy made upon a fifteen-year-old girl who had died of meningitis. No spleen was found in the normal situation of that organ; instead, attached to one corner of the large omentum was found a nodular tumor, deeply furrowed, grayish in color, the size of a small apple; further, two small masses, of the size of hazelnuts, of pale red color, were found in the neighborhood of the gastro-colic ligament. Along the blood-vessels were found about twenty small bodies of various size, resembling the above in form and appearance. All these masses, macroscopically and microscopically, showed splenic tissue. Tedeschi has found but one other such case in literature. The author explains these aberrant splenic structures by a dislocation of the true spleen, with torsion of its pedicle; in this wise, most of the splenic structure would be destroyed, and its function would be replaced by the growth of these spleens arising from the peritoneum. Griffin and Tizzoni found

similar splenic tumors in dogs from which the spleen had been extirpated. Tizzoni describes one case in which from sixty to eighty of these nodules were found after the above operation. That these were not supernumerary spleens, but really spleens newly grown after the operation, the experimenter concludes from the fact that supernumerary spleens are generally only two or three in number; the latter organs, too, are found in the gastro-splenic ligament at the side of the true, normally located spleen, while those that grow after operation are found either in the great omentum or in duplications of the peritoneal folds.

On the Results of Bacteriological Examinations of the Blood.—Kühnan (*Zeitschrift fur Hygiene*, 1897, xxv., p. 492) gives the results of one hundred and ninety-two bacteriological blood examinations. In the majority of cases (one hundred and sixty-nine times) the blood was taken direct from the median vein. He extracted ten cubic centimetres of blood in each case, which was mixed with fifty cubic centimetres of bouillon, so that the mixture might be spread over many agar (and gelatin) culture plates. In forty-one fatal typhoid cases he discovered in eleven instances the typhoid bacillus, but no other bacteria except colonies of those cocci which exist in the air, due to defective cleanliness of the plates. In twenty-three cases of general sepsis and pyæmia, the writer found bacteria in the blood of three—twice the streptococcus pyogenes, and once streptococcus pyogenes aureus. The number of bacterial colonies was small in each case. In twelve cases of ulcerative endocarditis, he found in only one case the staphylococcus pyogenes aureus: in sixty-seven cases of benign endocarditis—of which seven cases later became malignant—he found but once a fairly virulent staphylococcus pyogenes aureus. In no case of localized purulent disease could the writer find the specific organism in the blood, though staphylococci often grew in the culture media, which he attributes to accidental uncleanliness of the culture plates.

Waterborne Typhoid.—At the Sanitary Institute in London on March 9th, Dr. Childs of University College read a paper on the above subject. After discussing the various causes of typhoid fever he pointed out that the protection of water supplies was the one measure calling for immediate action. The present law was quite inadequate. The first requirement was the thorough and systematic inspection of the water supplies from source to distribution, but the duty of taking action was thrown on the sanitary authorities, who had only enabling not compulsory power, and were themselves often the greatest polluters. The chief obstacle to reform was the ignorance and indifference of the public. He concluded by recommending: 1. That sanitary authorities should have free access to water supplies and should provide for their inspection and analysis. 2. That water companies should publish full information as to their water. 3. That they should be required to make regular inspection analyses and publish the reports. 4. That they should be made responsible for the consequences of pollution. 5. That wilful pollution of water should be made a penal offence. 6. That public authorities should be appointed for the care and protection of watersheds. Dr. Childs laid stress on the primary necessity of diffusing knowledge among the people.

Treatment of Chronic Ulcers of the Leg.—Von Langsdorf (*Centralblatt fur Chirurgie*, November 20, 1897) declares that the most important item in the treatment of such ulcers is a very thorough disinfection of the base of the ulcer and of the surrounding tissue. This is effected by first thoroughly scrubbing the leg with softsoap. The ulcer itself is then covered with a thick paste of calomel, the paste having been formed by mixing very little water with the powdered calomel; over this covering is spread some ordinary table salt; the leg is then dressed with a gauze and absorbent-cotton dressing. The nascent sublimate thus formed produces a burning sensation for about three or four hours. After twenty-four hours the dressing is removed and the ulcer washed. One finds at this time a healthy, dry wound surface, occasionally also small sloughs. The pain has now disappeared. The growth of epithelium is encouraged by the application of ointments containing turpentine; exuberant granulations are touched with copper sulphate. After the ulcer has healed, a zinc-ointment dressing should be used for about two weeks.

Negro Lethargy.—A bacillus has been found by Cagigal and Lepierre, of Coimbra, in the blood of a young negro who had suffered for three years from that curious disease—negro lethargy or sleeping-sickness—which is endemic on the west coast of Africa. Cultivations of the bacillus when inoculated into rabbits cause depression, paresis of the hind limbs, wasting, and death in from twenty to fifty days. Should these observations be confirmed, the disease will afford a most remarkable example of the latency of a pathogenic organism, for the symptoms in some cases do not develop until years after the patient has left the endemic area.—*British Medical Journal*, February 12, 1898.

Puerperal Infection.—Norris (Somerville Medical Society) sums up as follows: 1. Puerperal sepsis is caused most frequently by the physician or midwife. 2. In a parturient woman internal examinations should be made as infrequently as possible. 3. Antepartum and post-partum vaginal irrigations are to be omitted. 4. At the first symptom of puerperal sepsis, circumscribed pelvic inflammations should not be overlooked and operative interference should be undertaken at the proper time. 5. For the further treatment, energetic stimulation, intravenous, subcutaneous, and intrarectal injections of a decinormal salt solution, and nuclein play a most important part. 6. The use of antistreptococcus serum proves efficacious only in those cases in which a pure streptococcus infection exists.

The Detection and Clinical Significance of Mucus in the Excretions.—If we desire to determine whether a sputum is composed entirely of mucus or whether there is an admixture of albuminous bodies—a question that is often of importance in the differential diagnosis between croupous pneumonia on the one hand, and pleurisy and hemorrhagic infarct on the other—Schmidt, of Bonn, advises as the best method staining of the sputum with a neutral mixture of acid and alkaline aniline dyes—for example, the Biondi triacid mixture (acid fuchsin, methyl green, orange G). If the basis of the sputum be composed of mucin from the bronchial mucous membrane, it takes up the alkaline (green) stain; whereas if it be composed of nucleo-albumin and fibrin from the alveolar contents, it is attacked by the acid (red) stain. This method is also of service in the examination of the fæces for mucus. Gastric juice digests mucin twice as quickly as it does albumin; trypsin works even more quickly. The bacterium coli commune dissolves, though slowly, the mucus of the intestinal tract. Still more slowly do the typhoid bacilli act; anthrax is somewhat more rapid in its action. Even in the respiratory tract mucin-liquefying micro-organisms are undoubtedly found. In putrid bronchitis and bronchiectasis mucus is often entirely absent in the thin purulent sputum.—*Wiener klinische Rundschau.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 23, 1898.

ARE SPECIAL SURGICAL HOSPITALS NECESSARY?

IN connection with the signs of revolt against specialism in surgery, to which we have called attention in former issues of this journal, we note a growing disposition on the part of the laity, as well as of the profession, to question the usefulness of institutions devoted to the treatment of a single class of surgical affections. While there is no disposition on the part of the fair minded to belittle the admirable pioneer work that has been done by some of the older special hospitals, one frequently hears this question: "Is there any good reason for their continuance, now that the field of surgery has become so broadened and general hospitals present such excellent results in every department?"

We do not believe that the time is ripe for giving a negative reply without reservations. It may not be amiss, however, to seek the reasons for the criticisms which have been offered against certain of these institutions. The *raison d'être* of special hospitals, as usually expressed, is threefold, viz.: to offer superior advantages, by reason of the better facilities of the hospital and special skill of the attending staff, to patients suffering from a stated disease: to advance the scientific study of the disease in question by providing more clinical material: and last, but not least, to serve for the training of internes, who may themselves become experts in the treatment of the affections to which special attention is given.

The visible proof that these aims are accomplished appears in the statistics of the hospitals, the scientific papers published by its surgeons, and the character of its graduates. Judged by this standard, it must be confessed that at the present time few of the prominent special surgical hospitals, either here or abroad, occupy the place which they did, say, ten years ago. We grant that their position is a difficult one. From the very fact that they claim superior advantages, their work is subject to searching scrutiny and comparison with that of general hospitals, whose surgeons make no pretensions to unusual skill in a single line of work. It is the same condition which confronts the specialist. Having assumed a certain plane of superiority to the rank and file of the profession, he must make good his claims or his reputation suffers.

This applies particularly to gynæcologists, who seem to be forced to act more or less on the defensive. The conditions prevailing a few years ago, when practically all the gynæcological surgery was left to a few experts, have essentially changed. Now general surgeons perform all these operations, and even the recent graduate essays to open the abdominal cavity in cases which were formerly regarded as too hazardous even for practised hands. It is fair to assume that gynæcology as a lucrative specialty is on the wane.

If this is true (and it must be admitted by every candid observer who notes the "signs of the times"), one would naturally ask: "Is there any need of hospitals devoted exclusively to the treatment of diseases of women?" Of their value in the past there can be no question. The wonderful advances in gynæcology made in this country furnish a sufficient proof of this fact. The Woman's Hospital is yet a name to conjure by when linked with those of Sims, of Emmet, and of Thomas.

But are these institutions still making fresh discoveries and improvements in technique, or have they become stationary or even retrograded? Are they really devoted exclusively to women's diseases? An inspection of the last annual report of the special hospital in this city to which we have alluded shows that a considerable proportion of the operations were performed for conditions not even remotely connected with disease of the pelvic organs. *Per contra*, the reports of general hospitals (having no separate gynæcological divisions) indicate a decided leaning toward pelvic surgery. Comparisons of statistics are notoriously misleading, yet it must be admitted that in abdominal surgery at least the results obtained in the public hospitals, under conditions far more unfavorable than those which prevail in special institutions, as regards patients, environment, and apparatus, may well awaken unfavorable criticism of their more favored rivals.

But it has been rightly argued that it is in the field of minor surgery and the non-surgical treatment of pelvic diseases that the superior excellence of the special hospitals is seen. This cannot be denied. It is in plastic surgery that its most brilliant achievements have been recorded, and in this line fresh triumphs may be looked for. The far greater number of minor operations performed, as compared with the work in general hospitals, implies wider experience, greater skill, and a constant tendency to improved technique. Let hospitals for the treatment of diseases of women, then, if they continue to exist, cease to challenge comparison with general hospitals in the field of abdominal surgery, avoid the inevitable criticism which must follow the extension of their work to operations that have no connection with the pelvis, and follow the lines originally laid down by their founders. Unless this course is adopted, we prophesy that they will not merely lose their prestige, but will cease to be recognized as special hospitals.

Dr. Budin has been appointed as Tarnier's successor to the chair of obstetrics in Paris

VINDICATION OF A PHYSICIAN CHARGED WITH MALPRACTICE.

We are gratified to learn that the recent suit for malpractice against Dr. Frederick H. Wiggin, of this city, resulted in a complete victory for the defendant, the jury reaching a decision after only a few minutes' deliberation.

Since every case of this character must necessarily possess more than a local interest for the profession, we think it only proper to make a brief statement of the facts for the benefit of those of our readers who are not familiar with them.

Dr. Wiggin, whose high personal character and professional standing are well known in this community, performed anterior colpotomy and vagino-fixation of the uterus (Mackenrodt's operation) for retroflexion complicated with disease of the left ovary, the indications for surgical interference being unquestioned. It was shown that all the necessary aseptic precautions were observed; but nevertheless suppuration occurred (presumably at the site of the stump, which was secured with a silk ligature), and an abscess formed, which was incised and drained through the posterior vaginal fornix. The patient made a good recovery and returned home, the abscess opening having apparently closed. She at first reported herself as much improved, but subsequently it appeared that a small sinus still remained, which continued to discharge pus. Naturally inferring that the source of irritation was located at the site of the ligature, the doctor proposed that an attempt be made to reach and remove the silk. The patient re-entered the hospital, was anæsthetized, the vaginal opening was enlarged, and an unsuccessful effort was made to find the foreign body.

After consultation with the patient's family attendant (himself a well-known surgeon), it was deemed advisable to open the abdomen and remove the ligature. This was done with considerable difficulty, as the patient was quite stout and took the ether so badly that it was necessary to suspend its administration in order to resuscitate her. Indeed, the pulmonary symptoms were so threatening that Dr. Wiggin remained with the patient for several hours after the operation, until she was out of danger.

Recovery from the second operation was retarded by the development of a mural abscess, attributed to localized infection in a thick adipose layer, which was treated in the usual manner by irrigation and gauze packing.

In spite of the doctor's assiduous attention, over a period of several weeks, the wound refused to heal. The patient, who up to this time had been in a private hospital, desired to remove to a public institution for pecuniary reasons, after which she was no longer under his care.

Without entering into details, it is sufficient to state that several weeks after she entered the institution the sinus was enlarged under ether and a piece of gauze, "the size of the thumb," was removed from the bottom of the wound, after which it closed and the patient was subsequently restored to health. This fact coming to the knowledge of the patient and her husband (through whose agency is not certainly known), it was intimated to Dr. Wiggin that the matter might be compromised, provided that the fee (a very moderate one) should be remitted. This the doctor properly refused to do, believing that an important principle was at stake, which concerned the honor of the profession as well as his own; hence the suit, with damages fixed at $10,000.

It is pleasant to record that the defendant was generously supported by his professional brethren, who, whatever may be their personal differences, are always united when it comes to questions which affect the good name of a colleague.

The grounds on which the suit was brought were, not that suppuration followed the first operation, which was recognized as an accident that may occur in spite of all precautions, but that the piece of gauze which was finally removed from the abdominal wall had been carelessly left behind during the performance of cœliotomy. It was claimed by the defence that the gauze was introduced while the sinus in the wall was being dressed, and that the end, instead of being allowed to protrude from the wound, was pushed down out of sight. It should be borne in mind that for several weeks, or after Dr. Wiggin ceased to attend the patient, the wound was dressed by other parties, often by nurses. There was, therefore, not the slightest evidence that he had introduced the offending gauze.

Considerable stress was laid by the prosecution upon the fact that the gauze must have been inserted at the time of the cœliotomy; hence the development of the mural abscess. But it clearly appeared from the evidence that the patient had no febrile or other symptoms such as would have resulted from the presence of a foreign body in the peritoneal cavity, and the subsequent excursion of the same from the cavity into the external wound. Moreover, it was admitted that the foreign body was not a pad or serviette, but merely a small bit of gauze bandage (!).

On this flimsy evidence was based the charge of incompetence against a gentleman, in regard to whose skill, judgment, and conscientiousness numerous medical witnesses were present to testify.

The verdict was inevitable; but the fact that the trial was allowed to proceed at all is a striking evidence of the risks assumed by every surgeon, no matter how slight the operation or how high his standing.

The lessons from this case, though not new, are worth remembering. Any operator may through an unfortunate combination of circumstances have an unsuccessful case aired in a court of law. The financial question is not the only one. Who can compensate him for the mental anxiety and loss of time and reputation?

In such a position, if ever, the profession should rally to the support of a persecuted brother. His suffering is vicarious, but not from mere selfish motives should our assistance be proffered. If any surgeon, apparently secure in the possession of a flawless reputation, is indifferent to higher motives than those of self-interest, he will do well to recall the admonition: "Let him that thinketh he standeth, take heed lest he fall."

THE ADMINISTRATION OF CHLOROFORM FROM AN UNPROFESSIONAL POINT OF VIEW.

In *The Hospital* of a few months ago, attention was called to the frequency of deaths from anæsthesia. It was stated that in the year 1897 no less than eighty-eight inquests were held on persons who had died from anæsthetics, seventy-five of that number succumbing to the effects of chloroform. It is doubtful, too, if all the deaths that have occurred from this cause have ever obtained publicity. This large death rate has naturally given rise to feelings of alarm, and medical men even in England itself are beginning somewhat to distrust chloroform as a safe anæsthetic. The general public, however, regards the question in an apathetic manner, so that the opinions of a lay writer on the subject are interesting as well as possessing the merit of freshness. A Mrs. King, writing in the *Nineteenth Century* for March, deals with the matter from an unscientific standpoint. This lady does not discuss the much-vexed point as to whether chloroform, ether, or one of the various other anæsthetics now in use is the safest, but gives her views in regard to the manner of administering chloroform. She writes as follows: "I have myself been under chloroform twice in England and yet oftener in India, and it is my own personal and painful experience of the difference in the manner in which it is administered in India and England that impels me to write, in the hope of arousing sufficient interest to stir up a revolt against the method of administering chloroform too commonly practised in England, and thereby save others from suffering as I have done. . . . It is the custom of many practitioners in England (I speak only from my own experience) to administer chloroform in direct opposition to the principles laid down by the Hyderabad commission and in the way practised in India. There the primary consideration is that nothing shall in any way impede the patient's breathing, and the operator consequently takes care never to place the pad or handkerchief very close to the mouth, holding it invariably at a distance of some inches, so that the chloroform may be freely diluted with air. In this way I have taken it some dozen times, and, far from having experienced the slightest distress, I found the sensation exceedingly soothing and agreeable as long as consciousness lasted. In England my experience has been far otherwise, and my dread of taking chloroform is now almost as great as the dread of being smothered or drowned. Having suffered great distress the first time, I entreated the administrator on the last occasion to allow me air the whole time, telling him how greatly I dreaded the feeling of suffocation I had experienced. He merely answered somewhat testily that I must allow him to act as he thought best, and those present assured me in chorus that he was one of the best-known chloroformists in London. I was helpless and I submitted. At first he held the hollow pad some inches from my mouth, and I inhaled the fumes with perfect ease and comfort, drawing deep and regular inspirations; but no sooner was I half-unconscious than he clapped the pad over my nose and mouth in the way I had so dreaded. I struggled furiously for breath, but could inhale nothing but the burning, choking fumes of the chloroform, that felt as if pure alcohol was being poured down my throat, and made me gasp and choke in an agonizing manner. I became frantic in my efforts to obtain air, and the few moments that elapsed before unconsciousness came to my relief were to me a prolonged agony. I am perfectly certain that had I not been physically strong and my heart and lungs sound, I must have succumbed, in which case I should have furnished another paragraph to be headed 'Death Under Chloroform,' and the public would have heard that my death was owing to 'failure of the heart's action.'"

While this account is probably exaggerated and somewhat open to the suspicion of prejudice, it still contains the germs of truth. There can be no doubt that very many of the deaths occurring from the administration of chloroform are due to the methods of administering the anæsthetic. This is the case both in America and in England.

News of the Week.

A Hospital at Key West.—The mother superior of the Convent of Mary Immaculate, at Key West, has offered to place the convent and two school-buildings at the disposal of the United States government, to be used as a hospital in case of war with Spain, and has offered the services of the sisters as nurses. Captain Sampson, commanding the squadron, has accepted the offer in case a naval hospital becomes necessary.

Health-Board Appointments in Brooklyn.—The following appointments have been made in the department of health in the Borough of Brooklyn: Drs. James J. H. Blakeney, James T. Gallagher, Charles H. Ermentraut, and Eugene J. Kenney, medical inspectors, and Dr. Peter C. Hughes, diagnostician.

The Cornell Medical School.—It seems to be definitely determined as the result of the disagreement between the council of the University and its medical department that there will be another medical school established here. The donor of the medical college to Cornell is said to be Mr. Oliver H. Payne, whose ambition to establish a medical school second to none in the world will be gratified by an expenditure of from a half to one million dollars. The president of the university says that the new department, which is to be designated the Cornell University Medical College, is to be located in the city of New York, although the first half of the course, comprising the pure sciences upon which practical medical training rests, will be duplicated by the faculty of arts and sciences at Ithaca, will be open to women on the same terms as to men, and students appointed to State scholarships by the superintendents of public instruction may obtain free tuition. The following members of the present faculty of the University Medical College have already been appointed to professorships in

the Cornell University Medical College: W. M. Polk, Lewis A. Stimson, R. A. Witthaus, W. Gilman Thompson, George Woolsey, and H. P. Loomis. Dr. W. M. Polk has been appointed director and dean of the medical college. The executive committee was authorized to complete the staff, and it is expected that about fifty other appointments will be announced within a short time.

Obituary Notes.—Dr. George Hoppin Humphreys, an old physician of New York, died at his residence, in this city, on April 15th. He was born in Philadelphia in 1834, and was graduated from Jefferson Medical College in 1856. He completed his medical studies in Paris and Vienna, and came to New York in 1859. On the breaking out of the war he joined the ninth regiment as surgeon. After the war he returned to this city and entered general practice. He was a member of the Academy of Medicine and the County Medical Society, and also of the Loyal Legion, and the Century and Union League clubs.—Major Henry McElderry, chief surgeon of the Department of the Missouri, died at Hot Springs, Ark., on April 17th, of Bright's disease. He was born in Maryland, and served during the rebellion in the tenth Maryland infantry, and as medical cadet in the regular army. He was appointed assistant surgeon in 1866, given the rank of captain in 1869, and that of major in 1884.—Dr. Francis R. Brooks, of Chicago, died at Geneva on April 13th. He was thirty-one years old and was a graduate of Harvard College, the Chicago College of Law, the law department of the University of Virginia, and of the College of Physicians and Surgeons, Chicago.

New York Neurological Society.—At the meeting of April 5th, the following members were elected to serve the society as officers for the ensuing year: *President*, Dr. Frederick Peterson; *First Vice-President*, Dr. Joseph Collins; *Second Vice-President*, Dr. J. A. Booth; *Recording Secretary*, Dr. Pearce Bailey; *Corresponding Secretary*, Dr. L. Stieglitz; *Treasurer*, Dr. G. M. Hammond; *Councillors*, Drs. B. Sachs, M. A. Starr, George Jacoby, C. L. Dana, and M. P. Jacobi.

The Florida Medical Association.—The twenty-fifth annual meeting of this society will be held in the rooms of the board of trade, at Jacksonville, on Tuesday, April 26th, under the presidency of Dr. R. B. Burroughs, of Jacksonville. The secretary is Dr. J. D. Fernandez, and the chairman of the committee of arrangements Drs. Sollace Mitchell, both of Jacksonville.

Hotel Accommodations at Denver.—The *Colorado Medical Journal* says: "We regret that the editor of the Medical Record has had some misunderstanding with the Brown Palace Hotel management as regards rates; and the former, through his official position, has seen fit to criticise the Denver hotel business in general, and to make statements about the hotel rates that are to be in force during the meeting of the American Medical Association, which are greatly in error." The editor of the Medical Record has has no correspondence and no misunderstanding as regards rates with the manager of any hotel in Denver, and the above statement of our esteemed contemporary is wholly independent of facts. The item to which objection is taken by our colleague in Denver was as follows: "The hotel proprietors in Denver, with the usual shortsightedness of people of that class, are purposing to make it as uncomfortable as possible for those in attendance at the meeting of the American Medical Association in June, in order that the meeting may be made as profitable as possible to themselves. The manager of one of the leading hotels in that city has already refused to make any reservations unless two persons will consent to occupy a single room. How many he expects to put in a double room, we have not yet ascertained." We have since been informed by a physician in this city that this manager has thought better of his refusal to allow any of his guests to sleep alone, and has offered to reserve single rooms at the rate of $4.50 a day, European plan—that is to say, for the use of the room only, without meals.

Governor Black has signed the bill making an appropriation of $158,000 for the Craig Colony. One hundred thousand dollars of this amount will be used in the construction of cottages for patients; the capacity of the cottages ranging from ten to twenty-five patients each.

Arsenic for the Prevention of Cholera.—A memorial has been introduced into the United States senate from a Minneapolis physician, praying that a test be made of the "arsenization method" of treating cholera. The petitioner says he has had practical experience in yellow fever and small-pox, and now seeks an equally practical experience in Asiatic cholera. He suggests that the testing of this method will consume five years with an annual appropriation of $10,000.

The International Congress of Hygiene and Demography was formally opened in Madrid on Sunday last. The cable announced that one delegate from Salt Lake City delivered a brief address at the opening session, in which he expressed his faith in peace and the speedy establishment of improved relations between Spain and the United States. It is difficult to imagine what else he could have said, considering the time and place.

A Nurses' Club House.—The Nurses' Alumnæ Association of the Post-Graduate Hospital held a fair at the hospital on Wednesday, March 30th, the proceeds of which are to be used for a club-house. The proposed club-house is to be rented in a central part of the city, and is to be provided with everything that could add to the nurses' comfort or pleasure. The first floor is to be divided into an office, with its registry and telephone, a reception-room for the entertainment of the nurses' friends, a dining-room, a kitchen, and a reading-room. Lectures will be given from time to time to enable the graduate nurses to keep up with newer methods of work. The other rooms will be occupied by nurses off duty. One

room will be reserved for the use of sick nurses. It will be fitted up in as attractive a manner as possible, and will be kept ready for use at all times. The house is to be under the management of one of the graduates. The fair was very successful, but much is still needed to carry out all of the proposed plans. The secretary and treasurer of the association is Miss Mary E. Thornton, 162 East 37th Street, New York.

The Astoria Hospital, which was obliged to close its doors on April 1st because it could not exist without receiving assistance from the public treasury, may possibly be reopened. Representatives of a hospital in this city a week ago visited Astoria for the purpose of inspecting the hospital, with a view to converting it into a branch. The name of the institution is withheld, but it is supposed to be the New York Hospital, which enjoys the good fortune of being independent of municipal aid.

Sanarelli's Yellow-Fever Serum.—Dr. Sanarelli, who announced his intention to take part in the proceedings of the International Congress of Hygiene and Demography, held this past week in Madrid, has been experimenting during the past few months in Rio de Janeiro and instructing a committee of Brazilian physicians in the method of employing his yellow-fever antitoxin, or "serum anti-amaryl," as he calls it. The Rome correspondent of the *Lancet* gives a brief report of these experiments and instructions: "Good results," Dr. Sanarelli premises, "are difficult to obtain if the treatment be applied when the disease is already advanced, when the 'amaryllic' poison largely accumulated in the organism has already induced those grave anatomical and functional changes which the serum cannot undo and which of themselves suffice to cause death. We must for the present, therefore, restrict our application of the serum exclusively to the first period of the malady." It will be much if good results can be obtained by this early treatment. It will be still more if the indications then observed will enable us to utilize with success the "serum anti-amaryl" in further stages of the malady. The serum is asserted to be in no respect hurtful; it can be injected in any desired quantity up to the moment when all hope of success is not yet definitively abandoned. We begin with a dose of 20 c.c., and if appreciable improvement fail to set in we may inject a second, a third, and even further doses, always being guided by the patient's resisting-power, or his general condition, or the period of the malady, or the complications, and so on. The injections are to be practised in the region of the thighs or nates, but in urgent cases it is preferable to introduce the serum directly into the veins of the forearm, rendered prominent by a bandage placed below the elbow. The results of these experiments at Rio would seem to show that the serum is fatal to the microbe which causes yellow fever, while it is impotent against the toxins produced by that microbe. If previously to the diffusion of the toxins the microbe can be met by a good injection of the anti-amaryllic serum it is at once destroyed and the patient is put out of danger. To hit the opportune stage at which injection is efficacious, to surprise the organism at the period when incubation is not yet mature, and to kill it before its toxins have become diffused should be the practitioner's aim if the serum is to be successful in his hands. But there is no time to lose, since yellow fever often runs to a final issue in less than two days.

The Cartwright Lectures of the College of Physicians and Surgeons (medical department of Columbia University, New York) will be given in the hall of the Academy of Medicine, 17 West Forty-third Street, on Tuesdays, April 26th, May 3d and 10th, at 8:15 P.M., by W. W. Keen, M.D., professor of the principles of surgery and of clinical surgery in Jefferson Medical College, on "The Surgery of the Stomach." The first lecture will deal with gastrotomy and gastrostomy; the second with gastro-enterostomy, pylorectomy, pyloroplasty, gastroplication, and gastroplasty and gastro-gastrostomy for hour-glass stomach: and the third with tumors of the stomach, ulcers of the stomach, and gastrectomy. The committee is composed of Drs. F. P. Kinnicutt, A. J. McCosh, and W. K. Draper.

The New York Mycological Club.—The New York Mycological Club has been organized with a view to bring together all those interested scientifically and economically in the study of fungi. Its principal objects are the study of edible mushrooms and toadstools and those poisonous kinds which may be mistaken for them, and the arousing of a wider appreciation of the value of a cheap and abundant food supply which has been hitherto comparatively neglected in this country. The secretary is Miss C. C. Bedford, 16 East One Hundred and Thirty-first Street, New York City.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending April 16, 1898. April 9th.—Passed Assistant Surgeon L. L. Von Wedekind detached from the Naval Academy and ordered at once to the *Minneapolis*. Passed Assistant Surgeon L. L. Spratling detached from the Naval Hospital, Philadelphia, Pa., and ordered at once to the *Columbia*. Assistant Surgeon H. H. Haas detached from the *Vermont* and ordered at once to the *Texas*. Assistant Surgeon E. V. Armstrong commissioned assistant surgeon from April 5th. Assistant Surgeon W. H. Bucher commissioned assistant surgeon from April 5th. April 12th.—Medical Inspector D. Dickerson ordered to marine headquarters, Washington, D. C. Surgeon D. N. Bertolette detached from the marine headquarters, Washington, D. C., and ordered to the *Vermont*. Surgeon W. H. Rush ordered to the *Dixie* at once. Surgeon J. M. Edgar detached from the *Vermont* and ordered to the *Prairie*. Passed Assistant Surgeon J. M. Pickrell detached from the hospital, D. C., and ordered to the *Yosemite*. Passed Assistant Surgeon A. M. D. McCormick detached from the Naval Academy and ordered to the *Yankee*. Passed Assistant Surgeon M. R. Pigott ordered to the Naval Academy at once.

April 13th.—Surgeon L. G. Henneberger ordered to the bureau of medicine and surgery. April 15th.—Medical Inspector M. C. Drennan detached from the *New York* and ordered home to await orders. Medical Inspector C. U. Gravatt detached from the *San Francisco* and ordered at once to the *New York* as fleet surgeon. Surgeon A. C. H. Russell detached from the Naval Museum of Hygiene and ordered to the *San Francisco* at once. Surgeon F. J. B. Cardeiro detached from the *Michigan* and ordered to the *New Orleans* at once. Assistant Surgeon W. H. Bucher ordered to the *Vermont* temporarily. Assistant Surgeon E. V. Armstrong ordered to the *Scorpion*.

A Belligerent Doctor in Salzbrunn.—A cable despatch to *The Sun* from Berlin tells of an irate German physician who had rather fight than pay a bill. A servant girl employed in a hydropathic institution kept by a Dr. Pohl in Salzbrunn cut her hand last October in her master's absence. Dr. Oliviero was summoned to attend her, and, after the girl was cured, sent a bill to his colleague for five marks for his attendance. Dr. Pohl considered the bill an insult, and sent seconds to Dr. Oliviero to demand an explanation, and to challenge him to a duel if the explanation was unsatisfactory. Oliviero refused to fight, and had Pohl arrested and imprisoned for a week for violation of the duelling laws.

New York State Medical Association.—The fourteenth annual meeting of the third district branch of this association will be held at Syracuse on June 2, 1898. Members intending to present communications are requested to notify the secretary, Dr. F. W. Higgins, of Cortland, N. Y. The president of the branch is Dr. H. W. Carpenter, of Oneida.

The Care of the Insane in Rhode Island.—In May of last year the legislature of Rhode Island passed an enabling act whereby the State institutions of Rhode Island were divided and the State Asylum for the Incurable Insane was made an independent institution under a separate head, its name being changed to the Rhode Island State Hospital for the Insane. Of this hospital Dr. George F. Keene has been elected superintendent.

Section on Diseases of Children of the American Medical Association.—The preliminary programme of this section contains the titles of fifty-nine papers and the names of nineteen members who have promised communications, the titles of which are not known to the secretary. We would remind ambitious members of the association that the atmosphere of Denver is rarefied and it is necessary for unacclimated visitors to be sparing of their breath.

The Wisconsin Medical Law does not appear to be enforced with great rigor. The Chippewa Falls *Herald* says it has been in effect several months and one certificate only has thus far been filed. The law provides that all persons hereafter commencing the practice of medicine or surgery in any of their branches in Wisconsin shall apply to the board for a license and shall submit to an examination in the various branches of medicine and surgery, or present to said board his or her diploma from a medical college that requires after January 1, 1897, at least three courses of not less than six months each before graduation.

To Guard against Yellow Fever.—The health commissioners have directed the sanitary superintendent to exercise special vigilance in the inspection of all sailors' lodging-houses and other places where refugees from fever-infested regions usually congregate. It has been reported that the department has called for the names and addresses of all physicians who have ever served on the health board, in order to form an auxiliary reserve corps to combat yellow fever, smallpox, or other infectious diseases that might be brought here in case of an invasion of Cuba.

St. Mark's Hospital.—The trustees of St. Mark's Hospital, in this city, have purchased the adjoining building, which was formerly occupied by the Italian Home. They will tear it down and soon build an extension to the present hospital.

Vaccination in Abyssinia.—A newspaper of Milan announces that at the Paris meeting of the International Medical Congress, Dr. Mandon will present, on behalf of the Emperor Menelek of Abyssinia, a communication by that monarch on "Small-Pox and Preventive Vaccination as it has been Practised in Abyssinia for Two Centuries."

The Late Dr. Ennis I. Geraghty.—At the regular monthly meeting, held on March 4, 1898, at the New York Foundling Hospital, the following resolutions were read and adopted:

"The medical board has again within a little more than a month to express its feelings of sorrow at the early demise of the junior house surgeon of this hospital, Dr. Ennis I. Geraghty, on February 17, 1898, aged twenty-three years. It is very sad to be called on to pay tribute to the many good qualities of one so young. He was graduated from the medical department of Columbia University in this city. Afterward he served two years in St. Vincent's Hospital, with distinction. On the first of the present year he entered on his duties at the Foundling Hospital, where he gave every promise of a most useful career. He was kind and gentle in the extreme, and endeared himself to everybody. The arduous labors imposed by his medical studies and hospital work were too trying for him. It can be justly said of him that he was a martyr to the cause of medical science. He stood on the very threshold of his chosen career when the dark shadow of death flung its mantle over him.

"Let us hope that higher duties have called him hence; and at the same time express the wish that the wild thyme, the cowslip, and the violet will forever blossom o'er his grave.

"*Resolved*, That we sincerely sympathize with his afflicted family. Also that a copy of this preamble and resolutions be sent to them; that a copy of the same be entered on the minutes of this board, and published in the medical journals of this city."

Clinical Department.

PLACENTA PRÆVIA.

By CHARLES WHITE BERRY, M.D.,

BROOKLYN, N. Y.

Mrs. H——, aged thirty-four years, has had five children, three of whom are living. No miscarriages. She says that always (except with first child) she has more or less discharge from the vagina while carrying her children, until about the time she first feels life, when it stops. With this last child she had a thick, viscous discharge, of a whitish color, for thirty-five days after feeling life. All previous labors were normal, except the one before this, when the bladder was torn by the attending physician, during an attempt to rupture the membranes. This was repaired later in a hospital. She has always been regular in regard to menstruation, it coming every twenty-eight days and lasting five days. Her last normal period commenced May 15, 1897. She had what she called a "slight show" in June; it contained very little blood. In August she had quite a little hemorrhage, which was laid to "change of life;" she also had another in September, but from this time until I first saw her she had no further trouble.

On January 9, 1898, she had a slight hemorrhage, and I saw her for the first time. I was informed that the patient was having a miscarriage; she had had four or five hard pains about fifteen minutes apart; also a severe pain in the left side for two days, which had been continuous. With each one of her hard pains there had been a gush of blood from the vagina.

On examination I found that the child was alive, being able to hear the fœtal heart distinctly in the left iliac region, but I could not make out the parts by palpation. She was a good-sized woman, and her abdomen appeared very small for a pregnancy advanced as far as she thought. The fundus of the uterus was midway between the umbilicus and the ensiform. On vaginal examination I found the vagina full of blood; a small, pointed, hard cervix with a deep laceration up the left side, and dilated just enough to admit one finger; there seemed to be a fulness in the anterior, posterior, and lateral fornices of the vagina. On introducing my forefinger into the cervix, I could feel quite plainly a soft boggy mass, extending over the internal os. I could not feel any part of the child or anything resembling membranes.

From the history and results of the examination I made the diagnosis of placenta prævia. The patient had only one pain after I arrived, and the bleeding stopped of itself. I washed out the blood, after waiting a while, and as a precaution packed the vagina well up into the fornices with gauze soaked in a bichloride solution. I could not pack the cervix without going up into the uterus, on account of the lacerations. She was instructed to remain quiet and to notify me at once on the advent of any more pain or feeling of bleeding. I saw her again that night, and there were no signs of any more hemorrhage or pains. The tampon was left in the vagina and the patient told to keep her bed.

The next morning the tampon was removed, and no further hemorrhage had taken place. She was then allowed to get up and go about the house, being cautioned against any undue exertion.

The next night the same thing happened again, the pains coming on after she had been in bed some time, and with each pain a gush of blood from the vagina. Again the vagina was packed, and the pains ceased.

Her condition was then explained to the family and a termination of the pregnancy advised, more especially as she was likely to be alone a part of each day. This was agreed to, and the following morning Dr. Edward Ferris was called in consultation, he confirming the diagnosis and agreeing that the pregnancy ought to be terminated as soon as possible.

At three o'clock that afternoon the following operation was performed. The bowels and bladder were emptied, and the patient was anæsthetized, chloroform being used. The external genitals were scrubbed and washed off with a bichloride solution, and a vaginal douche of the same was given. The hand, after being made aseptic, was then introduced into the vagina and the cervix dilated with the fingers, they being used as a plug to control the hemorrhage. As soon as sufficient dilatation was accomplished, the hand was shoved up into the uterus, boring through the placenta, which was situated nearly directly over the os, and the membranes were ruptured. This was quite difficult, there being no resistance to the hand. A podalic version was then done, one hand assisting on the abdomen. A foot was caught and brought down, thus plugging the cervix with the half-breech. The foot was used as a tractor and the delivery hastened as much as possible, on account of the patient taking the anæsthetic badly. The placenta followed immediately after the child, and was entire with the membranes, the opening made by the hand being nearly in the centre.

The child lived only a few minutes after being born. It seemed to be of about six or seven months.

The uterus was followed down by the hand and good contraction secured, but in spite of this a very profuse hemorrhage started in. Ergotin was given hypodermically, one drachm of the fluid extract of ergot swallowed, and a hot intra-uterine douche given, but with little effect. The bleeding, as seen through the speculum, seemed to come from the lower part of the uterus, where the placenta had been, that part not seeming to contract with the rest of the uterus, which was hard and firm. The bleeding did not come from the circular artery of the cervix.

We at once proceeded to pack the cervix and vagina, using iodoform gauze and pellets of cotton soaked in bichloride solution and tied around with strips of gauze, the ends of which were left hanging out. Another hypodermic of ergotin was given, and the patient put to bed, the pulse being very weak and rapid. She was wrapped up in blankets, surrounded with hot bottles; whiskey was given hypodermically, a pint of hot coffee injected per rectum; the pillow was removed and the foot of the bed raised so that the head was quite low, and one drachm of hot beef tea and whiskey given as soon as she could swallow, this being repeated every few minutes until she had taken a cupful of the mixture. Under this treatment the pulse picked up a little and she commenced to take fluid well, hot beef tea and milk alternately in drachm doses.

After a steady gain for about two hours, there was a sudden change for the worse, the face and body in spite of the hot bottles becoming cold and moist, and the pulse so weak as to be hardly perceptible, the patient being in a stupor. The uterus was well contracted, but the tampon in the vagina was soaked through and the blood came away at an alarming rate.

It was a question if it should be taken out and repacked or not, we being afraid of a rush of blood that would end life at once; but, as things were getting worse each minute, we concluded that it was the only chance, and after getting everything in readiness the packing was removed, a speculum introduced, the posterior lip of the cervix caught with a tenaculum forceps, and a long thick mass of iodoform gauze seized with dressing forceps and forced right up to the fundus, and then packed in as solid as possible, the vagina being then filled up with balls of absorbent cotton soaked in bichloride solution and packed in as hard

as possible, without delay to fix each piece with a string or strip of gauze. A T bandage was then put on and the patient surrounded with hot bottles as before. She was also given a mixture of opium and ergot. Again she rallied and seemed to pick up, but in an hour the same symptoms appeared again; the pulse at the wrist could not be felt, and the patient lay as if dead, her face and body as cold as ice, and covered with sweat. Ammonia was injected and after a while she rallied a little, but was delirious throughout the night, the fluid and stimulants being kept up.

In the morning there was a pulse of 160 at the wrist and she was conscious. The tampon was soaked with blood as before, but as she seemed to be holding her own it was left in.

The pulse gradually went down below 100 in two days. Sleep was obtained the third night with a mixture of chloral, morphine, and sodium bromide, and the fourth day the tampon was removed and an intrauterine douche of bichloride solution given. The vagina was perfectly dry, and no bleeding beyond the ordinary discharge has come on since.

The patient gained strength each day. On the tenth day she had a fainting-spell, due to straining at stool, but promptly responded to treatment. At no time has she had a temperature of more than 100° F., and she is now up and about.

AN ATYPICAL CASE OF TYPHOID FEVER.

By A. ROBIN, M.D.,

ALLEGHENY, PA.

It is often claimed that typhoid fever is typical only in the text-books; that it may appear with any clinical physiognomy, present any set of symptoms; that the temperature and duration are very seldom sufficiently characteristic to aid one in the differential diagnosis—in short, when the patient has fever and we do not know what is the matter with him, we make a diagnosis of typhoid fever and pay no attention to the books; just as an old professor in a certain medical school used to teach: "If you do not know what the matter is with your man, who is afflicted with some chronic disease, take it for granted that he has syphilis and put him on iodide of potassium." The following case seems to prove this assertion.

Mr. M. S——, a robust, hard-working Irishman, thirty-three years of age, and a bricklayer by occupation, came to me on December 8th, complaining of chilliness, weakness, severe backache, pain in the back of his head, slight coryza, and cough. Temperature, 103° F. He had had a severe attack of typhoid eight years before. I made a probable diagnosis of influenza, prescribed Dover's powder and a calomel purge, and sent him home. On the following morning he had a temperature of 102.5° F., coated tongue, a pulse of 85, and the pain in his back, especially at the neck, was much worse. I gave phenacetin and caffeine, but on the next day there was no improvement. I tried antipyrin, with no better results, and finally resorted to morphine, which controlled the pain. The patient was growing weaker and became emaciated, although his heart was good; pulse, 85–90. The temperature was gradually coming down, and on the tenth day became normal. There were no abdominal symptoms, except two or three attacks of severe cramps, which were due to the constipation and subsided after his bowels had moved by the aid of a saline. His diet consisted of milk, beef tea, and broths. On the eleventh day the patient developed pain in the right inguinal region, which gradually diffused all over the abdomen, a violent diarrhœa, the stools containing curdled milk, and vomiting. Temperature, 102 F.; pulse, 100. I stopped the milk, which he was consuming rather too liberally, and gave him small doses of calomel and deodorized tincture of opium. The symptoms were somewhat ameliorated; he could retain some nourishment, and on the following day his temperature came down to 99° F., and to 98° F. in the evening. His cough and pain in the back were gone, but his debility was rapidly increasing and his heart became weak. Pulse, 100; abdomen distended and tympanitic; mind perfectly clear; expression somewhat anxious—feared that he was dying. On the following day (the thirteenth of the disease) his temperature was 96° F.; pulse, 100 and very weak. There was tenesmus; the stools were less frequent, liquid, but presented no other peculiarity. There was great distention of the abdomen, with frequent retching and occasional vomiting. He could retain milk, but water would make him vomit. Stimulation and other medication failed to improve his condition, and on the following day I found him greatly prostrated, with a temperature of 105° F. I called in consultation a well-known physician. After careful examination he eliminated typhoid fever, appendicitis, and peritonitis, ascribing the patient's condition to a gastro-intestinal catarrh following an attack of grippe. The patient growing gradually worse—temperature, 104° F.—I sent him to the hospital. Although very much exhausted, he was still able to sit up in bed until his clothes were changed by the nurse. He died on the following day, December 25th. The autopsy revealed extensive typhoid ulceration and perforation.

PERFORATING APPENDICITIS IN AN INFANT.

By THOMAS R. SAVAGE, M.D.,

NEW YORK.

On February 6, 1895, I was asked to operate for supposed strangulated inguinal hernia on a boy, sixty-one days old. This rupture existed at birth, and the bowel had steadily made its way to the scrotum. About a week before the operation the hernia became irreducible. Persistent daily taxis by the family physician for several days had failed to dislodge the gut, and finally the so-called "last chance" of an operation was invoked when the boy was moribund and markedly septic. The colon was found to have descended into the scrotum, where it was firmly adherent at the caput, but not strangulated, and a dirty fluid welled up into the abdomen through the abdominal ring, when pressure was made upon the hernia. The gut was loosened from its scrotal attachments and replaced, when the appendix was found to be inflamed and a round perforation was discovered, about one-eighth of an inch in diameter, a short distance from its tip and upon the upper surface. From this opening the fluid escaped. The appendix was then removed and the stump inverted. In spite of all efforts to stimulate him and prevent further infection, the child died next day of septic poisoning.

This case is especially interesting and instructive, as it demonstrates that appendicitis with perforation can result from trauma.

In the specimen, which I have preserved, there are two distinct areas of necrosis within the appendix, each surrounded by inflamed tissue—the first, about one-third inch from the tip, resulted in the perforation; the second, which was about one-half inch from the colon, had penetrated through the mucous coat to the muscular. The appendix, as might have been expected, contained no concretions, fæcal or otherwise.

113 East One Hundred and Sixteenth Street.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Thirty-Eighth Regular Meeting, Held on Friday, March 4, 1898.

W. Gilman Thompson, M.D., President, in the Chair.

Traumatic Rupture of the Spleen; Extirpation.—Dr. Charles McBurney presented a young man, thirty years old, who, early in November, 1896, fell from his horse, and as the horse went over him he was struck on the left side of the thorax low down in the axillary line by the animal's hind hoof. He was brought to Roosevelt Hospital in a state of shock, and an examination showed a distinct bruise over the left side of the lower ribs, rather toward the back. The patient complained of considerable pain in this region, and on account of his pallor and the feebleness of his pulse the house surgeon gave him an infusion of twelve hundred centimetres of sterile salt solution. This immediately produced a marked improvement in the patient's condition, which continued until the following day, when Dr. McBurney first saw him. The symptoms of internal injury were then apparent: the patient's countenance was pale; he vomited frequently; there were profuse sweating, restlessness, and great thirst, with increasing dulness over the left abdominal region. An operation was undertaken immediately. The incision was made along the outer edge of the left rectus muscle. The peritoneum, which was purplish in color, bulged forward, and when it was cut through the peritoneal cavity was found completely filled with blood clots and fluid blood. It was readily ascertained that a rupture of the spleen had taken place; the tear was on the outer aspect of the spleen, running at right angles to the long diameter of the organ, and extending deep down into its tissues. The spleen was rapidly tied off, the pedicle first being divided into two or three sections, and then removed, together with the numerous blood clots in the peritoneal cavity. As none of the other abdominal organs appeared to have sustained injury, the peritoneal cavity was washed out with hot sterile salt solution and the entire wound closed tight, without drainage. At this stage of the operation, Dr. McBurney said, the patient was in a moribund condition; his pupils were widely dilated, he was very pale, and his breathing was hardly perceptible. A vein in the arm was opened and a saline infusion of two thousand centimetres was given, making, in addition to the one given on the previous day, thirty-two hundred centimetres in all. During the administration of the salt solution, a marvellous change for the better occurred in the appearance of the patient; his pulse improved, his pupils contracted and by the time he had received fifteen hundred centimetres he looked like a healthy man asleep. From that time on his recovery was uneventful, with the exception that on the seventh day after the operation he developed a temperature of 101° F., without any local signs. This fever persisted irregularly for over a month, sometimes rising to 102.4° F., sometimes falling to 100° F.; during this period the patient was nervous and restless, but he took nourishment freely. The temperature finally fell to normal and remained so. An examination of the patient's blood, made by Dr. James Ewing soon after the operation, showed an enormous loss of red corpuscles and hæmoglobin; at the second examination nucleated blood corpuscles and many broken-down white cells were found. The speaker said that since the operation, which was performed about eighteen months ago, a slight hernia had developed at the site of the cicatrix, for which the man was wearing an abdominal bandage. There was also a noticeable paresis of the rectus muscle on the left side, which, Dr. McBurney said, was not infrequently observed after operations for appendicitis, and was doubtless due to the division of certain of the muscular nerves in this region. Dr. McBurney said that several years ago he had another case of extirpation of the spleen after traumatic rupture of the organ, and that patient also recovered. In a third case coming under his care recovery would probably have occurred had it not been for the fact that a coincident laceration of the liver existed.

Dr. Beverley Robinson inquired whether it would be of advantage to give a saline infusion just before commencing an operation of great gravity, like the one reported.

Dr. McBurney replied that that expedient was resorted to in some cases. Personally, however, he preferred to get through with the operation as quickly as possible and then throw in the salt solution. By filling up the blood-vessels beforehand, it was possible that greater hemorrhage might be excited.

Dr. Robert F. Weir said he had not had much experience with the infusion of saline solution previous to operating.

Dr. Clement Cleveland asked Dr. McBurney how he had closed his abdominal wound; whether he took any precautions against the occurrence of hernia by using buried sutures or other means. The speaker said he was in the habit of using a specially prepared catgut in these operations, which was supposed to last for forty days. He closed the peritoneum, including the muscles, with the catgut, then the fascia separately with the gut, and lastly the external wound with silkworm gut.

Dr. McBurney said that when he had the time, he always closed the tissues layer by layer, making as many layers as possible; but in some emergency cases, when every moment was of value, he closed the wound by means of a single layer of sutures, which was passed through the whole thickness of the abdominal wall.

Dr. Weir said that his experience with removal of the spleen after injury was limited to two cases, and in both those instances the rupture was associated with injuries of other abdominal organs. His first case was that of a man, aged twenty-seven years, who, on January 21, 1891, discharged a 32-calibre revolver into his left chest, the ball entering one inch below the nipple and stopping beneath the skin, just below the twelfth rib on the left side, and four inches from the vertebral spines. The patient complained of pain in his left hypochondrium. Friction sounds could be heard in the left chest. There was no blood in the urine. Dr. Weir saw the man eight hours after the receipt of the injury, and at once operated. A short incision was first made over the site of the bullet, which was extracted. This incision showed that the kidney on that side was uninjured. A second incision was made through the wound of entrance, which showed that the ball had perforated the chest and that the pleural cavity contained air. A third incision was made in the median line, above the umbilicus; the splenic flexure of the colon was found to be wounded in four places, and the spleen was badly torn in its lower and middle portion. The openings in the colon were clamped, the spleen was extirpated, and the splenic flexure was then lifted out of the abdomen; the peritoneal cavity was then flushed with hot borosalicylic solution. The condition of the patient was so critical that no attempt was made to restore the integrity of the colon, and the injured portion was supported with glass tubes outside the abdomen. The

patient was vigorously stimulated, but died in a short time. A further examination of the abdomen revealed that his death was due to the great hemorrhage which had taken place from the splenic vessels.

The second case reported by Dr. Weir was one of simultaneous extirpation of the spleen and one kidney. The patient was a child of eleven years, who, twenty hours before he saw her, had fallen a distance of about twenty feet, striking her left side against an area railing. The peritoneal cavity contained much extravasated blood. The left kidney was dislocated from its normal position to the level of the iliac crest; on incision of the kidney it was found that two of the renal veins had been torn across, only the artery being left. The kidney was thereupon removed. A further search revealed that the spleen was also deeply lacerated on its median aspect above the hilum, and its removal was necessary. Death occurred nine hours after the operation.

Dr. Weir also called attention to the experiments of Jordan, on dogs. These observations, which were but recently published in *The Lancet*, showed that the removal of the lower half of the spleen after the employment of a locked ligature was a comparatively safe procedure, but that excision of its upper portion was decidedly more dangerous, owing to the difficulty of controlling the gastric arterial anastomosing branches and other vessels, and involvement of the diaphragmatic nerve plexus.

Dr. Robert Abbe reported the case of a boy who was run over by a heavy wagon, with the result of a fracture of the right lower ribs. There were also symptoms of internal hemorrhage which pointed to the right kidney, and when the abdomen was opened by an antero-lateral incision the lower part of the spleen came into view; it was found that this portion of the spleen had been completely severed from the rest of the organ and forced to the right side of the abdomen. The right kidney was also so badly crushed that it had to be removed. A left lateral incision was then made and the remnant of the spleen removed. The boy died in twenty-four hours, and at the autopsy it was found that the left kidney had also been torn completely through.

Dr. Robinson inquired whether the administration of morphine was advisable in cases of great shock after injury—whether the surgeons would advise it under the same conditions as when they give a saline infusion.

Dr. McBurney replied that he thought the administration of morphine was indicated and proper in such cases. It subdued restlessness and had a favorable effect on the heart. It also quieted the stomach. The use of the drug, however, should not be continued, one or two hypodermics usually being sufficient.

Dr. W. Gilman Thompson said the rapidity with which this patient recovered from his extreme anæmia after the removal of the spleen showed that that organ had comparatively little to do with the elaboration of the blood, upon which function it was once supposed to have such an important bearing. Animal experimentation seemed to indicate that the removal of this organ produced certain changes in the temper and disposition of the animal. Such changes had not been noted in human beings after extirpation of the spleen. Another interesting point in Dr. McBurney's case was the long-continued elevation of the temperature. One would expect the temperature to be subnormal after such a loss of blood. The spleen was not supposed to have any heat-controlling function.

Dr. McBurney said that similar rises of temperature might be seen in connection with aseptic blood absorption when the quantity of blood was considerable.

The Choice of Routes, Abdominal or Vaginal, in Intrapelvic Surgery.—Dr. Clement Cleveland presented this paper (see page 577).

Dr. Abbe said he was interested in the statement made by Dr. Cleveland, that after simple incision and drainage of pus sacs in connection with the tubes and ovaries there was usually no further trouble. This would obviate the necessity of removing the tubes and ovaries in cases in which these organs were not too badly tied up in the pelvic parts. Dr. Abbe said he had drained in a number of such cases through the retro-uterine cul-de-sac, and had found this a very satisfactory method of curing a pyosalpinx. Personally he preferred the posterior route in many respects, and for exploratory purposes it should be resorted to in preference to the anterior abdominal incision.

Dr. W. M. Polk said that, while in the main he agreed with the views expressed by Dr. Cleveland, there were certain points in regard to which he differed. In the choice of a route for the removal of a uterine fibroid, the speaker said, the operator should be governed by the formation of the woman's pelvis, rather than by the size of the tumor. If the woman had a "male" pelvis, particularly if she was stout and muscular, it might prove very difficult to remove even a small fibroid by way of the vagina. As regarded the preferable method of operating in cases of extra-uterine pregnancy, Dr. Polk said that this depended largely on the condition of affairs one had to deal with. If the fœtus was dead and one simply had to evacuate a sac, the vaginal route possessed undoubted advantages, as that method did not involve the peritoneal cavity or weaken any of the structures that held in the contents of the abdomen. When the fœtus was alive, however, he was inclined to feel a little sceptical about attacking it from below, unless one first aspirated and let a sufficient amount of time elapse to make certain that atrophy of the vessels of the sac had taken place. In the removal of large ovarian tumors, Dr. Polk said he failed to see any great gain in operating from below, even in the more favorable cases, *i.e.*, those of women with the typical female pelvis, wide and shallow, and with a voluminous vagina, and who were not particularly fat or muscular. In cases in which the sac was intraligamentous and small, it could unquestionably be removed from below; but not infrequently these tumors had many adhesions, and by making a good, free, abdominal incision one could undoubtedly do a cleaner and more thorough operation than by entering through the vagina. The abdominal operation also offered better facilities for doing conservative work in the way of resecting diseased ovaries and tubes, which often rendered a sterile woman fruitful. The question of treating a case of pyosalpinx from below by incision and drainage was a very interesting one. The important point to determine was whether one had to deal with an abscess of the tube or ovary. An abscess of the tube was much less likely to heal of itself than was one of the ovary. The latter variety might heal spontaneously if properly drained; this was also true of abscesses in the peritoneal cavity, but it was not true of those in the tubes. It was questionable whether these would heal spontaneously, and those cases in which there was long-continued discharge probably belonged to this variety. The speaker said that in cases in which he undertook to remove a pus tube from below he preferred to remove the uterus first, thus giving ample space for manipulation and averting the possibility of injuring the intestines—an accident which he had known to occur more than once during colpotomy, both anterior and posterior. In dealing with a prolapsed ovary, and possibly in cases in which the pelvis was very shallow, one might be able to perform certain conservative operations on the ovary from below, but in the main such work could be done better from above. In conclusion, Dr. Polk said that his main reason for preferring the vaginal route in certain operations on

the uterus and its appendages was that after an abdominal operation it was impossible to put the abdominal wall into as good condition as it was before.

Dr. McBurney said he thought the question of sepsis had considerable bearing on the choice of routes in the performance of intrapelvic operations. In a case, for example, in which one had to deal with a septic tube or ovary, its removal through the vagina would be more favorable to the patient than its removal through an abdominal wound; but this rule would not apply to many of the other intrapelvic conditions which were mentioned in Dr. Cleveland's paper. On the contrary, the abdominal operation offered certain distinct advantages over the vaginal—such, for instance, as thorough inspection of the parts, the more ready control of hemorrhage, etc. In obscure cases the speaker said he would certainly prefer the abdominal route to the vaginal. In operating through the vagina, much of the work must be done in the dark, and unless it was in very careful hands harm might be done. Incompetent or inexperienced operators were not infrequently induced to undertake these operations, as many women would submit to them who would not consent to an abdominal operation.

Dr. Cleveland, in closing the discussion, said he was fully in accord with Drs. Polk and McBurney, that many intrapelvic operations must be done by the abdominal route. In certain instances, however, the vaginal method possessed distinct advantages, among them being the perfect drainage that was obtained. In reply to a question, Dr. Cleveland said he tried to prevent the occurrence of ventral hernia by sewing first the peritoneum and muscles together with a specially prepared chromicized catgut, then the fascia with catgut, and lastly the integument with silkworm gut.

Pyæmia, with Abscess of Heart and Abscesses in Lungs and Kidneys, following Grippe; Pneumonia.—Dr. George L. Peabody exhibited the heart of a boy, seventeen years of age, who had died of this disease. Early in January, 1898, he developed consolidation of the lower lobe of the right lung, without initial chill, and soon became delirious. He entered the New York Hospital five days after the onset of his symptoms, which included severe pleuritic pain and great prostration. His fever was high, his temperature during the first week of observation frequently passing 104° F. Under cold packs and mild hypnotics he slept, and his delirium disappeared. In about a week the consolidation gradually resolved, without crisis, and indeed without especial change in the character of his fever or in his general condition. Before the right lung became entirely free from lesion, consolidation developed in the lower lobe of the other lung, and when this gradually resolved in another week it was succeeded by an extensive serous exudation in the left pleural cavity. His pulse and respiration were rapid. He gradually failed, and his temperature began to make wide excursions without any antipyretic treatment, and he died after three weeks' stay in the hospital—not quite four weeks from the onset of symptoms. The autopsy revealed the presence of 900 c.c. of serum in the left pleural cavity and numerous small abscesses in both upper and lower lobes of the right lung, and also in both kidneys. The heart was normal in size and its valves were normal. There was recent lymph over the upper part of both layers of pericardium. In the auriculo-ventricular groove, on its posterior surface, was a prominent abscess containing blood and pus, whose diameter at its base was 2.5 cm., and whose height above the level of the heart wall was 2 cm. It had ruptured at its summit. The pericardium contained 200 c.c. of bloody pus. Cultures from abscesses in all the affected organs, which Dr. Peabody also exhibited, showed pure growths of staphylococcus pyogenes aureus.

Orexin as a Stomachic Tonic.—Dr. Peabody also reported upon the use of orexin as a stomachic tonic and appetizer. He presented a tabulated statement of his experience with it in twenty cases of anorexia and malnutrition due to a large variety of causes. Among the conditions treated were the following: chronic endocarditis, senility with syncope, acute phthisis, malignant endocarditis, chronic phthisis with colitis, specific cerebral endarteritis, influenza, cirrhosis, pneumothorax, dry pleurisy, rheumatism, carcinoma of stomach, inanition, and several others. In sixteen cases the appetite and digestion were distinctly improved; in three cases it caused nausea; in one case it produced no effect. On the average, five days elapsed before beneficial effects were pronounced. Orexin, the speaker said, was a white powder, one of the coal-tar derivatives. If it be put into a mouth whose secretions were acid, it was then soluble and could cause much irritation, with a peppery taste. The hydrochlorate of orexin was always an irritant in the mouth, from its ready solubility. It was well, therefore, to administer the drug either in wafers or in capsules, in doses of three grains, shortly before each meal. It was not a good plan to administer it if there was much fever; but in anorexia from any other cause it was well worth a trial, it being distinctly superior to all the vegetable bitters.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, April 11, 1898.

W. W. Van Arsdale, M.D., Chairman.

Thyroidectomy for Calcified Cyst.—Dr. B. Farquhar Curtis presented a woman, forty years of age, who had been troubled for many years with a thyroid tumor. Twelve years ago it became very large, and was treated with injections by some physician. It contracted and gave no further trouble until last July, when it again enlarged until it caused paralysis of the left vocal cord. The tumor was about four times the size of the normal thyroid, and presented an uneven surface. From its history one would expect a benign growth, but from its hardness and general appearance malignancy was suspected. About two months ago he had removed the tumor. It being exposed, its hardness was explained. It was one of those rather rare tumors of the thyroid of the adenomatous type. One portion only was cystic. The tumor was calcified, and running down into the interior were septa which were also calcified. A thyroidectomy was performed in the usual way, and the wound healed satisfactorily. The wound was united by subdermal sutures of fine silk. The deformity now was very slight, there being very little scarring and none of the usual sinking in of the neck after the removal of a tumor of this size. As the gap was largely filled in with blood clot it was probable that there would be some depression later. The transverse incision passed only through the skin and subcutaneous tissue. The muscles that were divided in the operation were united again by sutures.

Fracture of the Neck of the Femur in a Child Treated by Operation.—Dr. Royal Whitman said that his first interest in fracture of the neck of the femur in childhood arose from the fact that it was not mentioned in the text-books as a possible fracture. These cases were peculiar in that the little patients could often move around for a few days before the nature of the injury was discovered. Since his attention had first been directed to this subject in 1890, he had seen thirteen cases of this kind in chil-

dren ranging in age from two and one-fourth to eight years.

Dr. Whitman presented a little boy who had fallen from a sixth story and had been treated for the contusions received, but in whom the injury of the hip had been overlooked. After six or seven weeks the child had been brought to the Hospital for Ruptured and Crippled for supposed hip-joint disease. As a result of such a fracture in children, a depression of the neck of the femur was produced. It had occurred to him that by a cuneiform osteotomy this depression could be corrected. This was the procedure that had been adopted in one of the cases presented. Being unable to control the upper part of the bone, he found it necessary completely to sever the bone at the point of operation. The condition had some points of resemblance to hip disease. There was marked limitation of abduction, but practically no restriction of extension. He thought that in all these cases the fracture was not complete, and thus the ability of the child to walk shortly after the accident was explained. If the limb was carefully measured and examined, the correct diagnosis should be made.

Dr. A. M. Phelps said that the cases presented were interesting because of the similarity to true coxa vara, and the operation performed was identical with one he had just done for the relief of a double coxa vara. He had passed a chisel into the bone at the lesser trochanter and taken out a wedge of bone. He had divided the bone completely, and during his endeavor to place the bone in proper position it was pulled out of place by the muscles. He had not succeeded in getting the cut surfaces together until he had divided most of the adductors. He believed in all the long-standing cases this contracted condition of the adductors would be found, and this operation seemed to him the only one likely to be of service in such a case.

Dr. Whitman said that in the ordinary type of coxa vara simple linear osteotomy was the better operation. He had operated in two cases, one patient being seventeen and the other eighteen years of age, according to this plan, and had found the operation simple and satisfactory. Cuneiform osteotomy had been done previously by others at the junction of the neck of the bone and the shaft, the base of the wedge being upward and forward, the idea being to rotate it forward.

Pistol-Shot Wound of the Diaphragm, Liver, and Stomach.—Dr. Irving S. Haynes presented a young man who had been admitted to the Harlem Hospital with a pistol-shot wound located between the cartilages of the fifth and sixth ribs. The bullet had passed through the diaphragm about three inches from the costal margin, then through the liver and into the stomach, entering that viscus close to the base of the œsophagus and to the left. At the operation, the lesser peritoneal cavity having been entered, the wound of exit was discovered and sutured. The patient was then in a condition of rather severe shock, so the wound was sutured rather hurriedly. As a result a supra-umbilical hernia developed. As twelve hours had elapsed between the time of the injury and that of the operation, it had been thought best to insert a strip of iodoform gauze for drainage. The patient did well up to the eighteenth day. At this time an abscess developed above the pubes. It was opened and drained, but no sinus could be found leading up to the probable location of the bullet in the back. It was found impossible for a long time to remove the gauze drain, but this was at last accomplished by the aid of a blunt curette having an eye three-eighths of an inch in diameter. The gauze was caught in this and twisted into a string, and so removed.

Forcible Correction of the Deformity of Pott's Disease of the Spine.—Dr. A. M. Phelps described this comparatively new method of treatment, and, after showing two patients who had been so treated, demonstrated the operation on a third patient. First was presented a girl of seven years who, four years and a half ago, had had a plaster-of-Paris corset adjusted for a spinal curvature. With all the force that he had dared exert he could not get the spine perfectly straight. There was no rise of temperature after the operation, and the child was up and around in a few days. The application of great force to a tuberculous spine, he said, was entirely at variance with the old teachings, which warned against the great danger of using much force. This newer and apparently heroic method nevertheless resulted in a rapid straightening of the spine, and was attended with little or no reaction. The second patient presented was a boy of five years, who had been first noticed by the mother to have a kyphos and a limp about one month before. It was probable, however, that the kyphos had existed for at least four months. The limp was due to marked flexion, yet a careful examination failed to show an abscess burrowing down through the muscles. The little patient upon whom the method was demonstrated having been etherized, he was placed in the prone position, and while assistants made powerful traction on the upper and lower extremities Dr. Phelps pressed forcibly downward upon the kyphos until the part had yielded perceptibly. A plaster-of-Paris corset was then applied under traction, care being taken to place a large pad on either side of the kyphos so that the plaster would not touch it. Unless the child developed fever he would be allowed out of bed in the course of three or four days; if fever supervened, he would be kept in bed until the temperature had dropped to the normal. In commenting upon the operation, Dr. Phelps said that no doubt all who had witnessed it felt as he had at first, *i.e.*, uncomfortable and fearful as to the outcome. He had approached the subject with much hesitancy and with many misgivings, and had not entirely gotten over them. The practice had been in vogue in the time of Hippocrates, and had been revived by Ambrose Paré. Once more it had been revived in our own time. Dr. B. E. Hadra, of Galveston, Tex., practised and advocated the method in 1891. He straightened a fractured spine and wired together the spinous processes in 1890. It was evident, therefore, that the modern revival of this very ancient operation should not be credited to France, as some had, but to America—to Hadra, of Texas. The speaker then proceeded to read descriptions and show pictures illustrative of the treatment as employed by Hippocrates and Paré. The method of Paré was almost identical with that used this evening. Dr. John Ridlon, who had been the first to do the operation in this country, had operated in seven cases, and had published his results. The operation was certainly not a dangerous one, metastases did not occur, and paralysis was extremely rare. The operation would certainly relieve paralysis due to bone pressure, and the method seemed to him comparable to that now employed by surgeons for the rapid reduction of the deformity of hip-joint disease. The operation should be avoided in cases of ankylosed spine with a large kyphos, also in cases with large abscessess. Good results should be expected in cases of beginning kyphosis, and in cases of recent origin without abscess, or in which the abscess had already discharged and a small kyphos still remained. Cases of lumbar disease were more favorable than those of dorsal disease, and dorsal more favorable than cervical. He felt sure that the operation would be found a useful one, but its indiscriminate employment by those unable properly to select their cases would probably again relegate it to that oblivion in which it had slumbered for over twenty-four hundred years.

Dr. Wilson, of Montreal, said he had never been able to convince himself that the breaking down of a kyphos which had been buttressed up was warrantable, but, being open to conviction, he had come here with the idea of observing the work done in this direction. He had been impressed with what he had seen, but was not yet a convert to it.

Dr. Whitman thought that too much credit had been given to Dr. Hadra, for his object had been to wire the spines so as to hold them together and obviate the use of a brace. He was not aware that Hadra had advocated forcible correction of the kyphos. Of course, the point was not whether or not we could straighten the spine in these cases, for it was well known that that could be done; the point to be determined was whether or not any permanently good results could be secured. He could not see how there could help being a relapse in cases in which there had been much destruction of bone. Cases of middorsal disease coming under observation in the early stage might, he thought, be greatly benefited in this way.

Dr. Curtis said that in watching the demonstration this evening he had noticed that very little change had taken place at the apex of the kyphos. This seemed to bear out the suggestion that had been made, that the deformity was apparently reduced by increasing the compensatory curves above and below the kyphos. He would like to hear further from Dr. Phelps on this point in connection with the case in which operation had just been performed.

Dr. J. A. Wyeth thought this operation would be a justifiable experiment in cases of paralysis from pressure due to acute deformity, and before any changes had occurred as a result of pressure. Such an undertaking seemed to him warranted, even though it resulted in injury to the cord. In the patient operated upon this evening he doubted very much if the deformity would be reduced as a result of the operation. Personally, he would feel more disposed to cut down upon the kyphos and chisel off the spines, if he desired in such a case to reduce the deformity. His objections were, of course, made at the present time solely on theoretical grounds.

Dr. Phelps said that he believed that unless the spinous processes were wired, the majority of cases would relapse. If the processes were wired they would rest firmly on the bodies, the two transverse processes and the articular processes, and hence he believed the wiring would be found necessary to secure permanent results. In the case operated upon this evening, he could distinctly feel the deformity give way under his hand. In justification of the position that he had taken regarding the credit due Hadra, a passage from Hadra's writings was quoted, showing that he had advocated forcible correction of the spine.

An Open Safety Pin Swallowed.—Dr. B. F. Curtis exhibited a safety pin which while open had been swallowed forty-eight hours before by a baby of six months. The infant had been brought to the babies' wards of the Post-Graduate Hospital the next morning. An *x*-ray photograph taken this day showed the pin lying just within the anus. The case was interesting, because a moderately small safety pin had been swallowed while open and had caused only slight reaction. The temperature had not risen above 101 F. The parents gave no purgatives, but fed the child freely on bread. Another point of interest was the very rapid passage of the pin through the alimentary canal. It was an excellent rule in practice, whenever a child was brought with the statement that it was supposed to have swallowed a pin, to examine the pharynx with the finger, as the foreign body would not infrequently be found within reach of the finger. In the present case it was shown that it was also desirable to examine the rectum even within twenty-four hours.

Dr. Van Arsdale emphasized the importance of giving these little patients solid food, such as potatoes, with a little milk, whenever there was reason to believe a foreign body had been swallowed. A diet of sweet potatoes was especially suitable.

Dr. John B. Walker referred to a case in which a nickel five-cent piece had been embedded in the œsophagus for five months. He had been fortunate then in seizing and extracting it with a "coin catcher."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOUSE OF COMMONS: CONCESSION TO ARMY SURGEONS, SEPARATE CORPS GRANTED — ASTHMA, VAGUS HYPOTHESIS—INTERSCAPULO-THORACIC AMPUTATIONS—ABDOMINAL SECTION THREE TIMES ON ONE PATIENT—ILEO-SIGMOIDOSTOMY—ACUTE ASCENDING PARALYSIS—MEDICAL COUNCIL—SMALL-POX—RECENT FATALITIES: DRS. LUCUS, BRETT, FAED.

London, April 1, 1898.

The government has given way and promised that a "medical army corps" shall be forthwith established, and that the ridiculous compound titles shall be abolished. The announcement was made when the estimates for the medical staff of the army were brought forward. Dr. Farquharson asked for the decision at which the war minister had arrived. Sir William Priestley made a capital speech, which cannot fail to increase his influence with his numerous medical constituents, for he is the representative of the University of Edinburgh. He congratulated the government on the concessions made, and then pointed out that their success must depend partly on the tact and wisdom of commanding officers. If it depended solely on them, I should not join very heartily in the congratulations that are being freely expressed. It ought not to be forgotten that one in high command declared an army surgeon had no more right to be called colonel than archbishop. As long ago as 1857 Lord Dalhousie showed a royal commission how absurd it was to call medical officers non-combatants, but ever since the impertinence has gone on. Sir William Priestley told the house that there are now forty medical officers who hold the Victoria cross, and that medical men go through a more thorough education than the combatants. Howbeit, this government is committed to a change. The war minister has promised the corps and the ordinary rank up to that of colonel. Above that he has not finally decided. The under-secretary said the title of major-general implied command. The objection is absurd, in face of the fact that surgeon-major-generals have heretofore exercised only limited command and other departments none, *e.g.*, education and fortification inspector-generals.

Non-medical members addressed the house from both sides, military men too, and all spoke highly of the medical department and urged that full justice should be done. The war minister, Lord Lansdowne, may therefore well act up to his own expressed opinion and insist on all grievances being removed, in spite of the grudging obstruction of the combatants.

Asthma naturally lends itself to speculation on the one hand and dogmatism on the other. This might perhaps be said of any disease of which the origin is more or less obscure. But asthma has such striking features, the fits are so distressing and provoked by such opposite causes, that the attention of the public as well as of the profession is strongly arrested. On Monday Dr. Kingscote read a paper before the Medical

Society, on the "Vagus Origin of Asthma," in which he blamed an enlarged heart for setting up the disease. He brought forward cases to show that asthma of long standing is often associated with enlarged heart—a fact that hardly required proof; but certainly such enlargement is not constant and therefore cannot be essential. Dr. Kingscote attributes the malady to pressure on the vagi by an enlarged heart, between which and the spinal vertebræ the nerves are, as it were, between an anvil and hammer. In support of this hypothesis he said treatment directed to reduction of the cardiac dilatation benefits the asthma.

Dr. Williams held that asthma is not so incurable as many represent, and extolled the value of iodide of potassium.

Sir F. Lemon mentioned a case in which he had cauterized the nose and Dr. Kingscote had treated the heart, and the patient recovered; but he confessed himself quite unable to decide what had done good.

Dr. Robert Maguire could not admit that an enlarged heart accounted for the symptoms of asthma, and he had no confidence in any form of the vagus theory. He had had many cases of asthma in which the heart was not at all enlarged. If pressure was present, we might be sure other effects would be observed. Neither could Dr. Maguire admit the theory of contraction of the bronchioles, which was opposed to the clinical course of the disease. He rather favored the view of a rapidly occurring congestion or inflammation of the mucous membranes, relieved by secretion, such a condition as he thought existed in false croup.

Dr. Morrison gathered from the narrative of the cases that they were most of them not asthma at all, but cases of cardiac dyspnœa. He thought a rise in endocardial pressure might set up the neurosis.

Other speakers offered suggestions, the president's contribution being that it is conceivable that the heart might be so greatly dilated as to put the pericardium on the stretch, and thus excite a reflex neurosis.

At the last meeting of the Clinical Society Mr. Barling read an account of two cases of interscapulothoracic amputation, both resulting in recovery. The operations were undertaken for sarcoma of the humerus. In one case, when first seen, a huge growth occupied the upper two-thirds of the right arm, overlapping the shoulder-joint, the outer end of the clavicle and spine of the scapula, filling the axilla and stretching under the pectoral muscles. Secondary growths appeared after six months. In the other case the patient had had a severe attack of pneumonia after the operation, performed sixteen months ago, but he quite recovered and was shown to the society. In both cases Berger's operation was done, except that the vein was tied through the anterior flap. Mr. Barling said that this operation had been performed at the Birmingham hospitals eight times during the last ten years, and all the patients had recovered. As nineteen cases of recovery had been recorded, it seemed likely that the mortality might prove less than had been supposed, but some fatal cases were probably not reported.

Mr. Stanley Boyd mentioned a case in which he operated a week previously. An axillary operation had been performed earlier, but the vein and nerves were found embedded in the sarcoma, so the wound was closed. Later on he did a modified Berger. He had to cut away the pectoralis minor close to the thoracic wall.

Mr. Spencer also contributed a case. In this the suprascapular artery came off from the third part of the subclavian. Nearly all the clavicle had to be removed. The case did well. Mr. Spencer said textbooks were wrong in continuing the statement that sarcoma did not affect glands. In a case of periosteal sarcoma of the knee-joint, he found a mass of enlarged glands in Scarpa's triangle. He amputated above the middle third of the thigh and cleared out the triangle ten months ago, and now awaited the result. Such cases usually were fatal within six months.

Next Mr. Bidwell read a paper on ileo-sigmoidostomy founded on a case in which he had resorted to it in order to close an artificial anus at the umbilicus. This had been made for supposed malignant tumor which could not be removed, but the patient was anxious for its closure. The abdomen was opened again and the ileum united to the sigmoid by the Halsted method. Still about half the fæces escaped by the colotomy opening, and two months later the abdomen was opened the third time, the portion of ileum between the cæcum and the anastomosis was divided transversely, and the two ends were invaginated on themselves. The patient was now well and the growth in the splenic flexure less, and therefore it was probably not malignant after all. Mr. Bidwell thought that as the patient's comfort was so much greater after ileo-sigmoidostomy than after colotomy, the former might well be preferred in irremovable tumors of the ascending or transverse colon. He had lately performed it on a lady of sixty-six, with a most satisfactory result.

After this the neurologists listened to a careful record of a case of "Acute Ascending Paralysis with the Bacteriological Examination"—a man, aged thirty-six, admitted under Dr. Buzzard, who said all the merit of the observation was Dr. Risien Russell's. These two observers regard the case as due to some infective agent. The cord was found at the post-mortem greatly engorged, softened, and with numerous hemorrhagic extravasations. Subsequent microscopical examination confirmed the existence of pronounced meningomyelitis. A diplococcus was also found in the exudation of the meninges and in the substance of the cord. Pure cultures of this organism were obtained, and proved fatal to mice and guinea-pigs in twenty-four hours, but a cat survived for a week and was then killed by an overdose of chloroform. This diplococcus seems to differ in several particulars from similar organisms.

A special meeting of the Medical Council is to be held on Tuesday. This is on account of the vacancy in the presidency and also because, the midwives bill being down for discussion in the commons on May 11th, it is important for the council to be able to reply to the government on any points referring to this or other measures.

There have been fewer cases of small-pox at Middlesborough this week, but the epidemic is by no means over.

Dr. Lucas, deputy-inspector-general of hospitals and fleets, met with a fatal accident on Friday last. When passing along the corridor of a train, he lost his footing, fell on the metals, and was killed by an approaching train. He served in the navy from 1857 to 1881, when he retired. He was a justice of the peace for Meath County and one of the directors of the Dublin Apothecaries' Hall.

Another fatal accident. Dr. Brett died on Friday at Bridlington Hospital, from injuries sustained by being thrown from his gig on the previous Wednesday. He had practised at Bridlington some thirty years, and reached the age of fifty-three.

Another fatality is reported. Mr. Faed, in a fit of acute melancholia, threw himself from the window of a hotel at Nice, in which he was staying.

Hydrophobia.—Some eminent medical men now declare that there is no such disease as hydrophobia. They claim that it is nothing more or less than a nervous terror which takes possession of the patient, who in reality dies of pure fright.

SCHLEICH'S MIXTURES FOR GENERAL ANÆSTHESIA.

To the Editor of the Medical Record.

Sir: Once more I would trespass upon your kindness by asking that you grant space in the columns of your esteemed journal, under the heading of "Correspondence," to the following preliminary remarks with reference to Schleich's mixtures for general anæsthesia.

Since reading my paper, entitled "The Improvement of General Anæsthesia by Adapting the Boiling-Point of the Narcotic to the Temperature of the Body (Schleich)," before the Medical Society of the County of New York, on December 27, 1897, I have purposely refrained from publishing the same. Up to that time I had conscientiously tried for almost four months the new anæsthetic mixtures of Schleich in all my hospital and private operations, accepting Schleich's publications in his book, "Schmerzlose Operationen," ed. ii., Jules Springer, Berlin, 1897, as indisputable facts. I read my paper with the sole intention of informing the profession of my personal experience with the mixtures in upward of one hundred cases. I then stated that I was delighted with the improvement in general anæsthesia by means of these mixtures, and tried to induce my colleagues also to make use of the same for the sake of their patients. That so extensive a report as appeared in the columns of the Medical Record of January 8, 1898, was made, I could not help. The stenographer of the Medical Record, known for his admirable accuracy, is responsible for it.

Thus it will appear that it is not correct to say, as a recent writer on "The Perils of Anæsthetic Mixtures," in your issue of April 2, 1898 ("Correspondence"), maintains, that I "published" my article. Before doing this, I wanted to await the results of the chemical analysis of Schleich's mixtures for general anæsthesia, which my friend, Dr. H. P. Weidig, had then just commenced. I also wanted to know more of the physiologic action of petrolic ether when inhaled into the lungs. Dr. Weidig soon found that Schleich's mixture No. 1 contains 53.76 per cent. in volume of free ether; No. 2, 46.64 per cent.; and No. 3, 36.96 per cent.

Having learned this to be a fact, I considered it my duty to make it known to the medical profession. I did so shortly afterward, on February 16th (Medical Record, March 5, 1898, "Correspondence"), stating at the same time that I was then using the "M. S." (molecular solution of ether and chloroform), which, by the help of a petrolic ether of a lower boiling-point (20° C. = 69.8° F.), could also be adapted to the temperature of the body.

On January 18, 1898, Dr. Weidig wrote me: "If there is, as Schleich claims to have established—and about which I have little doubt—a chemical or physical combination of ether and chloroform, he ought to have gone to the point of properly mixing both, *i.e.*, in their molecular proportion. Chloroform, $CHCl_3$, has the molecular weight 119.5; sulphuric ether, $(C_2H_5)_2O$, has the molecular weight 74; 119.5 grams of chemically pure chloroform and 74 grams of absolute sulphuric ether (or, the same expressed in volume, 43.25 per cent. of chloroform and 56.75 per cent. of ether), mixed together, should therefore give the proper molecular mixture to base experiments on."

To repeat: M. S. is the molecular chemical combination of chloroform and sulphuric ether = 43.25 per cent. (in volume) of chloroform and 56.75 per cent. of ether. It is not a mixture, but a real solution, a new anæsthetic of agreeable odor with a boiling-point of its own: 52° C. = 125.6° F. It contains neither free ether nor free chloroform; it is a "straight drink." It forms a part of Schleich's original anæsthetic mixtures.

By adding 3 parts of sulphuric ether to 1 part of M. S., we can reduce the boiling-point of M. S. to 42° C.; by adding 3.5 parts of sulphuric ether to 1 part of M. S., we can reduce the boiling-point of M. S. to 40° C.; by adding 5 parts of sulphuric ether to 1 part of M. S., we can reduce the boiling-point of M. S. to 38° C.

Were we to administer such a mixture (M. S.+ether) to our patients, the first part of the narcosis would then be a mixed anæsthesia of free ether plus M. S. After the ether with its lower boiling-point had evaporated, the anæsthesia would continue by means of pure M. S. alone.

In 1895, when making his first report to the twenty-fourth congress of German surgeons at Berlin, Schleich said: "With the air that leaves the alveoli during expiration, the sulphuric ether is evacuated in chemical combination with the chloroform and the petrolic ether. This combination is exactly the same as it takes place within the test tube. None of the three ethereal substances is evacuated at its partial boiling-point. Continually the same amounts of sulphuric ether, of chloroform, and of petrolic ether are evacuated during expiration, as had been absorbed during inspiration" ("Verhandlung der deutschen Gesellschaft für Chirurgie," 1895, i., p. 150). In Schleich's book, page 66, we find the following remark: "These ethereal substances, mixed with each other, do not evaporate separately; they represent a 'real chemical combination.'"

On the strength of these words, which I took to be correct, I proposed, when reading my paper above referred to, to call the new "anæsthetic mixtures" "Schleich's solutions for general anæsthesia," in contradistinction to the well-known "Schleich's solutions for local anæsthesia." (Schleich himself has always made use of the word "mixture.")

In the light of our present knowledge, however, we have no longer a right to call them thus. The anæsthetics made up according to Schleich's formulæ are mixtures, and not solutions. They contain the fixed molecular solution of chloroform and ether, the M. S., plus 36–53 per cent. in volume of free ether, plus petrolic ether. They contain, however, not a drop of free chloroform. Whether the petrolic ether is in total or partial chemical combination within the mixture, I am unable to say as yet. According to Dr. Weidig, the petrolic ether is, in all probability, not in chemical combination.

Therefore, our patients, when subjected to general anæsthesia by means of Schleich's mixtures, in the beginning of the narcosis inhale pure ether plus M. S. plus petrolic ether. As soon as the ether and petrolic ether which are not in chemical combination have evaporated—and this will probably soon be the case—the narcosis continues with M. S. In other words, in the administration of Schleich's anæsthetic mixtures in their present state, the anæsthetic is adapted to the temperature of the body in the beginning of the narcosis only; after a while the latter is continued with one of a higher boiling-point—52° C. (125.6° F.).

Since I have learned these facts, I personally have discontinued adapting M. S. to the temperature of the body, for the reason that, in the first place, I did not know anything with reference to the physiologic effect upon the human system of a petrolic ether of a boiling-point of 20° C.; and secondly, because of this petrolic ether, six times the quantity of that found in the original Schleich mixtures is needed to reduce the boiling-point of the M. S. from 52° C. = 125.6° F. to 38° C. = 100.4° F.

However, Mr. Editor, my purpose in addressing you to-day is not to state the facts just related: it is rather

to emphasize the fact that we shall most probably have to throw the petrolic ether out of Schleich's new mixtures, and direct our efforts toward finding something better to take its place.

Schleich, in his book, "Schmerzlose Operationen," page 68, says: "I gave this petrolic ether the preference, because I had seen in my experiments on animals that a by far greater amount of it could be administered hypodermically without producing serious disturbances than of any other ethereal substance known. Petrolic ether is a means of reducing the effect of the chloroform within the mixtures; it dilutes."

At my solicitation, Dr. S. J. Meltzer, of this city, has been good enough to narcotize a number of animals (rabbits and guinea-pigs) with pure petrolic ether of 60°–65° C. boiling-point, the kind we are wont to use for Schleich's mixtures. According to his communications of April 3d and April 13th, Dr. Meltzer found petrolic ether, when inhaled pure and not mixed with any other ethereal substance by mouth and nose or by tracheal cannula, to be not at all such an indifferent hydrocarbon as Schleich has stated; but to act, in these animals at least, as a real poison. Without becoming cyanosed, the animals, after a few whiffs, were seized with a tremor which soon increased to convulsions, later to tetanus and episthotonos, as we are used to seeing it in strychnine poisoning. The hind legs are the first affected; later the anterior portion of the body also succumbs. If the inhalation is interrupted, the animals slowly recuperate; if it is continued, they die with symptoms of tetanus. Petrolic ether has no narcotizing effects. If it be inhaled in combination with sulphuric ether, convulsions are absent, but the resulting paralysis remains unchanged. Hence the conclusion is justified that, if this mixed narcosis could be sufficiently extended, such animals would most probably die from paralysis of the respiratory muscles.

Dr. Weidig, when narcotizing a cat with petrolic ether of boiling-point 60°–65° C., some time ago, had a similar experience.

Whether the same phenomena would be found in the human subject, if made to inhale pure petrolic ether of 60°–65° C. boiling-point, cannot be said; it is probable, however.

That the physicians who have made use of Schleich's anæsthetic mixtures did not have deplorable accidents with some of their patients finds its explanation, it seems to me, in the fact that the percentage of petrolic ether is so very small—one-eighth to one-sixteenth part of the entire volume. That the results obtained by most observers with this new narcotic have, on the contrary, been rather good and encouraging, despite the dangerous nature of the inhalation of pure petrolic ether, clearly proves, on the other hand, that Schleich is on the right track in his investigations; that is to say, he is correct in that the question of finding a drug for general anæsthesia that is least poisonous to the human system—an absolutely non-poisonous substance will and can never be found—can be solved on a physical basis only, viz., by adapting the boiling-point of the narcotic to the temperature of the body.

It would certainly be a great step backward, if, on the strength of our latest discoveries, we were now to discard Schleich's mixtures entirely, ignore the truths brought to light by his investigations, and return to the administration of pure ether and pure chloroform. On the contrary, having found by our own researches what is good and what is bad in Schleich's anæsthetic mixtures, in a chemical as well as in a physiologic sense, we must continue our efforts and try to find that anæsthetic substance which, when added to M. S., will enter into a true chemical combination with the same and reduce its boiling-point of 52° C. to 38°–42° C. Chemists and physiologists must help in these researches.

I, for my part, am satisfied for the present with the pure M. S., the nucleus of Schleich's mixtures, which, when administered by the drop method, will be found to be a most excellent narcotic.

Willy Meyer, M.D.

700 Madison Avenue, New York.

GLOVES FOR ASEPTIC SURGERY.

To the Editor of the Medical Record.

Sir: Gloves for employment in aseptic surgical work have been recently advocated on theoretical grounds by so many prominent surgeons that many of the younger men feel in duty bound to use such gloves in order to be up to date. To all such younger men who have misgivings prompted by natural sense, I wish to state that one surgeon at least can be depended upon to fortify them by his example in refusing to adopt anything that will injure the surgeon's most precious possession—the sense of touch. I have been much interested in everything that seemed to be in the nature of progress in surgery, and have given close attention to the matter of gloves for aseptic surgical work, but have arrived at the conclusion that the practical disadvantages of gloves counterbalance their theoretical advantages. Surgeons who were doing first-class work three years ago seem to me to be doing second or third rate work now on account of the interference made by their gloves. The greatest danger to be feared is that the younger generation of surgeons may fail to develop the sense of touch to the highest degree, and we shall have much second-rate work done, particularly in abdominal surgery. If any one employs gloves in peritoneal work—in removing adherent appendices and pus tubes, for instance—he is liable to obtain statistics which are believed by his rivals, and he must make long incisions and do slow work that shocks the patient, and he must do much incomplete work when he is forced to depend upon the coarse, commonplace sense of sight.

I have watched various European and American operators at work with gloves, and have asked about their statistics. I will choose Weir's nascent-chlorine skin sterilization and untrammelled fingers that are quick to work deftly in doing neat, accurate work. My statistics will always be at the disposal of men who wish them for comparison with glove statistics. To the younger generation of surgeons, I say, fight with your might against the idea of using a means that will damage your most precious possession—the sense of touch. Put aside the temptation to be up to date theoretically, at the cost of adopting a destructive agent in your work. As a test of skill palpate a normal appendix instead of trying to secure a pediculus pubis with the aid of a pair of boxing-gloves.

Robert T. Morris, M.D.

49 West Thirty-Ninth Street, New York,
April 8, 1898.

Municipal Board of Health for Berlin.—The *British Medical Journal* says the question of a proposed separate municipal board of health for Berlin has been discussed at two meetings of the magistrates. There are difficulties in the way, for the head officials of the sanitary police are very much against transferring any part of their power to the municipal authorities. Still pourparlers have begun and will probably lead to victory for the Berlin municipality, which has proved itself such a brilliant organizer and successful director of its sanitary operations.

New Instruments.

A NEW FIELD TOURNIQUET.

By OLIVER D. NORTON, M.D.,

SURGEON, UNITED STATES NAVY.

THERE has been devised as an improvement on the present field tourniquet used in the navy, known as the United States army tourniquet, a substitute, which

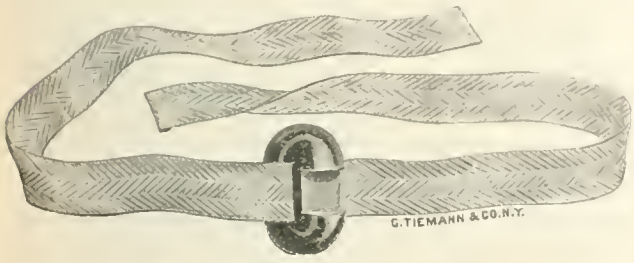

FIG. 1.—Tourniquet Complete and Ready for Use.

has among its advantages efficiency, readiness, and ease of application, the absence of buckle or screw, its size and weight, and its cheapness. The tourniquet consists of a hard-rubber pad, ovoid in shape, somewhat smaller in size than a hen's egg; the diameters are two and one-eighth inches by one and one-half inches; its weight complete is two and one-half ounces. A slot, one inch in width, is cut in the upper third at right angles to the long axis of the pad; through this slot passes the webbing. The webbing consists of a strip, sixty inches in length by one inch in width. The simplicity of the tourniquet is in its favor, for any layman can apply it. The traction is made on both sides of the pad equally by the downward pressure of the webbing, thereby preventing the displacement of the pad. The ends of the webbing, being brought around the limb, are tied directly over the pad with a square knot. The tourniquet can be sterilized without fear of injury or oxidation.

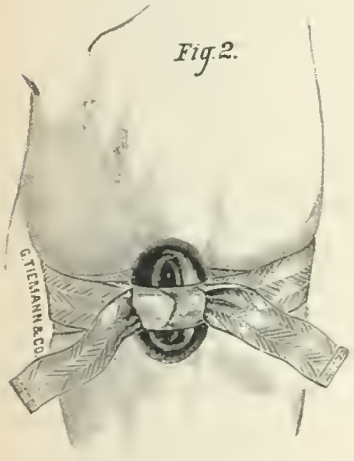

FIG. 2.—Tourniquet Applied, the Square Knot Resting in the Groove of the Hard-Rubber Pad.

It is made by George Tiemann & Co., of New York, and has been adopted for use in the navy.

U. S. NAVAL LABORATORY AND DEPARTMENT OF INSTRUCTION, BROOKLYN, N. Y.

Chronic Glandular Gastritis.—By means of the gyromele we brush off all the vitiated secretions and immediately wash them out of the stomach; if necessary, as suggested by Turck, using one drachm of tincture of green soap to one pint of water. This may be passed through the gyromele while it is revolving. After the stomach has been thoroughly cleansed, it is sprayed through a double tube by means of a nebulizer. The spray consists of oil of cinnamon, 2 parts; oil of cloves, 2 parts; menthol, 1 part; olive oil, 10 parts. By this means the finely divided essential oils are made to reach every portion of the mucous surfaces. —DR. E. P. HERSHEY, *The Colorado Medical Journal*, August, 1897.

Medical Items.

A River of Death.—The Yellow River, which has been named the "Sorrow of China," is probably the most destructive stream on the face of the earth. In less than a hundred years it has changed its channel four times, and the point where it empties into the sea has from time to time been moved up and down the coast a distance of three hundred miles. It runs through a vast alluvial plain, and is fed by streams from a great system of mountains in the north. When the snow melting on the range comes at a time of heavy rains, the result is sure to be a terrible flood. It has been estimated that in the past three centuries over ten million human beings have perished in the floods of the Yellow River. For destructiveness of both life and property this stream is unparalleled, and the sobriquet bestowed on it is amply justified by its history.—*St. Louis Globe-Democrat.*

Town without Dogs.—It is stated that Tisek, Bohemia, is probably the only dogless town in the world. In consequence of a death from hydrophobia, the authorities ordered every dog in the place to be killed.

Women who Smoke.—The *London Daily Telegraph* says that "the great middle class is smoking the cigarette as unconstrainedly as the aristocratic order, and working womanhood is taking it up to an extent which is certain ere long to attract the attention of those stern moralists who see in even the purchase of a pennyworth of sweets a growing tendency to self-indulgence. Inquiries among doctors, district visitors, tobacconists, and others who are most capable of expressing an opinion on the subject, have brought forward some very curious facts. Nowhere are to be found more inveterate female smokers than in those long streets in the less considered suburbs of 'genteel' residences, rented at from £24 to £30 a year. The clerk or the shopman marries the typist or waitress, and two such couples share one of these houses. The women soon fulfil their modest household duties, they have slight resources in themselves for reading or artistic work, and have very little, indeed, to spend on amusements. And so, alone or in company, they turn to the cheap cigarette, finding in it something at least to deaden the craving for more exciting pleasure. The low price, too, of the cigarette accounts largely for the increase of smoking among factory and servant girls. Thanks to exquisitely ingenious mechanism, by which one cigarette-making machine can do as much in a day as one hundred and fifty girls could turn out, and can produce five hundred finished cigarettes a minute, these are now within reach, not only of the man in the street, but also the boy, who begins to puff them while still in the infant classes at school. His small sister tries them also. The West End shop-girls 'living in,' on the other hand, scarcely ever smoke, probably because indoors it would be absolutely forbidden, and outside custom is still strong against it. Most convincing proof, however, of all, that smoking is on the increase among the sex, is that the great wholesale manufacturers are beginning to find it necessary to cater especially for female demands. Women, when they smoke for their enjoyment and not merely to puff a cigarette because it is Bohemian and daring to do so, have remarkably fastidious palates, and in the high-class West End shops demand the most delicate and refined cigarettes, when they do not call for cigars."

Test of Death.—The statement is made, in a well-known English weekly journal, that an eminent American oculist has discovered means whereby it can be

ascertained whether a person be really dead. This knowledge is said to be arrived at by an examination of the veins of the eye. The discovery referred to is doubtless that of Dr. Chalmers Prentice, of Chicago, who claims to have found a true and unfailing test of death, and which was heralded in the Chicago *Tribune* of a recent date in the following words: "Dr. Chalmers Prentice, of this city, is about to communicate to the medical world a discovery that he believes bound to prove a boon to humanity, and to rob death of this one of its terrors. He has found how, he says, to read death in the human eye, to tell by the appearance of veins and arteries whether life has departed or a spark yet remains, and to tell it with absolute certainty." It is said that the doctor's experiments began some twenty years ago. He had observed that in life the veins and arteries of the retina have distinct differences in color. The veins contain a dark, blackish blood, while the arteries contain bright crimson. At the back part of the eyeball these two shades of blood may be seen under the light of the ophthalmoscope, dividing the retina. Even in the case of the blind this distinction in shade may be seen, unless, of course, an opaque film has formed over the injured eyes or the eyes have been entirely destroyed. In death, however, the shade distinction entirely disappears. The blood in both arteries and veins is transformed into a pinkish color of uniform shade. An exhaustive examination has been made, and this simple test has never failed. In the case of suspended animation, when others had pronounced death, he has observed the shade distinction and saved the man from being buried alive.

Way to Kill Mosquitoes.—Two and one-half hours are required for a mosquito to develop from its first stage, a speck resembling cholera bacteria, to its active and venomous maturity. The insect in all its phases may be instantly killed by contact with minute quantities of permanganate of potassium. It is claimed that one part of this substance in fifteen hundred of solution distributed in mosquito marshes will render the development of larvæ impossible; that a handful of permanganate will oxidize a ten-acre swamp, kill its embryo insects, and keep it free from organic matter for thirty days at a cost of twenty-five cents; that with care a whole State may be kept free of insect pests at a small cost. An efficacious method is to scatter a few crystals widely apart. A single pinch of permanganate has killed all the germs in a thousand-gallon tank.—*The Public Health Journal.*

Anger a Disease.—An English journal thus comments on the injurious effects of anger: "Anger serves the unhappy mortal who indulges in it much the same as intoxicants constantly taken do the inebriate. It grows into a sort of disease which has various and terrible results. Sir Richard Quain said, not long ago: 'He is a man very rich indeed in physical power who can afford to be angry.' This is true. Every time a man becomes 'white' or red with anger, he is in danger of his life. The heart and brain are the organs mostly affected when fits of passion are indulged in. Not only does anger cause partial paralysis of the small blood-vessels, but the heart's action becomes intermittent; that is, every now and then it drops a beat—much the same thing as is experienced by excessive smokers."

A Prime Minister and his Wooden Leg.—The rapid progress made by the Japanese in adopting the arts and manufactures of the West has been watched in recent years with something like dismay by many traders, who fear that a profitable market may be lost to them by the development of native industry. There are still a few things, however, which the native of Japan who wishes for a superior article has to procure abroad. One of these is guns; another—not altogether unconnected with the first—is wooden legs. An American journal recently announced with natural patriotic pride that Count Okuma, the prime minister of Japan, had instructed the Japanese minister to the United States to order a wooden leg for him in that country. The artificial limb, which we are considerately informed cost $100, was shipped to Japan in two weeks. This is said to be the second wooden leg which the Japanese prime minister has bought in the United States. In 1890 a Japanese fanatic, named Hunekt Karushima, threw a bomb into the foreign office where Count Okuma was at work, the result being the destruction of the prime minister's right leg. A native cabinetmaker made for him an artificial limb, finely lacquered and inlaid with mother-of-pearl. This thing of beauty, however, did not prove a joy forever, and when Count Okuma visited the United States in 1894 he procured a wooden leg which, if less artistic, was more serviceable. The American article was recently—to use the expression of an ex-prime minister of England—smashed, shattered, and pulverized in a street accident. Hence the necessity of a further patronage of American manufactures on the part of the Japanese statesman.—*British Medical Journal.*

PERITYPHLITIS.

BY A MAN WHO HAS HAD IT.

Of human inflictions, and woes, and diseases,
From tuberculosis to innocent sneezes,
From strength-sapping typhoid to plain indigestion,
From tabes to toothache, there can be no question,
Though bad in their way, yet not one of them quite is
So utterly horrid as perityphlitis.

They've altered its name now, and so it thought right is
To know this affliction as appendicitis
(It matters not two rows of pins what its name is);
All those who affirm that "whatever is right is"
Can never have suffered from perityphlitis.

It comes not in stages; 'tis all one long stage on—
What's called by the doctors a "sudden invasion."
You feel like a worm; all at once, I affirm, you
Are limp as chewed string is or even chewed worm, too;
Your legs are like canes and your walk quite a sight is,
When six weeks you've had of this perityphlitis

What's worse than the pain and the weakness and fright is
The heartsick delay of this perityphlitis,
And when it is over the worst part perhaps is
The spending your hours looking out for relapses
My prayer then at noonday and morning and night is,
Oh, spare all my friends from this perityphlitis!

The Practice of Medicine in Turkey.—An English weekly is responsible for the following statement: "It is not generally known that medical science has made no progress whatever in Turkey, and that the poorer classes of that country have no skill at all in the treatment of disease. The popular belief among these people is that disease is God's will, and to attempt to cure disease would be to interfere with the divine judgment. Missionaries have frequently found people, ill from small-pox, entirely neglected, in order that the divine will should have its own way. The so-called cures that are practised show an equally unenlightened spirit. When, for example, a baby is suffering from croup, the following prescription is considered infallible: A hen's egg is obtained and seven round holes are made in the shell. The contents are poured into a bowl and the perforated shell is dipped into some water and lifted quickly over the basin so that the water will stream into the basin. This operation is repeated thirty-nine times. The contents of the basin may then be used for washing the little sufferer. The few doctors who have administered to the natives have been received as if they were

gods. Whenever travellers go into the interior of Turkey they are appealed to as if every one of them were a doctor. The average Turk or Armenian seems to believe that any man wearing a European hat is competent to treat all bodily ailments.

True Gratitude.—The following recently appeared among the obituary notices of the *Dublin Independent:*

"SMIT.—On the 28th inst., Amy Jane Mary Smit, eldest daughter of John and Wilhelmina Smit, aged one day, two and one-half hours.

"The bereaved and heartbroken parents beg to tender their hearty thanks to Dr. Jones for his unremitting attention during the illness of the deceased, and for the moderate brevity of his bill. Also to Mr. Wilson for running for the doctor, and to Mr. Robinson for recommending mustard plaster."

An Invidious Association.—In advancing arguments for a non-meat diet, the London *Vegetarian* says, among other things: "Your carnivorous gentleman is afraid of everything, including doctors, dogs, disease, and death." Too strong a protest cannot be made by the medical press against the use of the doctor's name in such uncongenial company.

Excessive Use of Hashish.—The reports of the asylum at Cairo as to the native patients there exhibiting the nature of the mental disturbance associated with the excessive use of hashish show some remarkable facts. It appears that in forty-one per cent. of all the male patients hashish alone or in combination with alcohol caused the mental symptoms, while this was the case with only seven per cent. of the females. As to whether there is a special recognizable form of mental disturbance produced by hashish, authorities conclude that in a considerable number of cases in Egypt the hashish is the chief if not the only cause of such mental disease. The usual types of the disease are hashish intoxication, that is, an elated and reckless swaggering state with optical illusions and hallucinations. Acute mania is another form of hashish insanity, involving terrifying hallucinations, restlessness, sleeplessness, incoherence, and exhaustion. Again this kind of insanity takes on the form of weak-mindedness, the patients being quiet and well behaved but overtalkative, easily pleased, excitable about small things, and unconcerned as to the future.

Opium Trade in America.—Some time ago, according to the *Scientific American*, an attempt to raise the opium poppy in California was made during a period of several years. The hot days seemed altogether favorable for the production of the plant and drug, but the accompanying cold nights and the absence of cheap labor proved fatal to the project, and it has been given up as a failure. In the very oldest books of the Arabs the poppy is mentioned, showing that the use of the gum is one of the most ancient of practices. The poppy used for the purpose is Papaver somniferum, a plant discovered in all probability by the Arabs and carried from Arabia by man over large portions of the globe. At first opium was used as a medicine. Theophrastus was familiar with it and Dioscorides in 77 A.D. wrote a learned paper on its properties. Up to the twelfth century Asia Minor was the source of supply, and from then on it was gradually distributed over the globe. The Chinese first obtained the drug in the thirteenth century, it being used purely as a medicine; but gradually its insidious effects were realized and it became so important a drug that in 1757 the great monopoly was secured in India by the East India Company. Nearly all the opium smoked by the Chinese in this country comes from the Fook Hing Company of Hong Kong, which pays the government $300,000 per year for the privilege of carrying on the business. The opium is packed in five-tael tins, which bring in San Francisco $8 each. Some excessive smokers use from $4 to $8 worth a week.

Novel Reading and Disease.—The writer of the London literary letter in the New York *Times* of March 5th says: "So far as can be ascertained influenza is the only disease that promotes the sale of novels. Consumption probably stimulates the sale of semireligious stories, and it is possible that prolonged indigestion, accompanied by nausea, tempts people of the homœopathic faith to read Sarah Grand's physiological novels; but as an aid to the spread of general novel reading there is nothing to be compared to influenza.

The Herpetomonas.—Prof. Ray Lankaster, in a lecture at the Royal Institution on the simplest living things, referred to the herpetomonas, a small and simple species of Flagellate belonging to the group Corticata. The professor said that these parasitic algæ had been sometimes noticed in the blood of rats, to which they did not seem to do any harm. Then the blood of animals affected with surra, a deadly form of cattle disease occurring in India, was found to contain a similar form, and later it was discovered in nagana, the disease supposed to be produced by the tsetse fly. Some three years ago the opinion was started that the fly was not the true cause of the disease, and experiment proved the bite of a newly hatched fly to be harmless, though the blood of an animal bitten in the open was found to be swarming with herpetomonas. It could not be discovered that the organism produced any poison, nor was anything like an antitoxin obtainable, but it was certainly the cause of the disease, which could be transmitted without the fly. It appeared that certain wild animals could have the organism in their blood without ill effects, and a fly which had bitten one of these could convey the disease to domesticated animals.—*London Times.*

Insanity.—Dr. Peper M. Wise, in an article entitled "The Past, Present, and Prospective Methods of the Treatment of Insanity in the State of New York," says: "It now seems incomprehensible that a symptom of disease as common as insanity, affecting at least one in four hundred and fifty of the population, should have received scarcely any attention from physicians and scientists. I cannot find that any medical school in the State gave special instruction upon this subject at a time when the proportion of the insane reached one per cent. of the entire population. Even at the present time, when one in every two hundred of the community is insane, and when the insane diathesis so permeates society that we dare not estimate its extent numerically in fear of scepticism, the schools dismiss the subject in almost a flippant manner."

Scurvy.—Captain Cook's name is associated with the suppression of the once prevalent disease, scurvy—a disease which, up to the latter half of the eighteenth century, decimated our armies and fleets, and often proved terribly fatal among the civil population. In Anson's famous expedition, some thirty years previous to that of Captain Cook, out of a total of nine hundred hands six hundred died before the expedition returned, and chiefly from scurvy. Captain Cook, in his first voyage of discovery round the world, from 1772 to 1775, proved beyond a doubt that the disease could be banished from every ship's crew, and that it could be entirely eradicated on land and sea. Captain Cook thus earned for himself a foremost place among the sanitary reformers of the eighteenth century. —Dr. George Wilson, "Handbook of Hygiene and Sanitary Science," page 10.

Long Dresses the Vehicles of Disease. — Trains or trailing street gowns are coming in, in spite of increasing knowledge of germs and the virtues—or vices—of a long gown as a germ catcher. It is a ball dress that a Detroit journal describes "as perfectly killing," but it might as well be a street gown.

A narrow waist, a neck cut low,
A heavy dragging train wears she.
Dressed to kill? Well, I don't know—
Dressed to kill herself maybe.

—*New York Times.*

Eating at Night.—A writer in the *Italia Termale* declares in favor of late suppers. He says that many people who remain thin and weakly in spite of all precautions in regard to diet, etc., owe the fact largely to habitual abstemiousness at night. He remarks that physiology teaches us that in sleeping as in waking there is a perpetual waste going on in the tissues of the body, and it seems but logical that nourishment should be continuous as well. The digestion of the food taken at dinner or in the early evening is finished as a usual thing before or by bedtime, yet the activity of the process of assimilation, etc., continues for hours afterward; and when one retires with an empty stomach the result of this activity is sleeplessness and an undue wasting of the system. All other creatures, says the writer, outside of man, are governed by a natural instinct which leads those having a stomach to eat before lying down for the night. The infant, guided by the same instinct, takes the breast frequently in the night as well as in the day, and if its stomach is allowed to remain empty too long it shows its discomfort by crying. The digestive organs have no need for repose, provided always that the quantity of nourishment taken within the twenty-four hours does not go beyond the normal limit. The fact that the intervals between meals is short works no inconvenience, but on the contrary tends to the avoidance of feebleness which is the natural result of an interval extended to too great a length. Feeble persons, lean and emaciated persons, and above all those suffering from insomnia, owe it to themselves not to retire without taking some nourishment into the stomach—bread and butter, a glass of rich milk, a few biscuits, or even a bit of juicy cold meat for instance.

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended April 15, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile	April 8th	1	
Kentucky, Middlesborough	March 29th to April 7th	5	
Ohio, Fairfield	April 1st to 8th	..	1

SMALL-POX—FOREIGN.

Bohemia, Prague	March 12th to 19th	6	
Cuba, Cienfuegos	March 27th to April 3d	..	3
Havana	March 24th to 31st	..	9
Regla	March 24th to 31st	..	1
Sagua la Grande	March 26th to April 2d	59	1
England, Gibraltar	March 13th to 27th	3	
London	March 13th to 26th	2	
Sunderland	March 19th to 26th	1	
India, Bombay	February 24th to March 15th	..	6
Calcutta	February 19th to March 5th	..	5
Italy, Messina	March 19th to 26th	..	1
Norway, Christiania	March 19th to 26th	4	
Russia, Moscow	March 12th to 26th	12	2
Odessa	March 5th to 19th	13	3
St. Petersburg	March 12th to 19th	..	9
Warsaw	March 12th to 19th	2	2

CHOLERA—FOREIGN.

India, Bombay	February 24th to March 15th	..	10
Calcutta	February 19th to March 5th	..	43

YELLOW FEVER—FOREIGN.

Brazil, Ceara	December 1st to February 28th	..	4
Rio de Janeiro	March 4th to 11th	65	44

PLAGUE—FOREIGN.

India, Bombay	February 26th to March 15th	..	3439

The Rapidity of Thought.—To illustrate the rapidity of thought, a distinguished scientist says that if the skin be touched repeatedly with light blows from a small hammer, the brain will distinguish the fact that the blows are separate and not continuous pressure, even when they follow one another as rapidly as one thousand in a second.

Causes of Death.—According to an English weekly journal it is estimated by a competent foreign authority that only 900 persons out of every 1,000,000 die from old age, while 1,200 succumb to gout, 18,400 to measles, 2,700 to apoplexy, 7,000 to erysipelas, 7,500 to consumption, 48,000 to scarlet fever, 25,000 to whooping-cough, 30,000 to typhoid and typhus, and 7,000 to rheumatism. The averages vary according to locality, but these are considered accurate as regards the population of the globe as a whole.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CARE OF THE SICK. By Dr. Th. Billroth. Translated by J. B. Endean. Fourth Edition, 333 pages. Illustrated. Sampson, Low, Marston & Co., Ltd., London. Price, $1.50.

THE INTERNATIONAL MEDICAL ANNUAL. 1898. E. B. Treat & Co., New York City.

DAYDREAMS OF A DOCTOR. By Dr. C. Barlow. 8vo, 251 pages. Illustrated. The Peter Paul Book Company, New York.

THE PURIFICATION OF PUBLIC WATER SUPPLIES. By J. W. Hill. 8vo, 304 pages. Illustrated. D. Van Nostrand Company, New York.

MAMMALIAN ANATOMY. Part I. The Skeleton of the Cat. By Dr. Horace Jayne. Royal 8vo, 816 pages. Illustrated. J. B. Lippincott Company, Philadelphia, Pa.

SURGICAL COMPLICATIONS AND SEQUELS OF TYPHOID FEVER. By Dr. W. W. Keen and Dr. G. E. de Schweinitz. 8vo, 386 pages. Illustrated. W. B. Saunders, Philadelphia. Price, $3.00 net.

INVESTIGATION, DIAGNOSIS, AND TREATMENT OF INTERNAL DISEASES. By Dr. C. Jakob. Edited by Dr. A. A. Eshner. 8vo, 259 pages. Illustrated. W. B. Saunders Philadelphia.

A COMPENDIUM OF INSANITY. By Dr. J. B. Chapin. 8vo, 234 pages. Illustrated. W. B. Saunders, Philadelphia. Price, $1.25 net.

SANITARY ENGINEERING. By W. P. Gerhard, C. E. 8vo, 132 pages. Published by the Author, 36 Union Square, E., New York.

INDEX TO THE TRANSACTIONS OF THE CLINICAL SOCIETY OF LONDON. Vols. I.–XXX. 8vo, 206 pages. Longmans, Green, & Co., London.

SOME INTERESTING CASES OF BRAIN INJURY, WITH A STATEMENT OF THE MECHANISM OF THE PRODUCTION OF CEREBRAL LESIONS BY BLUNT VIOLENCE AND A BRIEF SUMMARY OF THE PATHOLOGY AND SYMPTOMATOLOGY OF ACUTE CEREBRAL TRAUMA.[1]

BY R. VAN SANTVOORD, M.D.,

NEW YORK

TRAUMATIC lesions of the brain are so common and important that they are of as much practical interest to the physician as to the surgeon. It has seemed to me profitable to present for your consideration the following cases which have recently occurred in the services of my colleagues, Drs. Haynes and Hanbold, and in my own at the Harlem Hospital.

CASE I.—M. J——, female, aged nineteen, fell from a trolley car, presumably striking her head upon the pavement. She was picked up unconscious and bleeding from the left ear, nose, and mouth. This unconsciousness continued until her death a week later, some evidently voluntary movements of the hands made when her mouth was forcibly opened being the only indication that it was not complete. The right pupil was dilated and immobile; the left normal and responsive to light. There was a moderate amount of chemosis of the ocular conjunctiva of both sides, and later a line of opacity of both corneæ corresponding to the surface left exposed by imperfect closure of the lids. The right globe was slightly protuberant. Both eyeballs moved on irritation. On admission all the limbs were rigid. On the two occasions on which I examined her this rigidity was confined to the arms, but most of the time it was said to include the legs also. It continued until death. Swallowing was possible when liquids were placed in the pharynx, but rectal feeding was relied on. She was incontinent of both urine and fæces. The temperature was 102.8° F. on admission, and varied but little from 103° F. until the morning of her death, when it sank gradually to 100.8° F. The pulse varied from 110 to 146 irregularly; respirations from 18 to 40. About six hours before death clonic convulsions occurred, confined to the left side, including the face, at first only about a minute apart, later less frequently, and finally ceasing about three hours before death from gradual asthenia.

Autopsy: Small amount of blood effused under the scalp above the left ear. A lineal fracture extended from the apex of the petrous portion of the left temporal bone along its anterior surface, parallel to and about one inch below its upper border, and extending upward on the side of the vault as far as the temporal ridge. A second fine fissure was found, a little to the right of the median line of the body of the sphenoid, extending backward through the base of its greater wing. In a line with this was a third fissure, extending through the middle of the petrous portion of the right temporal. The sphenoidal sinus was filled with blood. A small amount of blood was found around the right optic nerve. A large epidural clot was found on the left side, extending from the base to a line about corresponding to the temporal ridge, and three fourths inch in thickness at its lower part. The surface of the right hemisphere was covered with a layer of partly clotted blood, thick below, thin above. The vessels of the pia were generally dilated, but more markedly so over the right hemisphere. A deep laceration with a cavity about the size of a pigeon's egg was found at the middle of the third left temporal convolution. A small superficial laceration existed at the apex of the same lobe and at the posterior part of the left third frontal convolution. Scattered areas of hemorrhage, varying from slight contusions to masses from the size of a pea to that of a five-cent piece and involving the cortex to varying depths, were found on both hemispheres, but principally on the right. The right first and second temporal convolutions were extensively lacerated and infiltrated with blood. The spinal cord showed a small amount of hemorrhagic effusion into the pia in the upper dorsal region chiefly.

No operative interference was considered advisable, because the symptoms pointed to lesions so extensive as to render such interference futile. Failure to recover consciousness after the accident, in the opinion of some authorities, indicates too grave lesions to warrant surgical interference, though in the experience of Phelps[1] some patients who have remained unconscious for several days have ultimately recovered, and the gravity of this factor in his opinion is to be estimated by coincident conditions. Elevation of temperature, as indicative of cortical lesions, is especially significant. Cases in which the temperature exceeds 105° F., in the experience of Phelps, never end in recovery. Cases in which the symptoms of compression are produced by pressure from blood clot alone are characterized by the absence of elevation of temperature. In the case under consideration the temperature of 102.8° F. shortly after the injury was symptomatic of grave cortical lesion. The only thing that the surgeon can do for such cases is to remove effused blood from between the dura and the skull when it exists. When a patient, after recovering from the primary unconsciousness due to the shock of injury, or after trauma without immediate insensibility, becomes gradually unconscious, the occurrence of hemorrhage is probable, and its site is frequently indicated by localized paralysis. Such hemorrhages, if epidural, are usually at the site of the external wound if one exists, and are due as a rule to lacerations of meningeal arteries, produced by the temporary displacement at the time of injury, or to splinters of the internal tables. Such clots have been removed with apparent benefit to the patient. Such a clot existed in the case cited above, but the coincident lesions rendered diagnosis impossible, and its removal would have been obviously useless. Hemorrhage under the dura occurs most frequently from cerebral laceration, and, as the more extensive of these lacerations occur on the side opposite to the injury, the more extensive of these

[1] A paper read before the Harlem Medical Association, December 13, 1897.

[1] "Traumatic Injuries of the Brain and its Membranes."

hemorrhages will also be found on this opposite side. It is not possible to remove these hemorrhages without unjustifiable manipulation of the cerebral cortex (Phelps).

Dilatation of one pupil, according to Phelps, bears no constant relation to deeper lesions, and is of no value as a localizing symptom. In twenty-four cases Weismann noted the pupillary dilatation on the side of the extravasation in twenty. Concomitant paralysis of the other ocular nerves was rare. The definite lesions with which it has been associated are epidural hemorrhage pressing on the third nerve and lesions of the optic nerve. In the case under discussion the symptom was manifest in the eye corresponding to the subdural hemorrhage.

The muscular rigidity was due probably to cortical irritation from the clots. The terminal left-side convulsions were due probably to cortical irritation produced by secondary hemorrhage from the lacerated brain, and it was the pressure from this hemorrhage which is to be regarded as the ultimately fatal factor, because the temperature fell during the last hours of life, instead of rising, as it probably would have done had an increase of meningeal inflammation occurred; and because the blood over the right side was largely fluid at the autopsy, showing that it was a recent effusion.

As I have never seen any adequate statement in general works on surgery of the most widely accepted theory of the production of cerebral lesions by blunt violence to the skull, it may not be unprofitable to give the following explanation, taken from Denet's monograph,[1] with certain amplifications which I found it necessary to formulate in order to make the matter perfectly clear and convincing to my own mind.

The skull is a hollow, elastic ovoid, whose cavity is completely filled by a soft, friable mass, permeated by systems of vessels containing fluid. The small arteries of the brain are surrounded by sheaths filled with fluid, which empty into larger trunks situated in the fissures between the convolutions, these all finally terminating in the subarachnoid spaces at the base of the brain, from which the lymph may find its way into the corresponding space of the spinal canal. Into this same space the fluid from the ventricles has access by way of the foramen of Magendie at the lower end of the fourth ventricle. The cerebro-spinal fluid serves to maintain the uniformity of the intracranial pressure by passing into the spinal canal, or the reverse, according as the amount of blood in the brain increases or diminishes with the varying phases of respiration, cardiac action, muscular effort, etc. The amount of this fluid was estimated by Magendie as sixty-four grams. Longet believed that this estimate, made from examination of the cadaver, was too low, and calculated that in life the amount was from two hundred to two hundred and fifty grams.

The observation which lead Duret to experiment on this subject was the following. As a result of suddenly forcing a considerable amount of fluid into the cranial cavity of a dog, he found the aqueduct of Sylvius widely distended, with hemorrhagic infiltration into its walls and into those of the fourth ventricle, distention and ecchymosis of the central canal of the spinal cord, and similar lesions about the great arachnoid spaces at the base of the brain. The obvious explanation was that the sudden increase of the cranial contents had squeezed the fluid contained in the lymph cavities of the brain in the direction of least resistance and into the only available outlet—the spinal canal—and that this sudden distention of the lower portions of these channels had caused the observed lesions. Moreover, this distention affects not only the main streams, but also the small tributaries entering into them, so that small hemorrhages are caused in the parenchyma of the pons, medulla, etc. Exactly similar lesions were caused by blows on the vault of the cranium, the lessened capacity of the skull due to its flattening under the blow acting exactly as did the sudden injection of fluid in forcing out the cerebro-spinal lymph.

When the skull is violently struck at some point of its middle zone, what happens is as follows: The skull at the point of impact is flattened or depressed, forming what Duret calls the cone of depression. The force of the blow is transmitted through the inelastic brain largely in the direction of its delivery, this line being called the axis of percussion. On reaching the opposite side of the skull, the elastic vault is driven out at this spot, thus forming Duret's cone of elevation. Now the effect of this is to diminish the size of the cranial cavity on the side of the blow, and, by rendering the surface of the opposite side of the skull more nearly spherical, to cause a sensible increase on that side. This increase produces a vacuum. The mobile fluid contents of the compressed hemisphere, lymph and blood, are forced out in the direction of least resistance, which is, of course, toward the expanded opposite side, their ingress being still further facilitated by the aspiration due to the changed shape above described.

The most marked effect will be produced by the forcing back of the fluid from the large spaces at the base into the smaller peripheral lymph sheaths. The major effect will be produced at the apex of the cone of elevation. The force of the blow, transmitted through the inelastic brain, springs out the cranial vault most extensively at this point, the effect being, as Duret states, comparable to that of a cupping-glass. The mobile fluids, especially the cerebro-spinal, rush in, and cause a more or less extensive laceration of tissue at that point by overdistention of their channels. The same mechanism is obviously operative, though less powerfully, in points remote from the axis of percussion in the expanded side of the skull. It is obvious, furthermore, that when the skull resumes its shape a reverse current is caused, and so minor lesions on the side of impact which cannot be explained by direct violence may thus be accounted for.

When, as in the experiments cited, the blow is delivered on the vertex, the force being expended wholly on the elastic vault, the cone of depression is more marked than when the force of the blow is in part broken by the inelastic base. Moreover, owing to this inelasticity of the base and its support by the spinal column, no cone of elevation is formed. On the contrary, the spinal column may be forced into the brain, owing to extensive fracture of the base, the cerebral contents being compressed between two forces. The cerebral contents will thus be placed under great pressure, and the fluids will tend to escape either into the spinal canal or possibly through some rupture of the skull caused by the excessive tension.

In injuries of the skull produced by violence applied to its median zone, the line of fracture in general will be found in an approximately vertical plane, extending most extensively into the base, less extensively toward the vertex. The bones of the base break because they cannot bend, and the fracture spreads more or less extensively by radiation toward the vertex. Fissures in a horizontal plane are not apt to occur, on account of the elasticity of the bones of the vault. Fractures occur also on the side opposite to that of impact. The bones on this side are impinged upon by the force transmitted through the brain, and may be broken when not able to bend. The case above quoted was an illustration. The body of the sphenoid and the petrous portion of the temporal bone were fissured.

[1] "Traumatismes Cérébraux."

I will now cite briefly a few other cases illustrating interesting phases of cerebral injury.

Case II.—J. K——, male, about forty years old, while intoxicated, fell, striking first on his buttocks, his head then coming in contact with the floor. He remained unconscious for twelve hours after admission, and on regaining consciousness passed into a state of noisy muttering delirium, without tremor. Two days before death coma followed. Slight right hemiplegia was noted. The temperature varied from 101° or 102° F. to normal, until the last two days of life, during which it rose gradually from 100° to 105.6° F. Death in ten days.

Autopsy disclosed a subdural clot over the left occipital and parietal lobes, large enough markedly to flatten those portions of the brain. There was no fracture. A laceration, the size of a pigeon's egg, was noted in the under surface of the left frontal lobe, which was diagonally opposite to a slight contused wound of the right side of the occiput. There was some effusion of blood under the dura on the left side. Minor lesions were noted elsewhere upon the cortex. There was general congestion of the meninges, with thickening of the pia.

This man evidently had a chronic alcoholic meningitis before his injury. The essential factor in his case was apparently a traumatic exacerbation of this disease.

Case III.—J. P——, male, aged twenty-five, was knocked down by a blow in the head from a timber, and brought into the hospital unconscious and bleeding from both ears and from the nose. He recovered consciousness next day, and never had any cerebral symptoms or fever after that. He had partial paralysis of the right facial nerve of the peripheral type, *i.e.*, the forehead being involved. Both sixth nerves were involved. Later the paralysis extended to all the motor muscles of the left eye and the fourth nerve of the right. It is possible that the latter was involved from the beginning; it was not at first noted. No other nerves were involved. He was discharged thirty days after admission, in apparently perfect general condition, but with no improvement in his above-narrated symptoms.

In this case certainly a fracture of the base existed, as proved by the bleeding from both ears, this bleeding being too profuse to have resulted from rupture of the drum membranes without fracture. The facial paralysis was due probably to pressure from a blood clot in the facial canal, that canal being involved in a fracture of the petrous portion of the right temporal bone. An epidural clot over the body of the sphenoid, with compression and subsequent neuritis of the ocular nerves, would most reasonably explain these lesions, as a central lesion was hardly possible, considering the absence of other symptoms. According to Phelps, while numerous instances have occurred in which each of the cranial nerves has been implicated in injuries of the kind under discussion, it is only in the cases of the second and the seventh that interference with function has been demonstrably due to lesions in the line of fracture; *i.e.*, central lesions are more probable. This case therefore is unusual.

Case IV.—A man, aged forty, was arrested in the evening after a fight when drunk, and was brought before a magistrate next morning. He was able to stand with difficulty. On admission to the hospital, at 6:30 P.M. of the same day, he was able to walk, but was stupid and not able to answer questions. The next day he was fully unconscious, and died comatose less than forty-eight hours after the injury. The autopsy showed a basal fracture and extensive laceration of the left temporal lobe, with subdural hemorrhage. His temperature was 101° F. on admission, fell to 99° F. the next day, and was 100° F. on the day of his death.

This case is cited as an example of the many in which the earlier symptoms of a fatal lesion are confused with those of alcoholism, and in which diagnosis is often very difficult. It shows also the combination of consciousness, continuing or recurring after the shock of an injury (it was not known whether or not there was primary unconsciousness), with subsequent lapse into coma, due probably to the occurrence of hemorrhage.

Phelps states that elevation of temperature is prominent in cases with laceration, in striking contrast with what has been observed in simple hemorrhages (in which the temperature is not elevated). In this case and the one following hemorrhage was the dominant factor and due to cerebral laceration. The absence of elevation or marked elevation of temperature did not exclude laceration. The fact is also illustrated that a return of consciousness after the shock of the accident is far from excluding the possibility of a very grave lesion.

Case V.—A young man was found in the early morning trying in a bewildered way to get into his house, having been well the day before. He appeared stupid, answered all questions by a single monosyllable, seemed to be in pain, judging from his expression and his groans, and would point to his head when asked where his pain was. A small scalp wound existed over his occiput. It was subsequently learned that he was injured in a fight. His temperature was never above 100.8° F. Pulse and respiration were normal. He died in coma on the sixth day after admission, general clonic convulsions having occurred during the last two days of life. Autopsy disclosed a fracture involving the left occipital and parietal region, a large subdural clot over the cerebellum, extensive laceration of the under surface of the right frontal extending backward into the temporal lobe, extensive subdural hemorrhage at the site of laceration, and minor lesions elsewhere.

Here again we have mental apathy and motor aphasia, the only symptoms of a very grave lesion. The terminal convulsion and coma were due probably to secondary hemorrhage from the lacerated cortex. Phelps states that injuries to the left frontal lobe are attended with marked mental symptoms in almost every case. Apathy results from subcortical lesions; perverted memory, lack of attention and mental control, incoherence, delusions, or stupor from confusion rather than from paucity of ideas, from cortical lacerations. In only four of two hundred and twenty-five such cases coming to autopsy were such mental deficiencies or derangements of mind present in which the right frontal lobe was not lacerated. Of these, in one a previous psychosis existed, in two there were general hyperæmia and œdema, and in one the frontal lobes were compressed by large subarachnoid serous effusions. Cases of stupor, coma, or delirium from general compression or meningeal inflammation were of course not included in this number. Lesions of the right frontal lobe were latent as far as any influence upon mental manifestations was concerned.

In conclusion, I will briefly summarize the prominent features of the pathology and symptomatology of the lesions under discussion, as follows:

Primary unconsciousness after an injury to the brain may be due entirely to shock, *i.e.*, reflex contraction of the cerebral arteries. This is rarely fatal, and if uncomplicated is recovered from in a few moments or hours. Apparent complete recovery, however, does not exclude the possibility of the existence of latent lesions, which may manifest their existence later. Sudden or rapid insensibility after recovery of consciousness indicates hemorrhage. Prolonged unconsciousness without elevation of temperature means compression from hemorrhage, either epidural or sub-

dural. The absence of fever does not necessarily exclude laceration. Prolonged unconsciousness with elevation of temperature indicates grave lesion of the brain substance with or without considerable hemorrhage. The suppression of the function of a limited portion of the brain by laceration, unless involving some vital spot, such as the medulla, is not a serious matter, as regards life at least. Such lacerated portions may, however, when undergoing secondary softening, give rise to grave or fatal secondary hemorrhages, or may be the point of departure of secondary inflammation. In these latter cases the multiple minor lesions scattered widely through the brain, comprehended under the term diffuse cerebral contusion, are often pathologically of more importance than the few or isolated foci of extensive laceration. The elevation of temperature associated with these lesions has been attributed to injury to the thermic centres. On this supposition it is difficult to account for the continued rise of temperature post mortem, so frequently observed. In one of Phelps' cases the temperature was 98.6° F. at death, and 109° F. thirty minutes after death. The diffuse cerebral hyperæmia with or without œdema found after death was not, in Phelps' experience, associated with cellular infiltration. Judging from symptoms, it must be regarded as indicative of grave alterations of nutrition of the cortex, which we may call "inflammation" or not, according to the definition we choose to give to that word. McEwen, in his work on infectious inflammations of the brain, describes an acute serous meningitis, due to bacterial infection, in which, as observed through a trephine opening, the vessels of the pia are seen floating in an extensive serous infiltration of that membrane. Post mortem much of this fluid was found to have drained away after the skull was opened, and nothing more than a slight hyperæmia remained. In the MEDICAL RECORD for December 4, 1897, Dana, under the heading "Acute Serous Meningitis," describes a similar process associated with degenerative processes of the nerve cells as due to alcohol, which is probably a factor in a large percentage of cases in our hospitals. Secondary bacterial infection plays its part in some cases, doubtless, but in one such as that described at the beginning of this paper, in which the temperature was 102.8° F. within an hour of the injury, this must surely be excluded. Gross lesions of vital centres, compression from primary or secondary hemorrhage, and the secondary effects of diffuse cerebral contusion and inflammation from infection, may be stated as the causes of death in cerebral injuries. It is the second of these only, when occurring between the dura and the skull, which is certainly susceptible of surgical relief, though it is possible that withdrawal of cerebro-spinal fluid by lumbar puncture of the spinal canal may be of service in cases in which serous effusion is an important pathological factor.

Treatment of Itch.—The treatment consists, first, in friction for half an hour of the whole body, except the head, with black soap, and it is continued by the patient himself during an hour while in a tepid bath. When he leaves the bath he is given to apply:

R Lard ..... 64 parts.
Sulphur..... 20 "
Potassium subcarbonate,
Water.....āā 8 "
M. S. Externally.

The patient then dresses, without wiping off the ointment, for the contact of this is necessary for the destruction of any remaining acari, and of any that might remain in the garments. Of 37,429 persons so treated at St. Louis Hospital in ten years, only 535 required a second application.—HARDY.

A CONSIDERATION OF AMPUTATION AT THE SHOULDER-JOINT FOR SARCOMA OF THE HUMERUS, WITH A REPORT OF THREE CASES—OPERATION AND RECOVERY.[1]

By ARTHUR L. FISK, M.D.,

SURGEON TO TRINITY HOSPITAL AND TO THE BABIES' HOSPITAL; ASSISTANT SURGEON TO THE CANCER HOSPITAL AND SURGEON TO THE NEW YORK HOSPITAL OUT-PATIENT DEPARTMENT.

WITHIN the last fifteen months I have removed the entire upper extremity three times for sarcoma of the humerus; in two of the cases I exarticulated the arm at the shoulder-joint, and in the third I resected about one-third the clavicle with the acromion process of the

FIG. 1.

scapula and disarticulated the joint. All three patients recovered excellently from the operation, and, inasmuch as each of the cases has features of interest, I present them collectively for your consideration this evening.

CASE I.—Barbara ——, German woman, aged sixty-seven years. Some time during May, 1896, she had occasionally pain in the left arm, which gradually became more severe and constant. She was given antirheumatic treatment without any benefit. In the latter part of September she was referred to me by a physician who had had her under observation for a few weeks.

At that time there was a very slight increase in the size of the left arm about the lower third. At this site there was a false point of motion in the shaft of

[1] Read at the meeting of the Hospital Graduates' Club, March 24, 1898.

the humerus, above and below which there was felt evident thickness of the bone. Manipulation was not painful and there were no glands palpable in the axilla. Mindful of the possibility of this being malignant disease of the bone, even though I could not obtain any

Fig. 2.

history of a distinct injury, still, considering the condition of the woman, her habits, and her intelligence, which were much lower than the average, I could but think that she had fallen when under the influence of alcohol, thus fracturing the humerus, which had not united in consequence of her age and some possible constitutional disease. Therefore I put the arm in plaster of Paris, which extended from the axilla to the wrist, the elbow being bent at a right angle. In addition I gave her large and increasing doses of the iodide of potassium.

Under this treatment there occurred a distinct improvement, both local and constitutional. The pain absolutely subsided, the swelling diminished, and motion at the point of fracture became less and less, until finally, the last of November, there was firm union.

This sequence of events made me believe that I was dealing with a fracture rather than with malignant disease. Early in December I had this *x*-ray photograph taken (Fig. 1), which shows beautifully the disease of the bone. I sent her into my service at Trinity Hospital, where I made an exploratory incision under ether and removed some of the growth for examination.

This is Dr. E. K. Dunham's report: "The specimen from the humerus on microscopical examination consists of bits of bone and of highly vascularized cellular tissue, containing round and short spindle-shaped cells, separated by only a very small amount of intercellular substance. The appearance of this tissue leads me to the diagnosis of sarcoma."

Three days after obtaining this report, January 1, 1897, I amputated the arm at the shoulder-joint, using Wyeth's pins with the Esmarch bandage and Racquet incision. The only blood lost was that contained in the amputated arm, which I had not exsanguinated by the application of the Esmarch bandage before the operation, because I did not think that it was wise to risk forcing any of the disease on into the general circulation, thus causing metastasis. The woman came out of ether quickly and without shock. The wound healed primarily, and on the fifth day she was dressed and sitting up. I examined her carefully on March 19, 1898, and there was absolutely no sign of any recurrence.

Case II.—B. C——, male, aged thirty-nine years. Had the grippe in January, 1897. Following upon this he suffered with pain in his left shoulder, which gradually increased in its severity. At the same time the shoulder began to increase in size. Internal medicine gave no relief. In June he was obliged to give up business because of his intense suffering. The last day of August he entered Dr. Abbe's service at the Cancer Hospital. The left arm he carried on a pillow, which he held either with the right or rested on his knees. The muscles of the left arm had atrophied greatly, and at the shoulder there was a large smooth elastic tumor, which extended down the arm as far as the insertion of the deltoid muscle. Manipulation was very painful, also the mere weight of the arm when unsupported. The man was greatly emaciated, and his face and pallor showed evidences of long and intense suffering. Aspiration of the tumor gave a dark red fluid. There were no palpable axillary glands. The examination of the heart, lungs, and kidneys was negative.

Dr. Abbe kindly gave me the operation, and on September 11th assisted me. Ether was administered. An incision was made on the outer side of the arm over the tumor, from the tip of the acromion process to the insertion of the deltoid muscle. The fibres of the muscle were separated so as to expose the tumor, which was found to run well up beneath the clavicle and acromion process. The incision was therefore carried higher up, so as to uncover the outer third of the clavicle and the acromion process. Through this incision the axillary artery was tied. The trapezius was cut from the clavicle and acromion process; both were then sawed through, and the shoulder was disarticulated. The wound was rapidly and loosely closed, and a dry aseptic dressing put on, because of the shock from which the man was suffering, and from

Fig. 3.

which he did not quickly rally. The wound healed slowly by granulation.

Dr. Buxton, the pathologist of the hospital, found that the tumor was a sarcoma showing myxomatous degeneration.

A few days after the operation the patient com-

plained of pain in the left side of the chest and of a persistent cough, which I thought must indicate a pulmonary metastasis with involvement of the pleura. Examination of the chest showed abundant moist râles; these, with the character of the sputum which he coughed up, led me to have this examined, and much to my surprise tubercle bacilli were found by Dr. Buxton. As soon as possible I had him wrapped up warmly and carried out of doors each pleasant day; and from that time on he made rapid improvement, so that on October 18th he was discharged. The wound was entirely healed, he had gained in weight, and coughed very little.

I have been unable to learn the outcome in this case. My letters fail to bring any response.

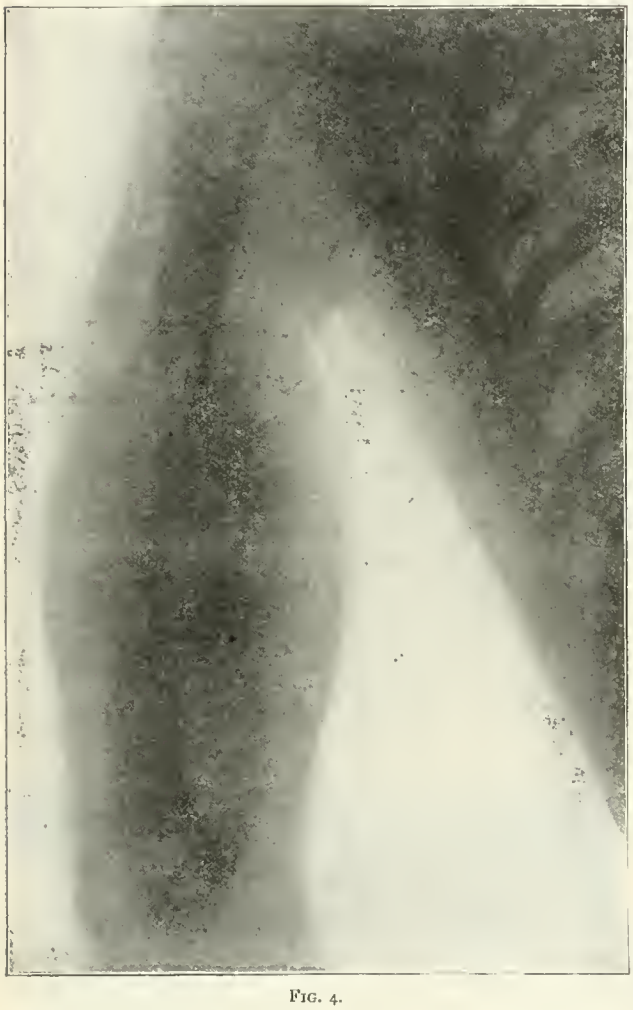

Fig. 4.

This *x*-ray (Fig. 2) shows the shadow of the tumor and enables a positive differential diagnosis between subperiosteal and central sarcoma to be made. The shaft and head of the humerus show no structural changes.

Case III.—Daniel ——, male, aged thirty-five years. While he was attempting to jump upon a lumber truck in April, 1897, something snapped in his left arm which made it powerless. Four days later, when he was trying to break a broomstick across his knee, there was a decided crack, after which he could not move his arm. The physician called said that the bone was broken; and the following day it was incased in plaster of Paris at Bellevue Hospital, which is presumptive evidence that no tumor was present at that time.

The last of October he was sent to me by Dr. Forbes. Then there was a large fusiform swelling of the left arm from the axillary fold to the bend of the elbow. The skin over this was normal and the tissues were firm and smooth. About the centre of the shaft of the humerus was a false point of motion. Manipulation was not painful. No enlarged glands existed. On the 8th of November, at Trinity Hospital, I amputated the arm at the shoulder by the same method as in my first case. The operation took less than an hour and there was no shock following it. The wound healed primarily; the patient was about within a week and discharged at the end of two weeks.

The specimen was examined by Dr. F. M. Jeffries, of the Carnegie Laboratory, who reported: "A melanotic mixed-celled sarcoma with fibro-sarcomatous portions."

I saw the man in January and then there were no signs of recurrence.

This photograph (Fig. 3) gives the appearance of the arm; the *x*-ray (Fig. 4) shows the involvement of the shaft of the bone, and the photograph of the specimen (Fig. 5) that the centre of the shaft has been entirely replaced by the neoplasm.

The three cases illustrate the two varieties, central and subperiosteal, of sarcoma which occur in the long bones. The surgical treatment of these, especially in the humerus, together with the mortality following the operation, I wish to set before you this evening.

Butlin[1] writes: "In considering and estimating the various methods of dealing with sarcoma of central origin, it must be borne in mind that in many instances there is a great difference in the relation which the tumor bears to the bone. Some of the growths are inclosed in cavities in the interior of the bones, which are smooth walled, clearly defined, and from which they can be shelled out without the slightest difficulty. Other central growths are certainly well defined, but are separable with difficulty from the surrounding bone." Therefore three operations have been practised for the removal of central tumors: (*a*) enucleation of the tumor; (*b*) resection of the affected portion of the bone; and (*c*) amputation of the limb. Attempts to enucleate central sarcoma of the humerus are not favorable and in many instances resection cannot be performed. The only treatment which offers a reasonable prospect of success is amputation at the shoulder-joint.

In the subperiosteal sarcoma of the humerus, his opinion is that in almost every case amputation must be at the shoulder-joint, because the disease often is primarily seated at the upper end of the bone; also because of the rapidity of extension when the origin of the disease is upon the shaft—in other words, that in no other way can there be any reasonable expectation of getting beyond the disease.

Senn[2] is of the opinion that a conservative operation is justifiable in small myeloid sarcoma of the long bones when the disease is limited to the bone, but that the cases adapted for this treatment are few and far between, and the conservative operation of enucleation and resection must be limited to the radius, ulna, clavicle, and ribs. Therefore, when the fibula, tibia, femur, or humerus is the seat of the disease, there is nothing to be done short of amputation.

Dennis[3] is more and more impressed with the fact that amputation is the only operation which should be contemplated in sarcoma of long bones. Excision and enucleation are not to be recommended, because the disease is not as a rule radically removed by these methods.

Jacobson,[4] in writing of excision of the shoulder-joint in cases of growth connected with the upper extremity of the humerus, says: "While the priceless

[1] "Operative Surgery of Malignant Disease."
[2] "Pathology and Surgical Treatment of Tumors."
[3] Dennis: "System of Surgery."
[4] Jacobson: "The Operations of Surgery," third edition.

value of the hand fully justifies the attempt in some instances, such cases must be extremely rare," and cites the cases reported by Mitchell Banks, Southam, and J. Hutchinson. Banks endeavored to excise the upper portion of the humerus, sawing though the shaft one inch below the insertion of the deltoid, for recurrent sarcoma in a man of fifty-six years, but he was compelled to give that up and quickly to amputate the arm because of the profound shock in which the patient was. This case certainly is rather positive evidence against excision in such cases.

Southam's case is certainly one of successful resection of the upper end of the right humerus for an endosteal (mixed-cell) sarcoma. The head and four inches of the shaft were removed. Six months later the woman could raise her hand to the mouth or use her arm for household duties and in operating a small sewing-machine.

Hutchinson's case was one of resection of the upper third of the humerus and removal of the diseased glands in a woman of twenty-seven years. There was recovery with a useful arm, but rapid reproduction of the disease occurred, with secondary growths connected with the bone, axilla, cervical glands, and lung, and death ensued within five months.

I find in Butlin's tables that the one case in which resection was done for subperiosteal sarcoma death resulted from the operation, and the one death from causes connected with the operation in eight cases of central growth was in one in which resection was performed. There cannot be much doubt, therefore, that the most conservative, surest, and safest treatment of sarcoma connected with the humerus is amputation. There are less hemorrhage and shock, less risk of sepsis, because of better drainage, and decidedly greater probability of radically removing the disease.

The mortality following amputation of the shoulder for disease has been very much reduced of late years.

Butlin, from the statistics of Schede and the reports of St. Bartholomew's Hospital for the twenty years previous to 1887, collected twenty-four cases with sixteen recoveries, which gives a mortality of 33⅓ per cent., but this includes the operations which were done before antiseptic methods were used. These same statistics for the ten years from 1877 to 1887 give fourteen cases with ten recoveries, which reduces the mortality to 28.5 per cent. The mortality in twenty cases collected by himself, which go back of the introduction of antiseptic surgery, and in which amputation was done, with five deaths resulting from the operation, was twenty-five per cent.

Wyeth has collected thirty-five cases of complete removal of the arm and of the shoulder girdle or a portion of this. To these I can add two cases, my second and a case reported by E. T. Elliot,[1] in which he removed the entire upper extremity in a woman of seventy-six years, for recurrent myxosarcoma of the scapula. This makes a total of thirty-seven cases; of this number eight were fatal from the effects of the operation, which gives a mortality of 21.5 per cent. In *The Lancet* of March 21, 1896, Frederick Page states that the number of major operations from April 1, 1878, to December 31, 1895, in the Royal Infirmary, performed antiseptically, was nine hundred and thirty-eight; of these forty were amputations of the shoulder. Seventeen of the forty were performed for disease, and of these seventeen but one was fatal—a mortality of 5.8 per cent. This great decrease in the mortality of shoulder amputations is in consequence of the aseptic technique, of the prevention of hemorrhage either by preliminary tying of the subclavian artery, which should be done in all cases in which the disease involves the shoulder girdle, or by some method such as was used in my first and third cases, and by the treatment of shock by intravenous infusion of decinormal salt solution. The control of the hemorrhage in the two cases was absolute, and the objection which Jacobson raises, of the possible harm which the pins may do, was not experienced in either case. When the technique is perfect the fear of infection cannot be an objection.

Before concluding I wish to call your attention to the improvement in my first case under the administration of the large doses of the iodide of potassium, whereby I was led into the belief that I had not a sarcoma of the bone; in the second case to the occurrence in the same individual of tuberculosis and sarcoma; and finally in my last case to what is evidently primary melanotic sarcoma of the humerus. The three skiagraphs demonstrate the great value of the *x*-rays as an aid in differential diagnosis.

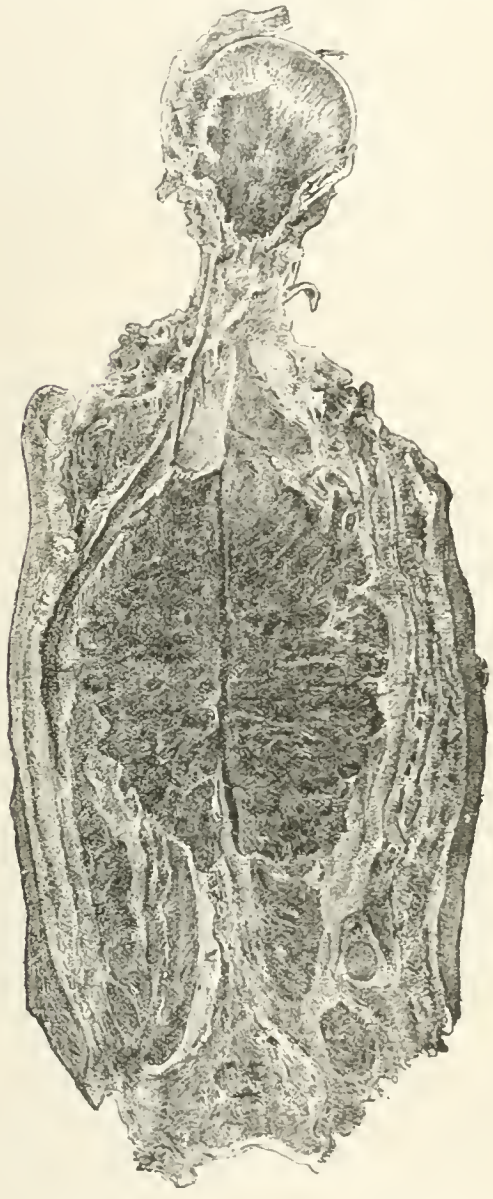

Fig. 5.

13 West Fiftieth Street.

[1] Lancet, November 7, 1896.

Eucaine can be used in all superficial operations in a three or five per cent. solution, without causing density or hardening the tissue, and in sufficient amount completely to surround the part to be incised. As much as nine grains has been used without any evidence of danger. It does not inhibit or prevent primary union, but the solution should always be boiled before injecting with a thoroughly sterilized needle. —M. H. Williams.

IMMUNITY AND SERUM THERAPEUTICS—A NEW THEORY: THE BIO-PHYSICAL THEORY.

By R. F. LICORISH, M.D.,

BARBADOS.

It was, I believe, Lord Beaconsfield who once said: "If you want to get up any subject of which you know little, set about to write a book on it"—or words to that effect. Sometimes, however, there is more in those words than appears on the surface. When Lord Kelvin, many years ago, was induced to write in an English magazine a popular description of the mariner's compass, the first part appeared with the notice that the subject would be continued, and interested readers watched month after month for its completion. This, however, did not happen for five or six years, for Lord Kelvin, when writing the first part, perceived that the compass of the day was defective; he therefore set about and invented the perfected instrument of the present day. With the writer of this paper, a circumstantial parallel led him to the above theory. In attempting in a local paper to define and demonstrate the action of medicines on the human subject, he became so dissatisfied with the accepted views that he again and again submitted the question to the closest criticism, bringing to his aid any biological and physical theory that he considered likely to help him in its elucidation. It was at or about the same time that Dr. McLaughlin, of Texas, was studying the same question from the standpoint of fermentation, as to its identity with infection and its bearing on immunity; and so similar was our reasoning, although from different bases, that up to a certain point all his arguments apply with equal force to my own theory. It is not until we attempt to illustrate the mode of action of these similar views on the various conditions of medicinal and disease action on the living subject that it will be found that his—McLaughlin's—views lead to only a partial application, while my own, I apprehend, illustrate the unity of vital laws in many and varied conditions and states. For it will be found that the theory here set forth not only throws light on all forms of immunity, serum therapeutics, etc., but also points in no uncertain way to that power on the environment of organic life which has hitherto escaped the senses of the observer and the reasons of the philosopher. There may be among the readers of this paper many, who boast of being practical men, who look askance at all theories that cannot be demonstrated practically by the senses. But is that the position to assume in the present day, when all science points to the truth that the chief advances therein to be made now lie in physical laws which cannot, at least for a very long time, be demonstrated to the senses of man? And have we not evidence in the past that theory is capable of leading to the most important and momentous truths? Some years ago a celebrated chemist was able to declare, basing his knowledge on laws mainly hypothetical, that a certain metal or mineral, an element of inorganic nature, existed, although as yet undiscovered. So sure was he that he indicated its chief properties. And do we not now know that this prophecy was fulfilled with startling reality? Not long ago, at a meeting of a great medical society in England, one of the most celebrated physicians of that country was led to exclaim: "Let us not decry theory, for by theory Pasteur was mainly enabled to arrive at his wonderful announcements to the scientific world"—or words to that effect.

So much for theory in general; but as regards the question of molecular and atomic physics, on which this theory is based, that "Napoleon of science," Lord Kelvin, has declared that so important are its study and its possibilities that he regarded his lifework as so much time wasted, compared with what might have resulted had he confined his studies to the elucidation of atomic and molecular action. Is it not, then, most important to study the action of medicine on an organic body in the light afforded us by the physics of molecular and atomic motion? Now the action of medicines on the living body must be mechanical, chemical, or physical: but we also know that the mechanical and chemical are really different manifestations of physical action: hence we logically must conclude that the action of medicines on the living body, except in the few and isolated cases in which chemical or mechanical action is directly apparent, must be a physical one.

Physiology is that science which treats of the various laws of organic bodies—laws which are chiefly manifested in the various functions serving the purposes of the living body. When we speak, then, of the physiological actions of medicines, we really mean a medicinal action which modifies in some way the normal physiological functions. The term "physiological action" should really be "pathological action," since a normal function modified by a medicine is really pathological. But neither of the terms "physiological" and "pathological" as applied to the action of medicines gives any idea of the real action. To express the real action of medicines on the system we should use the term "pathogenetic," which, although it does not tell us the nature of the organic disturbance, yet indicates that a change analogous to disease has been produced. Let us now try and learn the nature of the change in an organic body produced by a medicine. To do so we have, in the first place, to learn what an organic body is and what the nature of the remedy used, which, of course, may be either organic or inorganic. Huxley treats of the subject in this way: "Carbon, hydrogen, oxygen, and nitrogen are all lifeless bodies: of these, carbon and oxygen unite, in certain proportions and under certain conditions, to give rise to carbonic-acid gas. Hydrogen and oxygen produce water. Nitrogen and hydrogen give rise to ammonia. These new compounds, like the elementary bodies of which they are composed, are lifeless. But when they are brought together under certain conditions they give rise to the still more complex body, protoplasm, and this protoplasm exhibits the phenomena of life.[1] Now, then, what is the difference between an organic and an inorganic body? Clearly that the former—the organic—is more complex and therefore more capable of responding to its environment. Hydrogen and oxygen, under the influence of the electric spark, are converted into a more complex body—water. Carbon, hydrogen, oxygen, and nitrogen, under a condition analogous to the electric spark, are converted into protoplasm, having, not the few properties of water and its very limited capability of responding to its environment, but the many and various properties known as life, with its full capability of responding to its environment. What really happens appears to be this: Hydrogen and oxygen each possesses its own molecular and atomic motions, but under the electric spark these actions rearrange themselves, the H with the O, and form water. As regards protoplasm, O, H, C, and N each possesses its own peculiar atomic and molecular motions: but just as the electric spark causes a rearrangement of the H and O atomic motions with each other, giving rise to water—so an unknown influence, analogous to the electric spark, causes a rearrangement of the molecular and atomic motions of C, H, O, and N, and this rearrangement of motions gives rise to protoplasm, which possesses the properties of life.

[1] Huxley: "The Physical Basis of Life."

What we have learned, then, is that both organic matter, as represented by protoplasm, and inorganic matter, are really masses of molecular and atomic motions, the great difference between them being that the former—protoplasm—is so complex that it is capable of being influenced by the whole of its environment, while the latter—inorganic matter—is much less complex and but slightly influenced by its environment. We represent the lower organic bodies as being devoid of a nervous system. That is true to only a limited extent, for although such a low organism does not possess a specialized nervous system, yet its whole body is really a nervous system capable of responding to its environment.

Let us now turn to the highly organized bodies, including man. Although in these beings different functions and organs are specialized, yet we still have to look on them as representative masses of molecular and atomic motions, as the following celebrated scientists teach. Says Prof. Michael Forster: "We have, in speaking of protoplasm, used the words 'construction,' 'composition,' 'decomposition,' and the like, as if protoplasm were a chemical substance. And it is a chemical substance in the sense that it arises out of the union or coincidence of certain factors, which can be resolved into what the chemists call 'elements,' and can be at any time, by applying appropriate means, broken up into the same factors and indeed into chemical elements;" and he continues farther on: "but we may venture to assert that the more these molecular problems of physiology with which we are now dealing are studied, the stronger becomes the conviction that the consideration of what we call 'structure' and 'composition' must, in harmony with the modern teachings of physics, be approached under the dominant conception of 'modes of motion.'"[1] Professor Huxley writes thus: "But it must not be supposed that the differences between the living and the not living are such as to justify the assumption that the forces at work in one are different from those to be met with in the others." A mass of living protoplasm is simply a molecular machine of great complexity, the total results of the working of which, or its vital phenomena, depend on the one hand upon its construction, and on the other on the energy supplied to it; and to speak of vitality as anything but the name of a series of operations is as if one should talk of the horology of the clock.[2] Says Julius Thomson, in his introduction to "Thermo-Chemical Investigations": "Theoretical chemistry is based upon the molecular theory, according to which all matter is made up of molecules, and these molecules of atoms. The physical state of bodies depends upon the arrangement and motions of the molecules. Other physical and chemical properties depend upon the kind and number of atoms in the molecule, upon their arrangement and relative motions."

These quotations, and many others which could be made from equally eminent authorities, all demonstrate that organic bodies, from the lowest to the highest, owe their peculiar functions and activities solely to molecular and atomic motions; in fact, that we may look at all organic bodies as masses of motions, molecular and atomic. But, as we have seen, the same construction holds good for inorganic matter, for that too is a mass of molecular and atomic motions, only less complex in arrangement.

Having demonstrated so much on the authority of eminent scientists and from our own reasoning, let us see what is medicinal action or the pathogenetic action produced on the living body by medicines. Of course we shall, in the first place, confine ourselves to the action of medicines—or, more properly, drugs—on the normal body. We have learned that the body to be acted on—as, for example, the human body—is a mass of motions, and we have also learned that the medicine or active agent is also a mass of motions, only of less complexity. When a drug, therefore, acts on the living body, it really amounts to one series of motions reacting on another series of motions.

Now, as regards the action of a new incident force on an organism, Mr. Herbert Spencer thus speaks—speaks in a way that would tend to confute my contention; but it must be remembered that no one is more ready to recognize that evolution is just as powerful in ideas as in life, and no one has been found more ready to modify his dicta in the light of further evidence. Moreover, unless Mr. Spencer can modify his dictum as regards a new force on an organism, he cannot account satisfactorily for the colors of animals, as the tiger and lion, which are in harmony with their environment. Says Mr. Spencer, in "Principles of Biology": "It is an unquestionable deduction from the persistence of force that in every individual organism each new incident force must work its equivalent of change, and that where it is a constant or recurrent force the limit of the change it works must be an adaptation of structure such as opposes to the new outer force an equal inner force. The only thing open to question is whether such a readjustment is inevitable, and further consideration will, I think, show that to say it is not inevitable is indirectly to say that force does not persist."

The exact meaning of that statement is not quite clear, but we may, I think, assume to be the meaning that the change produced in an organic body by a new incident force is a change which is in composition opposed to the composition of the new incident force. This is the theory of opposition in nature; but, as I have said, the mere fact that the colors of animals harmonize with their environment points to another fact, that the change produced is not in opposition to but is really in harmony with the new incident force, whether constant or recurrent; in other words, that the molecular and atomic waves of the new incident force, being constant or recurrent, in time impress themselves on the organic body subject to its impressions. That this really takes place, I have already shown in the case of animals becoming colored and otherwise adapted to their environment.

But I can show that at least a path for the atomic and molecular waves is formed, on the strength of catalysis. Professor Leech, in his address on pharmacology at the last meeting of the British Medical Association, at Montreal,[1] said: "But there is also reason for thinking that the molecules of a compound may influence the protoplasm in a catalytic manner. We know, for example, that if dilute hydrochloric acid be added to an aqueous solution of methyl acetate it leads to the decomposition of the acetate into alcohol and acid, without itself undergoing any alteration." And, although the editor of the *British Medical Journal*[2] questions Professor Leech's example of catalysis, he supplied for my purpose stronger evidence as to the truth of my theory, for he mentions that McLeod has shown that on the preparation of oxygen from potassium chlorate with the aid of manganese dioxide, although the latter is unchanged at the conclusion of the process, it forms a succession of compounds during the continuance. What this really means and its application to my theory are this: the molecular and atomic waves possessed by the manganese dioxide actually pass through the chlorate, reforming themselves again as manganese dioxide at the conclusion of the operation.

Here we have, then, an instance in which a new in-

organic incident force affecting an inorganic body produces in the latter, the body acted on, a wave of disturbance, which wave is its own molecular wave. Now, as thus happens when an inorganic body acts on another inorganic body, producing not an adaptation of structure such as opposes to the new outer force an equal inner force, but a force in harmony with it—for we find that the catalytic waves of the manganese dioxide pass through the chlorate of potassium—so we are forced to assume that a like process takes place when an inorganic or organic body reacts on an organic body, as when a medicine from the inorganic or organic world acts on, say, the human body. As I have already stated, when a medicine acts on the human body it really amounts to one series of waves or motions—the medicine—reacting on another series of waves or motions—the human body. And by means of catalytic force I have shown that the nature of this reaction is that of a wave of motion passing through the body acted on, just as when we throw a stone in a pool of water the waves formed thereby pass through the whole of the water contained in the pool; and this is so, even if through distribution of force the ultimate waves be too small for demonstration. The action of the medicine on the system is, then, of the nature of a wave, which, once started, must pass, each medicine by its own path, through the tissues of the body; although I grant that a medicine may not, on the laws of physical interference, affect the system, because of meeting with similar waves—a fact which a little study of the physics of heat, light, and sound waves must demonstrate. But when a medicine acts on the human body there is little interference; hence the marked and almost universal action of medicines on the human body. Of course, this subject could be gone into much more deeply, and the poisonous action of common articles of food on some persons, and other processes be accounted for. I have, however, stated enough, I think, to establish my position as regards the action of medicines on the body.

But what happens when the atomic and molecular waves of the medicine, acting on the motions, molecular and atomic, of the body, are recurrent or persistent? Herbert Spencer, as we have seen, states that a structure is formed which in composition is opposed to the structural composition of the incident force. But, as I have already stated, I am opposed to that conclusion. What I do believe takes place is that the waves of the new incident force, the medicine, if persistent or recurrent, become an established feature in the body acted on; that, in fact, a path through the system is formed by the recurrent or persistent force or medicine—as, for instance, when one acquires a drug habit, a path for the peculiar waves of that particular drug is established in the body; hence the immunity established; for once such a path is there, no inimical action can be produced when the drug is taken. The path being there already, its waves pass through the body harmlessly as regards poisonous effects, although the path itself may have interfered with normal functions in an indirect way. Drug habit, therefore, tends to establish my theory of a path being formed in the body for the peculiar waves or motions, atomic and molecular, of the drug used habitually. Drug immunity or habit is therefore my first *point d'appui*.

Let us now turn to disease immunity. Disease immunity is of two kinds—personal, or that produced in any one after an attack of one of the self-limited infectious diseases; and racial, or that possessed by races of people as regards diseases endemic in their countries. I shall now endeavor to demonstrate my theory as regards those two classes of disease immunity.

Personal Immunity.—Let a person have an attack of any one of the self-limited infectious diseases—as typhoid fever or small-pox; in all probability thereafter, however exposed the person may be to a second infection, he will escape the disease. Now an infectious disease is doubtless caused and propagated by the germ of that disease; but really what causes the symptoms of the disease is not the germ itself, but a poison produced in the evolution of its life processes, and the nature of this poison is that of a chemical product. When a person is infected, no doubt some little time elapses before the symptoms of the disease set in. In that time the evolution of the life processes of the germ takes place, with the production of its peculiar poison. This poison, as I have already stated, is of the nature of a chemical product, and, like any other medicine or poison, possesses its own peculiar waves or motions, molecular and atomic. And, just as I have shown in the case of ordinary medicines, these waves pass through the system as water waves pass through a pool. But the production of these waves in the human body must be constant, because the germs must be constantly producing their poison at the site of infection in the body. Now why does convalescence set in after a definite time, approximately? Because after a certain time the atomic motions of the germ poison make a path through the human system, which path becomes fixed, because the force is a constant one and because vital action has always a tendency to repeat itself, and the longer the impressions the stronger the tendency. This physiology teaches us as regards all our functions, and disease itself is often a mere vicious habit. And, too, chemical experience bears me out as regards the permanency of the path, for the more severe the attack of infectious disease the less probability of a second attack. The path being in the body, then, for the germ poison waves, a subsequent infection does not give rise to the disease, because, the path being there already, no disruption of the normal albuminoids of the body takes place, and hence no disease.

Racial Immunity.—This takes us a step farther, for in its production we see a violation of Weisman's law that "acquired characters cannot be transmitted to the offspring." What is racial immunity? In a series of lectures in *The Lancet* for 1888, Professor Coates states that immunity is due to some structural condition. He says: "It is the living activities of the tissues with which we have to deal, and it is peculiarities in these, determined by inheritance, which I believe constitute the differences," *i.e.*, between susceptibility and non-susceptibility in races.

Now, then, in the light of my reasoning, what is this structural peculiarity, transmitted by inheritance, in the living activities of the tissues? Why, that the peculiar waves of the endemic-disease germ poison are found present in every individual of the race, from generation to generation. Doubtless, when a tribe first conquered the older inhabitants and took possession of the new country, its members suffered from generation to generation from the endemic disease, but I believe that in time, contrary to Weisman's dictum, the individual "personal immunity" to the disease possessed by the members of the tribe was gradually transmitted to the offspring, until the path became fixed in each individual and it became a racial feature securing the tribe from the endemic disease—a beautiful illustration of the laws and power of environment (on which I am now working), one which must cause great modification of accepted biological data.

Just as in personal immunity a path for the germ-poison waves is permanent usually for life, so the germ path for that or any endemic disease is found in all the members of the tribe from generation to generation.

Serum Therapeutics.—It is not quite clear whether, inductively from my theory, serum therapeutics could

have been arrived at, but doubtless light from other sources and thought on the subject would soon have led to its discovery. What is serum therapeutics? It must now be clear to the minds of my readers that just as any one can acquire a drug habit and thus become protected from the poisonous effects of that drug, so a person can be rendered immune to any infectious disease by the gradual introduction into the system of larger and larger doses of the germ poison; but that the serum of the immunized animal would be equally effective in immunizing others, and in the case in which the disease is present, more curative than minute portions of the germ poison (as may be with Pasteur's cure of hydrophobia) may not be so apparent on this theory. But as we do know that such are the results from serum therapeutics, the explanation is quite evident, for we have only to recognize that, the serum being an important tissue of the body, it contains within its albuminoids the peculiar waves of the germ poison to which the body has been rendered immune.

Thus when we use a serum we use not only the waves of the germ poison but waves which probably have been modified by the tissues, so that the serum becomes, if not a more potent factor for immunizing against the disease, yet, when the disease is present, a more potent and active one as a curative agent—as has been plainly seen, for instance, in experiments in which snake venom and serum from an immunized animal have been injected simultaneously. In this case the serum or the venom waves in the serum, being modified by living tissues, and therefore more adapted to them, make a path through the albuminoids for the passage of the poison waves, in pioneer fashion. But it must be plain, I think, that the serum is a vital or living body, which may be destroyed by heat or rendered less active or perhaps inert through age. I was therefore not at all surprised when Calmette proved that if fresh venom serum and venom be simultaneously injected an animal would develop no symptoms of poisoning, but if the serum and venom be heated to 68° C. the venom would take effect; the serum or antivenin then having no effect, because, it being a vital product and its action being vital, heat would destroy its protective power. And so when diphtheritic serum or antitoxin is used as a remedy, the earlier it is used the better, of course; but the fresher it is the better it is as a curative agent, because the vitality of the serum is more active. It is from this cause—that is, the disparity in the freshness of the serums used—that conflicting accounts as to their value in disease are recorded.

But it may be possible, although experiment would have to prove it, that an old serum, or a serum that has been submitted to a high temperature, may still be useful, although to a minimum degree, and especially for immunizing purposes; because, as we have seen in catalysis, the waves, being thereby liberated from the vital tissue, serum may reform, as it were, in a pure state, which, as in the experiment with venom serum or antivenin and snake poison or venin, although useless as an active curative agent, may yet, as I have stated, have some effect for immunization.

Now, practically, what does my theory teach? What position does it put us in as regards the discoveries of curative serums?

In the first place, it teaches us that vaccine or cow pox is really a modified small-pox. For many years I have held that position, and when, as has been the case, experiments have gone against that theory I have always maintained that such experiments were defective and the results in opposition to a grand law in nature. Now the position I have always held is the established one. Moreover, on this theory we can understand that all self-limited infectious diseases may be protected against by a vaccine.

Again, when Koch astounded the world by his announcement of a cure for consumption, on the strength of my theory I was able to make in a local paper this prediction: "If Koch's remedy is one of the nature of a lymph from the germ of consumption, it will fail to do what he claims it will do"—a true prophecy, as we all now know. I was able so to prophesy because consumption is not a self-limited disease. Moreover, as a matter of fact, it is not the germ of tuberculosis that really does the mischief, but the many germs concerned in ulceration and suppuration. Of course, it is plain from this theory why in all self-limited infectious diseases an antitoxin can be obtained, not necessarily from the blood serum, but perhaps from other vital tissue, which will act as a curative agent in the particular disease. In the case of the rinderpest disease, there is a great controversy, it would seem, as to whether the bile is capable of causing it. Koch and others maintain that it cannot, while Danyez maintains that it can do so occasionally. On the strength of this theory, I have little doubt that the latter is right, especially if an unusually large dose be used; for, although the bile is a vital fluid, carrying within its molecules the peculiar waves of the rinderpest disease, yet if a large dose be used it must take some time for the tissues of the healthy ox to accommodate themselves to the disease waves in the bile; and in the accomplishment of that disease symptoms must arise. Moreover, if the bile be dead, the poison waves may have reformed themselves into the pure toxin, as I have already shown may happen on the strength of catalysis, and in that case the disease may be produced. In the light of my theory, aided by a little experiment, the whole question, as raised by Dr. Turner in the *British Medical Journal* of September 11th, may be settled.

But, further, this theory teaches that, especially as regards organic drugs, the serum of any animal rendered immune to any drug may be used as a curative agent in case of poisoning with the drug, as has already been shown in the case of abrin and recin. In the case of the Styrian arsenic eaters, we have a drug immunity analogous, not to personal immunity, but to racial immunity. One eminent investigator, to my knowledge, is now carrying on investigations as to drug immunity and protective serums. From this, too, is apparent the truth of Behring's dictum, that "antitoxin is not a definite chemical compound, but a quality; for, indeed, serum antitoxin—there may be perhaps other antitoxins—is a vital principle."

As an instance of practical application of my theory, suppose a valuable life to be in danger from an infectious disease, as yellow fever; it must be plain that transfusion of blood from some one who has but recently suffered from the disease would save the valuable life. Of course, all lives are valuable; but circumstances may not always permit transfusion or making unusual efforts. And so, too, in the case of rinderpest, the use of fresh blood from an animal that has recently suffered, or from one that has been rendered immune artificially, would undoubtedly be the means of rendering immune a large herd; *i.e.*, the blood of one animal would protect undoubtedly hundreds.

In bringing my paper to a close, I must ask my readers not to dismiss it from their minds without thought, but to bring their thoughts and attention to it. For many years now I have been investigating the subject, and although unable from lack of opportunity to enter directly into experimental investigation, I have utilized to my purpose the experiments of others, and more and more have I received light as to the truth. When one finds a theory suitable and applicable to so many and varied conditions and states, its truth is already partly established. But not only does my theory make plain the question of disease

immunity and serum therapeutics: it indicates, as I have already said, the part played in biology by the power of the environment. It clearly shows that the fittest survives, not because literally the strongest, but the strongest because it is most adapted to its environment. It shows that there is in nature not opposition, as taught by Herbert Spencer, but modification or adaptation.

One word as regards Dr. McLaughlin, who is undoubtedly an able and original man. I have to thank him for many facts in support of my theory, as set forth in his valuable work, "Fermentation, Infection, and Immunity;" but not for the inception of my theory, which was wholly due to studies on medicinal action. Moreover, McLaughlin in his application comes short, as he worked on the theory of opposition in nature instead of adaptation.

When the light of this theory is applied to the question of the "origin of species," it must doubtless revive many of Lamarck's and Buffon's conclusions. It will tend to show that "natural selection" has not a universal application, but a very limited one—one wholly subservient to the great forces of "adaptation to environment."

Of course, on account of lack of space, I have not attempted to point out all the possibilities which I believe may arise out of this theory. Moreover, in this enunciation I have had, rightly I believe, to sacrifice elegance of diction to clearness, in hopes that thereby I shall the more attract the attention of my readers, as well as enable them to see it in the light in which it appears to me.

In conclusion, I beg to call the attention of my readers to these pregnant words of the able editor of the *British Medical Journal*, in his review of Professor Leech's address at the recent Montreal meeting: "We have emphasized this point, because it seems to us that the future of all physiology, and therefore alike of pathology and pharmacology, must depend upon the wider knowledge which we are bound to gain regarding catalysis."

Finally, I may remark that on the above theory the etiology of all diseases may be explained. It will be seen that what is called disease is an impression of inimical waves on the system, and it will be plain that, as each one in turn is born and grows up, he has to become, as it were, attuned to his environment as regards disease. It will explain why some diseases and evil customs, as drunkenness in certain races, lose their power gradually, as is the case with certain diseases and also with the southern races of Europe as regards the effects of alcohol. It will explain how man is gradually attuned to his environment. And if this theory be accepted, it will again, as Richet has recently told us, show us the unity of all science, and that all progress in medicine depends on the truths brought to bear on it from biological knowledge.

As an after-thought and for the benefit of those who may consider that it operates against my theory, I may state that the so-called relapse of typhoid fever is not a true relapse at all, but a case of exhaustion fever; *i.e.*, the vital forces, especially the nervous system, have been so reduced by the long continuance of the fever that they are unable to bring about the thorough elimination from the system of the metabolic products poisonous thereto; the truth of which statement I hope soon to demonstrate to the profession in a paper entitled "On the Nature of Fever in General and Typhoid Fever in Particular."

Aneurisms.—Fifty cubic centimetres of a sterilized one per cent. gelatin solution in a one-per-cent. salt solution injected into the gluteal region. Gelatin increases the coagulability of the blood.—LANCERNEAUX.

RETROSPECT OF FIFTY CONSECUTIVE INTRAPERITONEAL OPERATIONS, WITH SOME REFLECTIONS.

By A. BROTHERS, B.S., M.D.,

GYNÆCOLOGIST TO BETH ISRAEL HOSPITAL AND NEW YORKER FRAUENKLINIK; INSTRUCTOR IN GYNÆCOLOGY TO THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE object of the present paper is to offer, not statistics, but some truthful facts. General rules in the practice of medicine ought to be formulated only after sifting a large number and variety of individual experiences. From this point of view I frankly state my personal experience in intra-abdominal work during the past three years. Some of the cases have previously been alluded to elsewhere. I shall not endeavor to present detailed clinical pictures, but rather a bird's-eye view of a single group of cases. Most of my work has been done at the Beth Israel Hospital and New Yorker Frauenklinik, upon poor women, who were, as a rule, placed in the general ward after the operation. A few of the patients were operated upon before the class at the Post-Graduate School and two operations were done at the patients' homes.

In spite of our modern advances in the field of asepsis, the mere opening up of the peritoneal cavity continues to be associated with a certain amount of danger. I know of two of the principal abdominal operators of New York who lost patients from acute sepsis after a simple hysterorrhaphy. The risks, to be sure, are less in private rooms or private hospitals; in fact, Lawson Tait claims a preference for operating in a proper room at the patient's home: but a distinct risk in these cases is acknowledged by all. This risk is positively increased in public institutions, and, in my humble opinion, the larger the hospital wards the greater the risk.

The appended table explains itself:

TABLE OF FIFTY INTRAPERITONEAL OPERATIONS.

	Number of Cases	Recoveries	Deaths.
Exploratory laparotomy	2	2	
For ectopic gestation	6	5	1
For diseases of the adnexa	26	25	1
Ventral fixation for complete prolapsus uteri	1	1	
For abdominal fistula	1	1	
For appendicitis	5	4	1
For uncomplicated retroflexion of the uterus (Mackenrodt's operation)	3	3	
For fæcal fistula	1	1	
For pelvic abscess	1	..	1
Cæsarean section	1	..	1
Vaginal hysterectomy	2	2	
Abdominal hysterectomy	1	..	1
Total	50	44	6

Six patients were lost. The fatal cases were of a character to cause no surgeon to blush. At least three of the patients were practically moribund on reaching the operating-table. I do not believe in selecting cases for operation. I have lost and saved the most desperate. Still I am ready to confess that, were I gifted with the ability to distinguish the absolutely hopeless cases, I should certainly refuse to operate. Without this supernatural gift it becomes one's duty to resort to the knife in all cases in which there is the least glimmer of hope, and this irrespective of statistical results.

In my gynæcological work I have always tried to look at disease from the standpoint of the general practitioner. It has always seemed strange to me that certain of our operators will resort to palliative and conservative measures when their own wives or sisters are concerned, and will immediately suggest the most

extreme surgical procedures in other cases. I hope that my point of view will continue conservative in the future as it has been in the past. I have always regarded an operation as a necessary evil, and whenever possible have always tried to postpone it. Thus, to relieve a woman of an attack of pelvic cellulitis—even with the knowledge that the tubes and ovaries are involved—by prolonged rest in bed, appeals to me as far more rational than to subject her to a laparotomy. The mere removal of a hydrosalpinx or diseased ovary, within certain limits of course, does not in my mind entirely justify the severity of the intervention. My past experiences in the field of general medicine have taught me that a very large proportion of these cases, after weeks or months in bed, end in complete recovery. Similarly, to relieve a woman of a pelvic abscess by means of a vaginal incision, even though she remain in part an invalid, seems to me far more desirable than to subject her to the much greater danger involved in the removal of uterus, tubes, and ovaries, although I am ready to concede that, in very exceptional cases, this may be justifiable. In a number of early cases of ruptured extra-uterine pregnancy, in which the patients' general condition was good, I have placed a trained nurse in charge, with careful instructions to have everything in readiness for an emergency operation. I have seen such patients get well. Other patients, in whom opposite conditions existed, were subjected to immediate operation. Clear, cool judgment, as in everything else, must be exercised. It is just as wrong to lose a patient from delay as from a too hasty operation. The clear-headed, careful general practitioner will always act as ballast, steadying the ship of professional opinion from toppling over to one side or the other.

In the present series of operations, forty-four terminated favorably. By this statement I mean, of course, that if death occurred later, it could not be attributed to the operative interference. Thus, one patient with carcinoma of the peritoneum, in whom an exploratory section was done, succumbed a month later to the progress of the disease. In another case of fæcal abdominal fistula in which an intestinal anastomosis was attempted, the patient suffered a relapse and refused to submit to another operation. She was sent home unimproved, and nothing further was heard from her.

For diseased conditions of the adnexa—hydrosalpinx, pyosalpinx, chronic salpingo-oophoritis, ovarian cysts, hæmatoma, or abscess of the ovary—I have successfully opened the peritoneal cavity and treated surgically twenty-five cases. Various methods were resorted to. In some of the cases the peritoneum was opened through the vagina. If the tumor was large or promised numerous adhesions, the abdominal route was selected. In one case, in which the appendix vermiformis was supposed to be involved, an enlarged cystic ovary was removed through an inguinal incision.

I lost one of these cases. An outdoor patient, dragging herself from clinic to clinic, for years almost totally disabled from attending to her household duties, begged for relief and preferred death to her miserable existence. She was very much emaciated and run down at the time of operation. This being one of my earliest cases, the operation was performed under the kind supervision of Dr. H. J. Boldt, consulting gynæcologist to the hospital. A double salpingo-oöphorectomy, followed by ventral fixation, was done without any especial difficulty. The wound healed by primary union, but my patient succumbed on the tenth day, with evidences of septic absorption.

Although I am perfectly aware that the uterus may give rise to subsequent trouble after removal of the adnexa of both sides, I have in but one instance as yet permitted myself by older advice to remove the uterus at the same sitting. I cannot, however, help feeling that we have no right to remove the uterus because it is the seat of a chronic catarrh, even though we may be obliged to remove both tubes and ovaries. On the plea of better drainage per vaginam, in cases of bilateral purulent infiltration of the adnexa, there may be more justification in removing the uterus at the same time. But even here it seems to me that, in careful hands, the pus sacs can be reached from above and removed without molesting the uterus and without any greater risk to life than when an extensive exsection of uterus and adnexa is done from below. I am sure that most women will even subject themselves to an increased risk, if, by so doing, the uterus can be left. I have seen several cases of derangement of the mind in women, because they were told of the removal of their uteri. I have come to the conclusion that in attacking pus cases from above time is well spent in carefully separating omental and intestinal adhesions with the aid of sight, and isolating as completely as possible the pelvic contents from the general abdominal cavity by the intervention of a particularly large gauze pad. In several of my cases large pus-sacs have burst during enucleation, but, with the pus caught in a sterilized gauze diaphragm, I have dispensed with flushing the general peritoneal cavity, and have as yet not lost a case from this cause.

In various stages of collapse I have rapidly opened up the blood-filled peritoneal cavity in five cases of ruptured extra-uterine pregnancy, and removed the diseased tube with the products of conception. One case I attacked per vaginam. With one exception all of the women made excellent recoveries. In one of the cases the fœtus was found, after a diligent search, among the folds of intestine.

In the fatal case referred to I had to deal with a woman in profound collapse. I found her on the top floor of a tenement house, where she had lain for days without medical attendance. After carefully transferring her to the hospital I was afraid to touch her because of her pulseless condition. After twenty-four hours she seemed to rally sufficiently to risk a rapid operation; although I was again ably assisted by Dr. Boldt in work consuming only a few moments, she never rallied from the shock.

A small percentage of cases of extra-uterine pregnancy, with or without rupture, may terminate in spontaneous recovery. Without dilating on the matter, it is well to bear this possibility in mind. When the diagnosis of early ectopic gestation is made, with symptoms pointing toward impending rupture, our choice lies between an immediate laparotomy or intelligent delay. In the case of a well-to-do family I secured trained nurses to watch the patient night and day, after a positive diagnosis had been made by Dr. Boldt and myself: and, although every preparation was on hand for immediate operation, this woman made a perfect recovery. On the other hand, in two cases of unruptured tubal pregnancy, in which such measures could not be carried out, the patients were operated upon at my suggestion by colleagues, and also made perfect recoveries. In other words, under intelligent, unremitting supervision delay may be tolerated in certain cases, but in poor people without proper facilities for such care operative intervention should be resorted to at once.

The operation itself in unruptured cases is very simple in experienced hands. After rupture there may be greater technical difficulties. The main object in all cases is to tie off the affected tube and as quickly as possible when ruptured. Once the tube is properly tied off there need be no further anxiety regarding fresh hemorrhage. In my first cases the wounds were drained with gauze; in my later cases, after the removal of free clots and as much blood as possible, they were immediately closed. I have had

reason to feel more satisfied with the latter mode of procedure. In a clean operation I think it perfectly safe to close the wound and leave the remaining blood in the peritoneal cavity for nature to absorb.

In this connection I may allude to one laparatomy which I was unexpectedly called on to do while removing an ovarian tumor through the vagina. The hemorrhage became uncontrollable in the small field at my command, and I was left the choice between a rapid vaginal hysterectomy or an abdominal incision. I selected the latter. It is the only case in a fairly large series of vaginal sections in which I was seriously disturbed by inaccessible hemorrhage. Still the risk is present, and ought to be taken into account when one is working by this route.

I have done one ventral fixation for complete prolapsus of the uterus. The result was ideal. To be sure, plastic vaginal work was done at the same sitting; but previous experience has taught me that such plastic work in itself is insufficient to overcome an advanced case of prolapsus uteri, even when the cervix is amputated in addition to narrowing the lumen of the vagina anteriorly and posteriorly. With Freund's operation of narrowing the vaginal canal by means of a series of circular sutures I have had cause to be disappointed. I do not see how a shortening of the round ligaments can be of service, and therefore have never employed this method in these cases. The only choice then remains in removing the uterus or attaching it to the abdominal wall. I prefer the latter method, and would only select the former as a *dernier ressort*.

I would most strenuously protest against the performance of ventral fixation in cases of uncomplicated mobile retroflexed uteri. There are far less dangerous operations—like that of Alexander—from which we can obtain equal if not better results. Vaginal operations I have for various reasons abandoned. I am among those who believe that in recent years too many patients have been operated on who might have got along with simple supporting measures.

In one case I performed a laparotomy for an abdominal fistula left after the removal of an adnexal tumor by another surgeon. After the peritoneal cavity was opened into alongside the fistulous tract, through which a large probe had previously been passed, the agglutinated intestines were carefully separated from one another down to Douglas' sac. As no irritating suture or pus collection could be discovered, the abdominal wound was immediately closed, after excision of the fistulous tract, and in two weeks the patient was completely cured.

In five cases I have opened up the peritoneal cavity through an inguinal incision for appendicitis—ulcerative, gangrenous, suppurative. In one case only was it not considered practicable to remove the appendix. In this case a counter-incision in the vagina became necessary some weeks later. Although in former years I have incised and drained so-called "perityphlitic abscesses," I have come to consider such operations as incomplete. I have seen subsequent trouble and relapses in a number of cases. The proper inspection and removal of the appendix—after its careful isolation from the general peritoneal cavity, in skilful hands offer no additional risks to the patient and afford greater security against subsequent relapse.

One patient was lost—a young man suffering from perforative gangrenous appendicitis with general suppurative peritonitis of three days' standing. The chances were all against the patient from the outset, and it was only the fact that several months previously I had suceeded in saving a case of a similar nature which induced me to operate.

Not having fully overcome my great respect for the possession of a uterus by a woman, I have always hesitated to remove this organ without full and justifiable provocation. This may account for there being only three hysterectomies in my list. The two vaginal cases terminated in recovery, although one of them required subsequent operative relief on account of a ureteral injury.

The abdominal hysterectomy, done for a large impacted multiple fibroid uterus in a very much exsanguinated woman, resulted fatally. During the progress of the operation, which presented almost insuperable technical difficulties, the patient lost a considerable quantity of blood. Although I was ably assisted by Drs. H. N. Vineberg and L. S. Rau, the operation consumed over two hours, and at its termination my patient was in a state of profound collapse, from which she never rallied.

One of my patients died after laparatomy for pelvic abscess. Although the subjective symptoms clearly indicated the presence of pus, the exploring needle introduced in various directions per vaginam failed to locate it. On the following day, at the suggestion of an eminent colleague, an incision was made in the median line of the abdomen and the pus sac discovered in the pelvic cellular tissue on the left side. After careful isolation of the mass from the general peritoneal cavity with strips of iodoformized gauze, the abscess was opened and counterdrainage through the vagina made. The patient died in about thirty-six hours from acute sepsis. In any future case I should open up the cul-de-sac with an incision and search for the pus with every preparation, in case of necessity, for a vaginal hysterectomy.

The Cæsarean section was undertaken in a dying woman. The fœtus was known to be dead and the mother was in the last throes of eclampsia. The operation itself presented no difficulties and was done rapidly, but it failed to modify the eclamptic state, from which the patient never emerged.

My experience thus far teaches me that the field of operative gynæcology is a very broad one. Still, after having mastered the essentials of technique by proper training on the cadaver and in a number of living subjects, under the supervision of a master, one will find that most cases fall into distinct groups which, after some experience, will suggest themselves at the time of operation.

There are three principal sources of danger in operative work—anæsthesia, hemorrhage, and sepsis. It occasionally happens—sometimes through the inexperience or carelessness of the anæsthetizer, sometimes on account of individual peculiarities—that the patient becomes profoundly cyanotic or stops breathing. Although such conditions have caused me much anxiety at times, I have as yet lost no case from anæsthesia. Of course this danger does not depend on the nature of the operation. It may occur in connection with a simple examination under narcosis. It is a good practice to watch the color of the oozing blood and to inquire of the anæsthetizer at regular intervals regarding pulse and breathing.

With increasing experience one needs to fear hemorrhage less and less. Occasionally a case will prove annoying, perhaps serious, from the fact that every cut or needle puncture will excite profuse bleeding. A good rule to bear in mind in such cases is that laid down by one of our most eminent New York gynæcologists, "Don't get rattled." An operator with a good knowledge of anatomy and his instruments, a clear head, and a steady nerve has little to fear from hemorrhage.

The greatest danger to fear is sepsis. When the general peritoneal cavity is invaded, all the operator's precautions will be of no avail if his instruments and dressings are not aseptic, if his ligature and suture material is not above suspicion, if his assistants at

the wound and at the instrument tray, as well as his nurse in charge of the sponges, are not thoroughly schooled and drilled in every detail of asepsis. Even with trained assistants the carelessness of one individual may result in the introduction of sepsis. A drop of sweat into the wound, the touching by nurse or assistant in a thoughtless moment of something not rendered sterile, may cause the death of the patient in spite of the most skilfully performed operation.

To reduce this source of danger to the minimum it is desirable to work with as few assistants as possible. It is a good plan to watch one's assistants so that they are constantly on the *qui vive*. As far as possible I introduce only my own hand into the peritoneal cavity. In pus cases it is well to spend some time in the introduction of pads, pushing the intestines up toward the diaphragm. In such cases, even if pus escapes, it will do little mischief, provided the escaping matter is caught in the gauze. I have been so well satisfied with this plan of procedure that in my later cases I have entirely dispensed with intra-abdominal flushings. Drainage I still resort to, but only in doubtful cases. As a rule, if hemorrhage is entirely controlled and any septic material has been thoroughly removed, it will be quite safe to close the wound without drainage.

Progress of Medical Science.

The Coating of the Tongue. — 1. In severe infectious diseases the tongue is coated with a brownish fur, which consists partly of the remains of food and partly of dried blood. The microscopical examination of the coating removed from the tongue exhibits, in such cases, a profusion of epithelial cells and hosts of fungi of various forms. In addition to these, there is a multitude of dark cellular bodies, derived doubtless from the corneous and exfoliated epithelium of the part (Bizzero). Schech again calls attention to the occurrence of a black fur, which is probably occasioned by the formation of pigment papillæ on the tongue. Ciaglinski and Hewelke trace an appearance similar to that of a pigment-forming yeast fungus. 2. The tongue of infants is normally coated with a white fur, and a similar appearance is found in adults when the stomach is deranged. Microscopical examination shows epithelium, a few salivary corpuscles, and very few fungi.—Dr. Rudolf v. Jaksch, "Clinical Diagnosis."

Croupous Pneumonia in Children. — Dr. E. Schlesinger (*Archiv für Kinderheilkunde*, xxii., 3–6 Hefte) reports one hundred and seventy-three cases, most of which began in the second half of the fourth year in the children examined. Boys are affected more frequently than girls. In cases without prodromal symptoms, the fever begins in about ten hours; in those with prodromata, fever begins in about two or four hours. The younger the child the greater is the inclination to higher and also to intermittent and remittent fever. Lysis is less frequent than with adults. Procrises (morning remissions to normal temperature directly before the crisis) seem to be peculiar to childhood. Temperature and pulse become lower by crisis; the frequency of respiration by lysis. The pulmonary consolidation is not so markedly lobar as in adults; more frequently the consolidation is only partial, seldom it extends into the neighboring lobe. Pneumonia of long duration, delayed resolution, tendency to phthisis and gangrene are all very rare. In cases with prodromata, marked initiatory symptoms are lacking; while in those cases beginning suddenly there are almost always initiatory symptoms. Chills are rarer; vomiting is more frequent than in adults. Convulsions are infrequent, except in young children. Before the crisis the patients are often very sick. Abortive forms of pneumonia occur; pneumonia migrans is dangerous: recurrence is rare. The anomaly most frequently seen is the cerebral type of pneumonia. Complicating meningitis generally runs a latent course. Leucocytosis and marked blood changes are the same as in adults. The complication most frequently observed is pleurisy, generally serous, less frequently developing into empyema. Other complications noted are collapse, diarrhœa, follicular enteritis, splenic tumor. Albuminuria is rarer and its consequences are less severe than in adults. Hemorrhagic nephritis was observed in one case, erythema twice, icterus seven times, herpes in eighteen per cent. of the cases. Otitis media occurs frequently, generally runs a mild course, though often causing high fever and cerebral symptoms. The mortality is less than among adults (twenty per cent.). Fatal complications are pericarditis, meningitis, broncho-pneumonia. Therapeutically, medicinal antipyretics ought not to be used: mild hydrotherapy (cold packs) is of service.

Acholic Stools.—The stools may be deficient in bile in cases of jaundice from obstruction of the biliary ducts, or they may be so in the absence of this condition. They are characterized by: (1) their whitish-gray color; (2) the abundance of fat which they contain; and (3) a profusion of fat crystals, probably soaps of soda, lime, and magnesia. Such stools in connection with jaundice imply an obstruction to the flow of bile by blocking of the ducts. When this occurs independently of obstruction, the underlying cause is not yet sufficiently understood. Many theories have been framed to account for the phenomena: (1) It may be that the bile pigment has undergone some change in the intestine which prevents the formation of its metabolic product (urobilin); or (2) the secretion of bile may be so scanty that there is not enough pigment for the elaboration of urobilin; or (3) it is possible in such cases that the latter is replaced by certain colorless metabolites or chromogens of bilirubin (v. Nencki's leuco-urobilin). The latter view is supported by the fact that considerable quantities of urobilin may be obtained from acholic stools by extraction with acid alcohol. The stools may be devoid of bile in cases of the most varied origin—as in tuberculosis of the intestine, chronic nephritis, and chlorosis—when no trace of jaundice is present. They are commonly so in the fatty discharges which accompany indigestion in children. Berggrün and Katz have observed acholic stools in chronic tuberculous peritonitis in children. In these cases, as usual, the fæces contain an excess of fat. It therefore follows that we cannot infer the character of the stools from the presence or absence of this symptom. But in all cases, when colorless stools concur with jaundice, gas is to be found, as has already been said, in obstruction of the biliary passages.—Dr. Rudolph v. Jaksch, "Clinical Diagnosis."

Epithelioma of the Face Successfully Treated by Swabbing with Arsenious Acid.—At the meeting of the Society of Dermatology, held in Paris on March 10th, Dr. Hermet showed a patient who, in October, 1897, was found to have epithelioma of the face. Arsenious acid was applied, the surface of the ulcer being left exposed to the air, after the method of Czerny. The new growth was destroyed by the early days of January, 1898, and cicatrization was completed by February. The patient had previously been treated with chlorate of potassium without the slightest benefit. Czerny's method, employed by Dr. Hermet, consists in using three solutions of arsenious acid in equal parts of water and ethylic alcohol. The first solution, of

the strength of 1 to 150, is applied to the ulcerated surface. The second and third solutions, which are stronger, are applied to the scab. The ulcer is swabbed with the solution every day, and excessive pain is kept in abeyance by hypodermic injection of morphine. When the scab falls off the raw surface is treated as an ordinary wound.—*Lancet.*

Leukæmia in the Newborn.—Pollmann (Erlangen) reports a case of splenic-myelogenous leukæmia, which originated *in utero* and which led to death nineteen days after birth. The condition of the blood was that of acute leukæmia. The case was complicated with defect of the ventricular septum, patency of the ductus arteriosus Botalli, together with endocarditis of the tricuspid, all this pointing to an infectious foundation of the process.—*Wiener klinische Rundschau*, January, 1898.

A New Method for the Detection of Albumoses in the Urine.—Ten cubic centimetres of urine is heated in a reagent glass with eight grains of $(NH_4)_2SO_4$, and then boiled for one minute. The warm fluid is poured into a centrifugal machine and centrifuged for one-half or one minute. The fluid is poured off and the sediment is rubbed with alcohol. Now pour off the alcoholic solution, dissolve the remains in a little water, boil, filter, and with the filtrate make the biuret reaction.—Ivar Bang (Upsala).

A Very Delicate Test for Bile Pigment.—A modification of Ehrlich's diazo-benzol-sulphuric-acid reaction is recommended by Drs. Krokiewicz and Batko (*Wiener klinische Wochenschrift*, No. 8, 1898). The following reagents are necessary: (*a*) A one-per-cent. aqueous solution of sulphanilic acid; (*b*) a one-per-cent. aqueous solution of sodium nitrite; (*c*) pure concentrated hydrochloric acid. The test may be made according to one of three methods: 1. To two cubic centimetres of the reagents (*a*) and (*b*) add from two to five drops of the urine, and shake; if bile pigment is present a ruby-red color develops, which changes to amethyst violet upon the addition of one or two drops of hydrochloric acid. 2. To a few drops of the solutions (*a*) and (*b*) add an equal quantity of urine and one drop of hydrochloric acid, and mix; a deep violet color results. 3. Shake together in a test tube several drops of the solutions (*a*) and (*b*), and pour out; if five cubic centimetres of icteric urine be added, the mixture turns ruby red, changing to amethyst violet upon the addition of hydrochloric acid.

Thyroid Congestion in Young Men.—Dr. A. Hallipré, *La Normandie Médicale*, December 15, 1897, in a long article on this subject concludes with the following propositions: Thyroid congestion may appear in boys at puberty. Increase in the volume of the thyoid gland is sometimes sufficiently marked to cause, either by direct compression or by irritation of the recurrent nerves, laryngeal spasms, with hoarseness of the voice and symptoms approaching suffocation. The iodide treatment is valuable, together with the ingestion of the thyroid gland of a sheep or its pharmaceutical preparations.

Clinical Deductions from Lumbar Puncture of the Spinal Cord.—As a result of about one hundred cases of exploratory spinal puncture, Stadelmann (*Deutsche medicinische Wochenschrift*, 1897, Nos. 46 and 47) concludes as follows: 1. Meningitis tuberculosa, fourteen cases. The pressure of the cerebro-spinal fluid is here generally increased, though it is sometimes diminished, and rarely no fluid issues at all. These differences are explained by adhesions of the arachnoid and pia; further, by clogging of the foramina of communication (foramen Magendi, etc.). The fluid is frequently light colored and clear, containing very few leucocytes; at times it is cloudy; rarely it contains much pus and even blood. The writer found tubercle bacilli in only twenty-two per cent. of his cases. The comparatively infrequent discovery of bacilli, Stadelmann accounts for thus: clogging of the communicating foramina; puncture of the subdural instead of the subarachnoid space; the exudate may lie, not in the subarachnoid space, but in the meshes of the arachnoid itself; finally, the disease may be meningitis serosa simulating meningitis tuberculosa. 2. Meningitis purulenta, seven cases. Here the liquor cerebro-spinalis is cloudy, containing more or less pus and many bacteria (meningococci, streptococci, pneumococci). The amount of albumin in this fluid is generally increased, but this is at times the case in the cerebro-spinal fluid of those having brain abscesses and tumors; hence it is not of diagnostic importance. Sometimes, in those with meningitis purulenta following otitis media, the liquor cerebro-spinalis is clear and light amber colored; this occurs when the meningitis has remained local and has not gone over into the subarachnoid space. 3. Brain abscess. Lumbar puncture gives extremely various results. In one case Stadelmann found that the fluid was under very high pressure; in a second the liquid was cloudy and purulent; in a third, by the first puncture purulent fluid resulted, by the next a clear fluid. A complicating meningitis cannot always be proven by means of lumbar puncture, since circumscribed areas of meningitis may give rise to clear watery fluid; hence a negative result of puncture is of no value. A differential diagnosis between brain abscess and sinus thrombosis cannot be made by lumbar puncture. 4. Brain tumor. The hopes for the great therapeutic value of puncture (thus relieving brain pressure) have not been realized. The diagnostic value of this procedure is *nil*. 5. Brain hemorrhages may alone be diagnosed when the blood is upon the cortical surface or when the blood has forced its way into the ventricles. Pachymeningitis hæmorrhagica, because of its anatomical relations, cannot be diagnosticated by this method. 6. The differential diagnosis between apoplexy, embolism, and brain softening cannot be made by puncture of the spinal column. 7. In hydrocephalics, Stadelmann has not found puncture (lumbar) of any therapeutic value; neither therapeutic nor diagnostic value was obtained in encephalitis hæmorrhagica, chronic lead poisoning, uræmia, nephritis. Concluding, Stadelmann does not consider lumbar puncture of the spine of therapeutic worth; regarding diagnostic worth, the positive results alone are of use.

Experimental Injuries of the Heart.—Dr. Bode has experimented on animals in order to study the effect of trauma on the heart. He has found (*Beiträge zur klinischen Chirurgie*, Bd. xix., Heft 1) that a wound of the auricle is much more serious than the same wound of the ventricle; further, that small and moderate-sized wounds of the left ventricle do not cause so much hemorrhage as similar injuries of the right ventricle, because of the thicker walls of the former. The first result of a cut or a heart suture was generally a stoppage of the heart's action for a very short period, followed by a longer or shorter period of irregular action. The heart's action was not visibly affected by the knotting of the suture. After thorough closure of the wound, the cardiac action and the general condition of the animal were visibly improved. The sutures left *in situ* in those animals which recovered did not disturb the heart's action. Deep wounds of the auricles and of the great vessels at the base of the heart invariably led to death, the fatal results not being prevented either by suture or by tamponade.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, April 30, 1898.

THE WAR OUTLOOK.

Now that war with Spain has been declared, the situation is viewed with becoming and practical interest by members of the medical profession. Always eager in the exercise of their vocation along legitimate lines, they are always particularly anxious to be of service in all times of emergency. The wide distribution of troops, the complicated conditions pertaining to a foreign climate, and the varied requirements of modern warfare, will necessarily develop entirely new experiences in the care of the sick and wounded. While it is quite likely that most of the fighting will be done at sea and that the majority of the wounded will be in the naval service, it is equally reasonable to expect that the exposure of the army to pestilential influences will correspondingly balance the mortality list.

As everything in war must bend to the necessity of strategic manœuvres, the health and safety of the rank and file are necessarily matters for secondary consideration. The latter point of view especially applies to the prospective occupation of Cuba by unacclimated troops. It is in making the best of such a situation on a pestilential island and in a foreign clime that the resources of the medical service will be taxed to its utmost in maintaining the average sick limit of an invading army. The danger of an outbreak of yellow fever is not to be lightly considered when so much fresh fuel is offered for the constantly smouldering fire. At this season also, when the periodical rains are due, when the disease is apt to take a fresh hold and increase in virulence, the outlook is by no means promising. Save for the exigencies of the hour, it would be the height of folly to submit raw, untrained, and unacclimated troops to such exposure. Especially would this be the case if the ordinary militiamen and volunteers from our Northern cities were detailed for such service. The veterans of the regular army, inured as they are to camp life, hardened by constant exposure to the elements, and disciplined to the privations of the field, are so much better calculated to bear the brunt of this extra hazard of war that there can be no doubt of their claims for such enviable preferences. But safer far would be the detail of colored troops for such purposes, as it is well conceded that the negro not only enjoys a comparative immunity from yellow fever, but in him the attacks are comparatively mild and the mortality is correspondingly low.

It is also with considerable solicitude that we view the possibility of a return of the yellow-fever epidemic of last summer in some of the camps of the South. Although appearing late in that season and not having much opportunity for gaining headway before frost, there is no guarantee that a fresh outbreak may not be heralded with the incoming warm weather. If such should be the case, the result would be disastrous, not only to the soldiers themselves, but to wide districts of surrounding country. The responsibility for the prevention of such a calamity rests entirely on the health authorities of the different Southern States. Fortunately we still have the Marine Hospital service for help in time of need. So far, however, the military authorities have displayed great wisdom in the selection of Chickamauga as the principal rendezvous —an exceptionably healthy district, with all the natural requisites for a model camp.

It can be reasonably anticipated that much if not the greater part of the surgical work of the campaign will be concentrated in hospitals provided for the purpose and within convenient reach of transportation from battles on land or sea. The battleships when in action are not calculated for proper care of the wounded, and the new naval ambulance, the *Solace*, will be an experiment in its field of work which will doubtless prove a striking realization of entirely new possibilities. It is to be a receiving-ship, transport, and operating-theatre all in one, and, flying the Red Cross flag, will be amply protected against fire even when between the lines. It is on this ship that most of the operating will be done, the staff being specially trained in all the modern methods of technique. This, with its companion ship shortly to be perfected, will doubtless enable the surgeons so to systematize and expedite their work that no time or opportunities will be wanting in rendering valuable, efficient, and needful aid in the shortest possible time consistent with opportunity and place.

Thus, with everything in readiness for the sick and wounded yet to be, we await with grave suspense the ominous raising of the dark curtain of war's grim drama.

WOUND TREATMENT AND MODERN WARFARE.

IT is quite likely that during the progress of the present war there will be entirely new experiences in the character and treatment of the wounds inflicted in battle as compared with those of thirty years ago. Since that time the destructive machinery of the battlefield has been brought to such a degree of perfection in regard to distance of range, accuracy of aim, and power of penetration, that the percentage of such as may receive slight wounds, from which recovery may be possible, will be exceedingly small in proportion to such as are destined to be killed outright. It will be a question of wholesale slaughter, in which the winner can show the greatest amount of annihilation in the shortest possible time. The mill that has the best

grinding-power will be the first to receive the prize. The game is to be played with stakes in job lots. It is to be a wholesale business entirely, the mere retail exhibitions of personal bravery, individual tact, or military genius being virtually unnecessary for the desired end. The best-equipped machine shop will turn out the most goods. Hence it will be impossible to estimate the amount of damage that may be done, or the number of lives that may be sacrified. The wounds will be on a large scale and numerous in proportion. Especially will this be the case on the battleships under fire. Extensive lacerations from exploding shells, submarine mines, and torpedoes, and splinters of steel and wood will be the rule. The wide areas of tissue involved and the corresponding intensity of shock will necessitate new rules for operative interference and new methods of surgical technique. Comparatively speaking, amputation will be more necessary than resection.

When once the danger of operation itself is past, aseptic surgery will abundantly demonstrate its opportunities. What is lost in one direction will be gained in another. Hospital gangrene, the dreadful bane of wound treatment in our late war, will be virtually impossible, and suppurating stumps will no longer propagate their poisonous influences. Intestinal surgery has also elevated itself almost to a science, and death on the field, virtually inevitable before, is now most effectually thwarted by the modern and ingeniously skilful methods of the present day. Thus, while the war may inflict larger and more dangerous wounds than ever before, there is a comfort in contemplating the compensatory balance of odds in favor of the corresponding advances in operative methods and the improved technique of wound treatment.

The experiences along the new lines of surgical procedure will be of the greatest interest to the profession in demonstrating on a large scale the value of those general principles upon which the recent surgical advances have been based. Every pains will be taken to give all available information on these points to the readers of the MEDICAL RECORD. Aside from arrangements for special correspondence from the field, we are particularly gratified to state that a representative of this journal, himself one of the operating surgeons on the *Solace*, the new hospital ambulance ship, will furnish our readers with such surgical data as may be interesting, suggestive, or instructive.

WOMEN NURSES FOR THE ARMY.

THE commendable alacrity of the Red Cross Society in enlisting volunteer nurses for active service in the field brings us face to face with a necessity which can be properly appreciated only by such as are conversant with past history. Notwithstanding the report that the government does not care for females in such a capacity, the time must come when such an error in judgment will be most clearly demonstrated. In point of fact, no arm of the service can afford to proclaim itself independent of such aid. Every battlefield, from that of the Crimea to the most recent engagements, has demonstrated the peculiar fitness for such work as hundreds of willing women throughout the land are willing to offer. In the war of the rebellion an army of such helpers was furnished by the United States Sanitary Commission, and the amount of efficient assistance given by its members on field and in hospital is a matter of thankful remembrance. The practical usefulness of such a corps is so well acknowledged by the British government that it has long since established a school in connection with Netley, wherein the nurses are specially trained for the privations and necessities of the field, and subjected to the discipline of army regulations. This is very necessary in view of the altered conditions of such work as compared with that in civil life. It implies the development of resources in times of emergencies—the utilization of the means at hand, few as they may be, to the requirements of the end. No matter what may be the proficiency of the ordinary trained nurse, she can never properly comprehend her new duties until their real nature and varied purposes are practically demonstrated. The emergencies of the field are so distinct, peculiar, and urgent, that nothing short of special training and the possession of natural adaptability to existing circumstances will determine real fitness. The Red Cross Society has very properly taken the initiative in this line, and promises to be the leading organization of its kind in the country. Commencing with the trained nurse as found in our hospitals, it gives, so to speak, a post-graduate course in army work by a thorough and systematic training in all the detail requirements for the sick and wounded soldier. The selection of candidates is made from the best material at hand, and the after-teaching is correspondingly easy and practically efficient.

It is unnecessary to dilate on the peculiar fitness of women for such a vocation. Next to being the nest bird in her home, she becomes the natural nurse with soft touch, tender word, and hopeful spirit, who nearest of all approaches the ministering angel in our hour of direst need. Her highest aspirations and best capabilities can have no prouder badge than that of the Red Cross.

THE PLAGUE OF "EXTRAS."

AN intolerable nuisance, annoying to the well but absolutely harmful to the sick, is the crying of "extras" in the streets of this city and, we presume, of others in the country. From early morning to midnight, weekdays and Sundays, the hoarse shouts of half-grown lads and the shrill treble of midgets deafen the ears and rasp the nerves of invalids, by whom the ordinary and what we may call normal city noises are in themselves almost unbearable. If the city authorities can regulate the playing of musical instruments in the streets, surely it is within their power to abolish this new terror. News stands are to be found at almost every corner on the business avenues, and people whose eager thirst for war news is not to be satisfied with the regular morning and evening editions of the papers can find the extras at these stands, while

invalids and others to whom war is something more serious than a football match can be spared the useless suffering of these rancorous cries.

News of the Week.

Acting Assistant Surgeons. — Over eight hundred medical men have offered their services to the army authorities and more than a thousand to the naval medical department. These are by no means all young men or recent graduates, for many offers are received daily from men, some of whom saw service in the civil war on one side or the other, and others who have come on the stage since that time but who stand in the front rank of the profession.

Cornell Medical College. — The following men, practically the entire faculty of the University Medical College, have been appointed to the faculty of the Cornell Medical College, recently organized in this city: W. M. Polk, dean and professor of gynæcology and obstetrics; Lewis A. Stimson, professor of surgery; R. A. Witthaus, professor of chemistry, physics, and toxicology; W. Gilman Thompson, professor of medicine; George Woolsey, professor of anatomy and clinical surgery; H. P. Loomis, professor of materia medica, therapeutics, and clinical medicine; J. Clifton Edgar, professor of obstetrics; Frederick H. Gwyer, professor of operative and clinical surgery; Irving S. Haynes, professor of practical anatomy.

War Nurses.—Offers have been received in Washington from over four hundred women who are ready to go to Cuba or any part of this country as army nurses. Among them are sisters of charity, deaconesses of the German Lutheran Church, members of the Salvation Army, and individual trained nurses. In addition, the Red Cross Society has had many applications from women desiring commissions as Red Cross nurses.

Shorter Hours for Drug Clerks.—Mayor Van Wyck has vetoed the bill passed by the State legislature reducing the hours of labor of drug clerks in this city to sixty-six a week, on the ground that the provision giving the health board the authority to decide how the daily and weekly hours of services should be distributed was not drawn in the interests of the public.

Care of the Sick and Wounded.—It has been decided that the naval ambulance ship *Solace* shall be used as a transport for the sick and wounded of both army and navy. She will carry men physically disqualified for active service from the fleet or from Cuba to Key West and Tampa. A hospital train will run from Tampa to northern points, in order to give the sick the benefit of a change to the cooler climate of the middle and northern Atlantic seaboard. A general army and navy hospital will also be established at Key West, and hospital tents will be sent there to accommodate any overflow of incapacitated seamen and soldiers. The selection of Key West for this general hospital is due chiefly to the fact that the island is more healthful than places on the mainland, and, in the event of a fever outbreak among the men in Cuba or on the warships, the treatment of the stricken there would lessen the danger of a spread of the disease to the coast proper. Other hospitals are to be established in the department of the Gulf, but that at Key West will be the headquarters of the medical corps of both military services, in addition to the Marine Hospital service.

The Hospital Saturday and Sunday Collection. —The total collection for the hospital fund this year was $68,000, and the expenses were $3,000. The undesignated fund of $65,000 was apportioned to thirty-seven institutions, according to the number of days' care of free patients in the year.

The Will of Mr. Ernest Hart, late editor of the *British Medical Journal*, was recently offered for probate. His personal estate was valued at £15,966 (about $78,000), the greater part of which is left to Mrs. Hart.

The Medical-Practice Law in Pennsylvania.—A medical man, who was registered in Allegheny County, Pa., recently opened an office in another town and began to practise there several days in each week on the strength of this registration. The county society in his new home had him arrested for practising without a license. The court decided, however, that, having been licensed to practise in one county, he could do so in any other part of the State, and that, having a permanent office, he could not be looked upon as a "transient" doctor, even though he was not there every day.

A Medical Patriot.—Maine's oldest volunteer to fight Spain is ex-Governor Garcelon, of Lewiston, aged eighty-six. He has served Uncle Sam through one war, and he was then, thirty-seven years ago, over the exempted age.—*The Kennebec Journal.*

The Plague is reported to have appeared at Calcutta. A year ago it was stated that pestis minor prevailed there and that the sanitary conditions were so bad that there was imminent danger of the plague becoming epidemic. The persistence of the disease in India is exciting apprehension lest it reach Egypt by way of Mecca. In view of this danger the quarantine board at Cairo has appealed to the Egyptian government to prohibit the pilgrimage for this year, and the ministers have forbidden provisionally the issue of passports to intending pilgrims. The final decision rests with the Khedive, who, it is thought, will not refuse his assent.

Dr. Cornelius N. Hoagland died at his home in Brooklyn on April 24th. He was born in New Jersey in 1823, and was a graduate of the medical department of the Western Reserve College in Cleveland in 1852. He served through the civil war, and in 1868 removed to Brooklyn. He founded the Hoagland Laboratory ten years ago, and since then has presented to that institution nearly $200,000. He was the president of the board of directors. He was also interested in the

Brooklyn Free Kindergarten Society and the Brooklyn Eye and Ear Hospital, and had made large contributions to each. He was a fellow of the Microscopical Society of London, and a member of the Kings County Medical Society and of a number of scientific societies in this country.

The American Gastro-Enterological Association.—The annual meeting of this association will be held in Washington, on May 3, 1898, under the presidency of Dr. D. D. Stewart, of Philadelphia. The secretary is Dr. Charles D. Aaron, 32 Adams Street, Detroit, Mich.

The American Orthopedic Association will meet in annual session this year in Boston, Mass., on May 17th, 18th, and 19th, under the presidency of Dr. R. W. Lovett. The secretary is Dr. John Ridlon, 103 State Street, Chicago.

Qualifications to Practise in the Yukon.—Physicians desirous of legally practising in the Klondike region may do so (1) if they hold British qualification and pay a registration fee of $50; (2) not having such qualifications, they must pass an examination and pay the same fee. Dr. H. N. Bain, Prince Albert, N. W. T., is the registrar of the territories. The authorities are insisting on the strict carrying out of these regulations.—*The Canadian Medical Review.*

The Third Pan-American Medical Congress.—The committee on organization of the third Pan-American medical congress, which is to be held in Caracas, Venezuela, in Christmas week of next year, has been appointed as follows: *President*, Dr. José Manuel de los Ríos; *First Vice-President*, Dr. Nicanor Guardia: *Second Vice-President*, Dr. José I. Cardozo: *Third Vice-President*, Dr. Alfredo Machado; *Treasurer*, Dr. Luis Ezpelosín; *Recording Secretary*, Dr. Luis Razetti; *Corresponding Secretary*, Dr. Francisco A. Rízquez; and Drs. B. Mosquera, P. Acosta Ortiz, H. Rivero Saldivia, E. Ochoa, M. A. Seco, S. A. Dominici, E. Rodríguez, and M. Herrera.

A queer story is cabled by the usually trustworthy London correspondent of *The Sun* to the effect that the United States government has invited the medical staffs of several London hospitals to assist in securing the services of surgeons for our army and navy, and that many advanced students and recent graduates are already making preparations to come here. We hardly think any one authorized to speak for the medical department of either the army or navy could be guilty of any such absurd move, in view of the numbers of American surgeons who have already offered their services to the government.

The Skaguay Hospital.—Bishop Barker, of the Episcopal Church, has issued a letter to the people of the State of Washington, appealing for assistance for the Skaguay Hospital. The people of Skaguay have established an emergency hospital and have placed it under the charge of Bishop Rowe, of that place. At present the hospital building is simply a low cabin, thirty feet long and eighteen feet wide. One room on the ground floor answers for kitchen and ward. Another ward above is but half-story or attic. In this room are twelve cots, most of them occupied constantly with patients suffering from pneumonia and meningitis. There is one woman nurse in the hospital, with two male helpers and a cook. Sickness was increasing rapidly when the last mail was received, and it had been found absolutely imperative to build an addition to the hospital, the present accommodations being so entirely inadequate. If some of the rich donors to our palatial hotels for well-to-do invalids would turn their benevolent eyes to the Northwest, they would find here a place where a hospital is really needed and where their charity would be productive of good.

Recovery from Electrical Injuries.—At the meeting of the Tri-State Medical Society on April 5th, Dr. J. J. Brownson, of Dubuque, Iowa, reported the case of a man who was terribly injured by coming in contact with a live electric wire. He lost one arm and part of his other hand, besides being burned on other parts of his body. The man received twenty-four hundred volts and still lived—the greatest number ever received by a human being and recovered from. The next greatest number of volts passed through the human body without causing death was received by a lineman in New York, who sustained a shock of one thousand on two different occasions, and whose miraculous escape from death has earned for him the sobriquet of the "human lightning-rod."

A Medical Man's Opinion.—Dr. Guido Baccelli, of Rome, who was president of the Eleventh International Medical Congress, has published his views of the Spanish trouble. He thinks Americans are more to be dreaded than Chinese. The yellow race, he said, no longer menaces Europe, but there is actual menace from the United States, "where the expanding, absorbing Anglo-Saxon energy must grow and spread and ultimately overwhelm that part of European civilization which it does not renew. War with Spain is the beginning. Afterward it will be a mere question of the survival of the fittest."

The medical schools of Baltimore, which three years ago adopted a four instead of a three years' course, will graduate very few students this year on that account.

The Maryland Public Health Association will meet in Baltimore on May 11th and 12th. The opening address will be made by Col. George E. Waring, Jr., former commissioner of street cleaning in New York City.

Mixed Typhoid and Malarial Infections.—Dr. W. S. Thayer, of Johns Hopkins University, Baltimore, writes: "Permit me to call your attention to a slight error in your review of my 'Lectures on the Malarial Fevers.' The reviewer appears to have regarded my discarding the terms 'malarial pneumonia,' 'typho-malarial fever,' etc., as a denial of the existence of mixed typhoid and malarial infections. This, as he justly says, would be absurd. But, as a matter of fact, I have described these mixed infections upon the same page (203) from which the quotation is made

and on the preceding one. I regret extremely that my remarks should have led to so serious a misinterpretation."

Erratum.—Dr. G. F. Cook, of Oxford, Ohio, writes: "My article on 'A New, Rapid, and Accurate Method of Estimating Uric Acid' appeared in your journal, vol. liii., No. 11. There is a typographical error which I would like very much to have corrected. In the last paragraph the article reads: 'Each 1 c.c. as marked on the graduated tube indicates 0.001176 gm. of uric acid in 10 c.c. of urine.' This should read: 'Each 0.1 c.c. as marked on the graduated tube,' etc."

Marriage Licenses.—A bill has been introduced in the Maryland legislature to prohibit the issuing of a marriage license to any person suffering from consumption, insanity, dipsomania, syphilis, and tuberculosis. This bill has excited much interest and a variety of opinions among the physicians, but it is generally considered impracticable.

Actinomycosis.—A patient in the Hebrew Hospital of Baltimore has recently died of actinomycosis. Being orthodox Hebrews, whose creed forbids the use of a body after life is extinct, the family of the young man refused to allow an autopsy, which would have been of great benefit to the cause of medicine.

Assistant Quarantine Physician of Baltimore.—Dr. Ruhrah, the quarantine physician of Baltimore, has appointed as his assistant Dr. Melvin Rosenthal.

Surgeon in Maryland National Guard.—Dr. J. T. M. Finney, associate professor of surgery in the Johns Hopkins Hospital, has been commissioned chief surgeon of the first brigade, Maryland national guard, with the rank of colonel. He succeeds Dr. Robert W. Johnson.

The Maryland Ophthalmological and Otological Society was organized last week in Baltimore by the principal eye and ear surgeons of the State. Dr. Russell Murdoch was elected president, and Dr. H. O. Reik secretary. The society meets the second Thursday of each month.

Dr. Abel Huntington, medical director of the New York Life Insurance Company, has been made consulting medical director. Dr. S. O. Vanderpoel, heretofore assistant medical director, will succeed Dr. Huntington in the active duties of the office.

The Academy of Medicine of Syracuse and the Antivivisection Bill.—The Academy of Medicine of Syracuse, N. Y., has forwarded a letter, signed by the officers and fellows, to Senator Platt, protesting against the senate bill purporting to prevent further cruelty to animals in the District of Columbia. The letter reads: "The bill is delusive. It is but an entering wedge, having as an ulterior object the prohibition, practically, of vivisection in the District of Columbia, and as an ultimate object the prohibition of vivisection throughout the United States. The passage of the bill is favored by many well-meaning but misled people, who have been influenced by persistent misrepresentation and exaggeration on the part of certain persons whose fanaticism is aimed at the foundation of scientific progress in medicine. Only too few investigators are engaged in that practical study of physiology and pathology which demands for its profitable pursuit, in interests of suffering humanity, perfect freedom in the matter of vivisection. We protest against the passage of a bill which is a part of a cunning scheme intended first to hamper and then to stop the most important investigations scientific medicine has ever attempted. We hold, rather, that the government should liberally encourage in every proper way the continuation of the work, impossible without vivisection, begun by such men as Pasteur in France, Lister in England, Koch in Germany, and Sternberg in the United States."

The English Hospital at Nice.—The English in Nice commemorated the Queen's diamond jubilee by adding a wing to the Protestant hospital in that city. The hospital is for the use of Protestants and members of the Greek Church. It is managed by a committee of French, Swiss, English, and German Protestants, with a representative of the Greek Church. The new wing contains a special ward, called the Victoria Ward, for English patients, and two or three other rooms for the general purposes of the hospital. The fund raised has been sufficient, after defraying the cost of the building, to endow one bed. One of the members of the royal family who accompanied the Queen to Cimiez will probably open the new wing. The new ward has been furnished by an anonymous lady.

Medical Museums in St. Petersburg.—In commemoration of the thirtieth anniversary of the establishment of the clinic of psychiatry in St. Petersburg, it is proposed to establish a psychiatric museum, in which will be collected plans, photographs, models, etc., of asylums for the insane; models of dress of the insane; work done by the insane; photographs of the insane at different periods of their disease; the apparatus used in examining the insane; skulls and brains of the insane and microscopical preparations; documents relating to the care of the insane. At the same time there will be established a neurological museum to contain normal brains of men and the lower animals, and microscopical preparations of the nerve tissues; preparations of pathological brains; instruments for weighing and methods of preserving the brain; photographs and representations of pathological processes; the different forms of apparatus employed in treatment; plans and photographs of neurological institutions. These museums will be open to students of any nationality, and an appeal is made to those interested in these subjects in all countries to contribute plans of buildings, samples of the work of patients, statistics relating to institutions, signed photographs of physicians connected with institutions, anatomical and pathological preparations, and anything, indeed, of interest to neurologists or psychologists. All contributions should be addressed to the Clinique des Maladies Mentales et Nerveuses, No. 9 Samarskaïa Ulitsa, St. Petersburg, Russia.

Reviews and Notices.

LESSONS IN HYPNOTISM AND THE USE OF SUGGESTION. Based upon the Neuron-Motility Hypothesis. By LESLIE J. MEACHAM. Cincinnati: The Bishop Publishing Company. 1898.

WHEN Wiedersheim made his studies on the large ganglion cells of Copepods he little thought of the wild fancies that his observations would bring forth. From them has sprouted the so-called "movability of the neuron" theory to account for many of the phenomena of hysteria, shock, aphasia, and many functional neuroses. The idea was elaborated by many European physicians and made popular in this country by Dercum. The present small volume assumes the correctness of the "movability" theory, and in an ingenious manner discusses many of the problems of hypnotism and its congeners. Like many of its kind, the work is more anecdotal than philosophical. It is illustrated with a number of photographs showing the author's methods, and, on the whole, adds but little to the meagre amount of actual knowledge on the subject of hypnotism. Nevertheless, the book is interesting and entertaining.

THE ESSENTIALS OF EXPERIMENTAL PHYSIOLOGY. For the Use of Students. By T. G. BRODIE, M.D., Lecturer on Physiology, St. Thomas' Hospital Medical School. London, New York, and Bombay: Longmans, Green & Co. 1898.

THE present volume aims to give a short account of those experiments which can be carried out by students during class time, together with a selection of experiments suitable for class demonstrations. The work is a very excellent one, in that it does not attempt to make a physiologist, a physiological chemist, a pharmacologist, etc., of a student in one course of lectures, but confines itself to the more important physiological facts that are essential for the medical man to know.

A HANDBOOK OF DISEASES OF THE NOSE AND PHARYNX. By JAMES B. BALL, M.D., Physician to and in charge of the Department for Diseases of the Throat and Nose, West London Hospital. Third Edition. New York: William Wood and Company. 1898.

THIS work presents in small compass and compact form the essential features in the diagnosis and treatment of diseases of the nose and pharynx. A very desirable feature of the work is the large amount of space devoted to the treatment of the diseases considered. The therapeutic directions are made simple and comprehensive by a large number of illustrations. All in all, the treatise is an excellent addition to the series of manuals for students, and will be of use to them and to the general practitioner.

THE ROENTGEN RAYS IN MEDICAL WORK. By DAVID WALSH, M.D. Ed. With an Introductory Section upon Electrical Apparatus and Methods, by J. E. GREENHILL. New York: William Wood and Company. 1898.

THE subject of the *x*-rays can be presented in at least two different ways. The one considers them from the electrical point of view, and treatises of such a character are appreciated by the physicist rather than by the medical man. The other class considers what can be done with the rays in the way of diagnosis and in the treatment of the ills of human kind. It is to the latter class that the present work belongs. The introductory chapter is clear and sufficient to give all the essentials of the physical phenomena, the major portion of the book being devoted to the use of the rays in diagnostic work. Little is left unsaid in the practical applications of these rays. The book is well illustrated, the frontispiece being very fine.

THE X-RAYS: THEIR PRODUCTION AND APPLICATION. By FREDERICK STRANG KOLLE, M.D. New York: J. S. Ogilvie Publishing Company. 1898.

THIS small and practical manual treats of the subject of the *x*-rays in two parts. Part I. deals with the elements of electricity, whereas Part II. deals with the practical and theoretical advances made in radiography. There is little in the first part of the book that is not to be found in any elementary text-book of physics, and the *raison d'être* of so many pages being thus used is not evident, inasmuch as their contents have very little to do with the production of the *x*-rays. The discussion, both historical and explanatory, of the nature of the rays and the methods of skiagraphy, found in the second part of the work, is more to the point and, though somewhat disfigured with a little too much of the ego, it gives an excellent account of the subject. The work is fairly well illustrated, although the illustrations are by no means so fine as those given by Williams or Walsh. The application of the methods of skiagraphy in practical medicine is hardly more than touched upon, thus making the volume one that would be of more value to the electrician and photographer than to the medical man.

A LABORATORY GUIDE IN PHYSIOLOGY. By WINFIELD S. HALL, Ph.D., M.D., Professor of Physiology, Northwestern University Medical School, Chicago. Chicago: Chicago Medical Book Company. 1898.

THE field of didactic lectures in medicine is daily becoming more restricted, and, as an evidence of the large amount of time that is being devoted to the, more strictly speaking, observation methods of teaching, the number of laboratory manuals that have recently appeared is manifest. The use of such guides is necessarily limited. They appeal to but two classes of workers, the teachers and the students. The above manual in a way misses, we believe, each function; it is not extensive enough or thorough enough for the teacher, although it would prove of great service in the hands of the laboratory assistant, and it is too extensive for the student who is to take a prescribed course in experimental physiology —at least, too extensive for the usual student of the American colleges. That it would serve very excellent purposes in the particular institution in which the prescribed course herein laid down is taught we very readily grant, but for another type of practical course given by another teacher, who of a necessity would have different ideas, we think it would give less satisfaction. Our criticism in this respect serves more to indicate the lack of "excuse for being" of such manuals, as a class, rather than of the particular one, which of its kind is rather above than below the average. Detailed instructions as to how to do this and that, as for instance in the adjustment of the sphygmograph, partake of the nature of kindergarten instruction, rather than information for a student of mature years. It is with the general rule-of-thumb methods adopted in works of this kind that we are not in sympathy.

A MANUAL OF PRACTICAL MEDICAL ELECTRICITY. By DAWSON TURNER, B.A., M.D., Lecturer on Medical Physics and Electro-Therapeutics, Surgeons' Hall, Edinburgh. New York: William Wood and Company. 1898.

WHAT to do in certain diseases of the nervous system and how to do it, and with what electrical necessaries, are well told in this small elementary treatise on medical electricity. In six parts the book treats of electro-physics, electro-physiology, electro-diagnosis, electro-surgery, electro-therapeutics, and the Roentgen rays, indicating in short and succinct chapters the main facts with reference to these several general subjects. The work will prove a handy and convenient elementary text-book to the practitioner who employs electricity as a remedial agent.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, and Text-Books, of the Leading American and Foreign Authors and Investigators. Collected and Arranged, with Critical Editorial Comments, under the General Editorial Charge of GEORGE M. GOULD, M.D. Philadelphia: W. B. Saunders.

DESPITE the size and weight of this year's issue (1,077 pages) some of the collaborators intimate that lack of space has prevented their dealing with particular subjects in full. For comfort in reading such a book should be published in a number of volumes or divided as is Braithwaite's "Retrospect." Retrospects should come under the general heading of light literature, and should not necessitate a poring-pose. When the day's work is done the doctor should be supplied with reading-matter which will enable him to lean back and rest his shoulders, and publishers should aid in preventing him "painfully to pore upon a book," as Shakspeare puts it. The first chapter, on "General Medicine," by William

Pepper and Alfred Stengel, gives a summary of the year's work and is followed by a lengthy *résumé* of what has been written about typhoid. After this come the other infectious and general diseases, over to page 225, where "General Surgery" begins, under the charge of W. W. Keen and J. C. Da Costa. Duhring has the skin department; Gibney the orthopædic; Abel, of the Johns Hopkins, physiologic chemistry; Samuel Abbott, public hygiene and preventive medicine; and Wyatt Johnston, legal medicine.

A System of Practical Medicine, by American Authors. Edited by Alfred Lee Loomis, M.D., LL.D., and William Gilman Thompson, M.D. Vol. III. New York and Philadelphia: Lea Brothers & Co. 1898.

This third volume of the series contains chapters upon diseases of the alimentary canal, peritoneum, liver, gall bladder, spleen, pancreas, and thyroid gland, and upon chronic metal poisoning, alcoholism, morphinism, etc. The list of contributors contains nineteen well-known names. There are a few illustrations, those in M. Allen Starr's article on cretinism and myxœdema deserving special mention. Some chapters are exhaustive or almost so, while others are scarcely full enough. That upon the tongue, for example, is quite brief. The articles are for the most part prepared with great care and accuracy, and reflect the newest views. This volume compares favorably with those already out, keeping up the high standard set.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 21, 1898.

Edward G. Janeway, M.D., President.

The meeting was in charge of the section on medicine.

The State of the Vasomotor System in Acute Lobar Pneumonia.—Dr. Richard Van Santvoord read a paper with this title. After referring to certain experiments made in Germany, which seemed to show that in certain infectious diseases, notably pneumonia, cardiac failure was mainly the result of vasomotor paralysis, he described some of his own recent observations at the Harlem Hospital. His sphygmographic tracings showed that in pneumonia the primary wave was generally sharply pointed, with but a faint indication of the tidal wave. This form of pulse curve was strongly pronounced in all cases in which the constitutional symptoms were very marked. His observations also showed that the mean arterial pressure was often low. When the general arterial tension was weakened, as a result of feebleness of the heart or of vasomotor paralysis, the blood tended to gravitate to the more dependent parts. The peculiar position assumed by those suffering much from dyspnœa was favorable to the development of cerebral anæmia, and this, in turn, probably explained certain nervous phenomena observed in pneumonia. It was stated in many books that the pulse of pneumonia was one of high tension, but this did not accord with his experience, although there was a bounding character to the pulse that might easily cause it to be mistaken for a high-tension pulse. If the tension approached or exceeded the normal, in pneumonia, it could be only by increased exertion on the part of the heart. The ability of the heart to respond to this demand might determine the outcome in a given case. The weak point in adapting the results of experiments on rabbits with the pneumococcus to the human subject suffering from pneumonia was that in rabbits the infection produced only a septicæmia, without pulmonary lesions; nevertheless he thought the animal experiments shed light not only on the cases in which toxæmia was prominent, but on those in which the pulmonary element was an important factor. Post-mortem examinations sometimes showed œdema of the non-hepatized lung. In this connection it was instructive to recall the experiments made years ago by Welch on the artificial production of pulmonary œdema. He demonstrated that pulmonary œdema was the result of relative insufficiency of the left heart, the right heart continuing to pump the blood into this organ. In pneumonia, owing to the increased strain thrown on the right heart, the conditions were reversed, and the result was congestion of the abdominal organs, especially of the liver. Dr. Van Santvoord said that in a few cases he had endeavored to secure contraction of the vessels by the administration of barium chloride, in doses of four grains, every four hours, but the result had been practically negative. Some good effects were observed in the few cases in which ergot had been given in half-drachm doses, every three hours. There would seem to be an indication for the use of digitalis in these cases of vasomotor paralysis, as this remedy slowed the heart and contracted the peripheral vessels, but opinion had long been divided on this point. In cases exhibiting embarrassment of the right heart, Dr. A. H. Smith had earnestly advocated the administration of nitroglycerin. It seemed to him very much like "carrying coals to Newcastle" to administer nitroglycerin in many of these cases, although it was possible that a still further dilatation of the vessels might sometimes give relief.

Different Types of Pneumonia.—Dr. Andrew H. Smith said that at the outset in such a discussion as this it was well to remember that there were great differences in different cases of pneumonia, and that reasoning which would apply to one case would not apply to another. We used to hear much of the distinction between sthenic and asthenic pneumonia, and he thought this distinction was well taken. For example, in a given case, the pulse might be firm and strong—such a one as our forefathers thought demanded immediate venesection—and the nervous symptoms few. There might be quite a high temperature, and also a marked increase in the leucocytosis. In another case—one of the asthenic type—delirium occurred early; there might be a prolonged and severe initial chill; the pulse was small, quick, and feeble; everything indicated a profound intoxication of the nervous system. The leucocytosis might not be greater than in health. In the first case the high leucocytosis seemed to indicate a vigorous struggle on the part of the system against the inroads of the disease, and in the latter the system seemed to surrender almost at discretion. These asthenic patients were really suffering from septicæmia, and when death occurred it was associated with symptoms of septicæmia. It was evident that reasoning which would apply to the first class would hardly be applicable to the second. This same difference between sthenic and asthenic cases was observed very frequently in the experimental pathology of pneumonia. Welch, for example, had shown that a given specimen of the diplococcus would produce a toxin which would very slightly affect the nervous system, while another specimen would produce a toxin which would immediately overwhelm the nervous system. It was for this reason that the theory had been advanced that there were two different toxins in pneumonia, varying greatly in their power to affect the nervous system. But there was still another condition, dependent, as a rule, upon some previous fault of the circulatory apparatus—either age, alcoholism, or something of that kind. In this type there was great respiratory distress as a result of the mechanical condition.

When Nitroglycerin is Indicated.—In some cases the outcome seemed to depend entirely upon the abil-

ity of the right heart to move the mass of blood through the lung. These cases were marked by dyspnœa, cyanosis, and a generally congested condition of the vascular system. The right side of the heart would be found, on percussion, to be enlarged, and there would be decided accentuation of the pulmonary second sound. In this class of cases he thought nitroglycerin was of value. Whatever the theoretical views on the subject, he felt satisfied that any one who would give a fair trial to nitroglycerin or to nitrite of sodium in these cases in which there were cyanosis and other indications of overfilling of the venous system would confirm what he had said about the value of these remedies. It would not do, however, to label a case "pneumonia," and then give certain remedies which have been recommended in a general way for that disease.

The Use of Digitalis.—He would hesitate a great deal about giving digitalis. Medical practitioners, the world over, did not freely use this remedy in pneumonia, and this too notwithstanding the fact that many years had elapsed since Petresco first published his wonderful statistics. It should be remembered also that his observations were made upon exceptionally healthy soldiers seen in a military hospital, and at an exceptionally early stage of the disease. These men were all young and were in excellent physical condition. In times of peace it would be found that everywhere the mortality from pneumonia in military practice was far below that in civil practice.

The Mode of Preparing the Digitalis Important.—Again, the infusion of digitalis employed by Petresco contained digitanin and digitalinin, but no digitalin or digitoxin. The digitoxin was the chief poisonous principle of the digitalis; the digitalin, on the other hand, was what was commonly used subcutaneously. Dr. Smith said he had found that by ordering the U. S. P. preparation without the alcohol one could obtain effects which were quite different from those observed when the usual formula was followed, because the alcohol in the latter acted as a solvent for the objectionable principles. With increasing experience he felt more and more confidence in strychnine as a cardiac stimulant.

Our Forefathers had Stronger Hearts.—Dr. Leonard Weber said that he had often observed in recent years that his results had been worse in the treatment of pneumonia than in former times, and this had led him to ask himself if the individual or the type of the disease had changed. There was nothing to lead us to infer that the pathology of the disease had changed, and hence he was disposed to believe that the individual had changed more or less. This change in the individual, in his opinion, consisted in a greater weakness of the heart in the average person.

The Symptomatic Treatment.—As regarded the treatment, he must say that there was no real treatment for pneumonia, except a symptomatic one. From 1858 to 1862 it had been the fashion to give digitalis as a routine measure in pneumonia. He would not like even now to treat many cases of acute lobar pneumonia without digitalis, although he did not use it in all. He used an infusion of half a drachm of the leaves to seven ounces of water, and gave of this one tablespoonful every two hours. This he did at the beginning of the disease, when the pulse indicated that the heart would soon show signs of weakness. He also relied upon the wet pack to the chest. This accomplished two things, *i.e.*, (1) stimulation of the pneumogastric centre and improvement of the action of the heart, and (2) a tonic effect on the nervous system. Sometimes it was necessary to give this quantity of digitalis—seven ounces—two or three times. As supporting measures in pneumonia he favored the free hypodermic use of strychnine and camphorated oil. So far as this city was concerned, he felt positive that the mortality from pneumonia in people from forty to sixty years of age was now greater than it was many years ago.

Dr. Van Santvoord said that he wished to emphasize the fact that while nitroglycerin was of service in just the class of cases described by Dr. Smith, it was useless, and indeed decidedly harmful in other cases. The object of his paper had been to direct attention to an additional factor of the disease, which had not received its share of attention. Camphor and strychnine had been recommended by one of the speakers. The former was a pure cardiac stimulant; the latter not only exerted a strengthening action on the heart, but acted powerfully on the vasomotor system.

Injuries after Exposure to the X-Ray.—Dr. William Vissman read a paper on this subject, describing at length a case which had been under the care of Dr. James P. Tuttle. The patient, who had been injured in the civil war, had been subjected to a prolonged examination by the *x*-rays on September 14th, the vacuum tube being placed, it was said, about four inches from the surface of the limb. Nothing unusual was observed until October 14th, when the skin became reddened. In a few days the skin broke down, and there was severe burning over the affected area. The lesion, it should be noted, appeared on the side of the knee-joint opposite to that which had been exposed to the Crookes tube.

Results of Microscopical Examinations.—Sections of tissue from the edges of the ulcer and from the adjacent tissues, as well as from the centre of the defect, were examined. It was found that the epithelium and the papillæ had disappeared, and that there was a marked infiltration of round cells extending down even to the muscle. All the coats of the walls of the blood-vessels had taken on this process of connective-tissue growth, so that in many places the lumen of the vessels was contracted or nearly obliterated. The round-cell infiltration was marked around the outside of the fat tissue, but completely disappeared in the centre of this tissue, thus constituting a marked exception to what was found in the other tissues. The round-cell infiltration was most marked around the blood-vessels and lymph spaces. There was a line of demarcation such as would be expected in ordinary gangrene. The microscope showed no foreign particles, either in the fresh or in the hardened tissue. Dr. Vissman said that he had been able to find reports of only two other microscopical examinations in cases of this kind. Several French observers had endeavored experimentally to produce *x*-ray injuries in rabbits, but the most that they could accomplish was the production of alopecia.

Various Theories.—Dr. Vissman said that various theories had been advanced to explain the lesion. One theory was that it was the result of malnutrition of the cells, caused by the absorption of the *x*-rays, which disintegrated the organic fluids, and the acids or alkalies thus produced disorganized the tissues. Others believed that the changes produced in the skin and subcutaneous tissue were of tropho-neurotic origin. Tesla claimed that a certain irritation of the skin was produced through the electro-static influence. He had found that this influence could be entirely avoided by using a screen of aluminium or aluminium-wire gauze, but only when this screen was connected with the ground. The irritation of the skin, he thought, was the result of the abundant production of ozone. This generation of ozone ceased abruptly at a definite distance from the electric terminal, and the same was true regarding the production of this irritation. Dr. Vissman said that in a recent interview he had understood Mr. Tesla to express the view that particles torn from the electrodes played a not unimportant part in the

production of *x*-ray injuries. It should be recalled here that the fat tissue escaped injury. This was apparently due to the fat being a non-conductor of electricity. The direct effect of the electricity on the blood-vessels might be responsible for some of the earlier phenomena observed, such as erythema.

X-Ray Injuries very Different from Burns.—Dr. E. B. Bronson said that the paper just presented was an interesting contribution to this very obscure subject, yet he thought the mystery was still far from being solved. The term "burn" was a misnomer as applied to the injuries produced by the *x*-rays. There was no immediate injury apparent on the surface; it was usually after an interval of a week that the first manifestation was noted. This was ordinarily an erythema, although in certain cases, possibly dependent upon idiosyncrasy, the inflammation was deeper and might even be gangrenous. In the case reported by Gilchrist, that of one of Edison's employees, the nerves and even the bones had been affected. He had seen this patient himself, and had observed a very distinct enlargement and induration of the nerves. It was evident that the active agency in producing these injuries exerted more than a superficial influence; it probably affected the deeper parts first. He was inclined to think that the active agent was not the ozone, or the electrical current, or the bombardment of the tissues by particles of platinum, as suggested by Tesla and others. All these theories had been tested, and with negative results. If the injury was due to bombardment with particles of platinum, why should not similar results be observed in metallic cataphoresis?

Evidence that the Nerves are Primarily Involved.—He believed that the first injury took place in the deeper tissues, and probably as a result of the action of the Roentgen rays themselves. It seemed to him not unlikely that the nerves were first involved. This view found some support in the fact that the pain was usually excruciating. He had had under observation for a number of months a young woman who had been skiagraphed because of disease of the hip-joint. This had been followed by an ulceration which had lasted for about three months. It then appeared to be healing, but the pain became doubly severe and none of the applications ordinarily suitable for burns gave any relief—indeed, they aggravated her suffering. It was a full year before the part cicatrized. The appearance of the part before healing had been that of a moist ulcer coated with a soft yellowish covering, resembling wet pasteboard. Scattered over the centre of this area were a number of red and exceedingly sensitive papillæ. In this case the entire abdomen now showed numerous dilated blood-vessels, apparently indicating a grave involvement of the vascular system.

The Alopecia is Temporary.—In the effect produced on the hair we probably had another example of the involvement of the blood-vessels. It was a curious fact that the alopecia did not seem to be associated with any distinct hyperæmia. In most of the reported cases the growth of hair had returned.

Lupus Treated by the X-Rays.—A German investigator had tried the effect of prolonged exposure of lupus to the Roentgen rays. The patient was kept under the rays for two hours at a time, for eighteen consecutive days. It caused the lupus tubercles that had been before imperceptible to become visible, and produced an effect similar to cauterization. After five months cicatrization occurred, and the skin no longer presented any evidence of lupus.

Evidence of Primary Involvement of the Blood Vessels.—Dr. James P. Tuttle said that he was disposed to believe that the affection was one primarily of the blood-vessels and not of the nerves. The pain was due to the involvement of the nerve-endings in the growth of dense connective tissue. When excision was made wide of the affected area and the part was removed, the pain ceased, apparently showing that it was the result of the inclusion of the terminal filaments of the nerves in the connective tissue. Although ichthyol usually gave relief in common burns, he had found that it aggravated the pain of an *x*-ray injury. Cold water ordinarily proved soothing to burns, but in the case reported by Dr. Vissman this evening, as soon as the temperature of the carbolic-acid solution fell below 85 F. the pain increased. He had known this patient for ten years, and could positively state that, although there was disease of the knee-joint, there had been no tendency to inflammation of the skin over the joint. Even the scar tissue left after a former operation, although close to the affected area, remained unchanged. The injury in this case certainly extended into the capsule of the knee-joint, and possibly even into the bone.

Treatment.—One surgeon in this city claimed to have cured twenty-five or thirty cases of *x*-ray injury by cutting down clear through the affected part, and then dressing with carbolic acid until granulation set in. After this balsam of Peru was applied, and healing took place by granulation. It seemed reasonable to believe that one could, in certain situations, cut down below the region in which were the affected blood-vessels, and so secure comparatively rapid healing. He knew personally of four cases in which skin grafting had been used, but with only temporary benefit. He had ascertained in a number of cases that even after healing had occurred the severe neuralgic pain had persisted.

Need for Greater Caution in Using these Rays.—Dr. Tuttle said that, while in his reported case it had been deemed justifiable to amputate the limb, this would never have been necessary had the Roentgen rays not been used. This showed the need for the exercise of greater caution in the use of this valuable but powerful adjunct, and the necessity for having these examinations conducted only by thoroughly competent persons.

Dr. Vissman closed the discussion. He said that Mr. Tesla had found that these *x*-ray injuries could be avoided if an aluminium screen was used, provided it was "grounded," but that if it was not grounded the screen did not seem to be effective. Again, Mr. Tesla asserted that if the limb was placed between the metal plate and the Crookes tube the injury on the limb would be on the side on which was the metal plate. The distribution of metal by an electric current through tissue could be followed under the microscope by a suitable arrangement of apparatus, and in this way it had been found that the metal was not forced into the cells. It was possible, however, to decompose the sodium chloride in the tissues, thus giving rise to the formation of irritants. The speaker expressed the belief that the pain experienced in these cases could be explained by the same theory as had been advanced to account for the severe colicky pain felt when there was spasm of the muscular coat of the intestine.

The Treatment of the Hypertrophied Prostate by the Galvano-Cautery.—Bottini (*Archiv für klinische Chirurgie*, 1897, Band liv., Heft 1) claims for the operation the following points: 1. The unmistakable efficiency of the operation—a patient who has not urinated for years passing his urine voluntarily a few hours after the operation. 2. The harmlessness of the operation, even in patients over eighty years of age with foul urine. 3. The permanency of the cure, no case as yet having been known to recur. 4. No post-operative bad effect or effect upon the *morale* of the patient. 5. The operation is painless, and can be done without anæsthesia.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 18, 1898.

GEORGE TUCKER HARRISON, M.D., PRESIDENT.

Abdominal Gestation.—DR. E. H. QUINN presented a specimen from a case of abdominal gestation. The patient, thirty-seven years of age, had had her last child nine years ago, and had enjoyed good health up to September 23, 1897. At that time she began to complain of pain in the lower part of the abdomen. On November 12th the pain became more acute, and she was attended by a French physician. When the patient came under the speaker's observation, he learned that the illness had begun with rapid and marked emaciation and abdominal pains. He found her with a temperature of 103° F. and a pulse of 140. She apparently had had a decided fever for some time previously. There was considerable abdominal tumefaction. Under chloroform an examination was made per vaginam. There was no special bluish tinge of the vagina; the os was very slightly softened; a mass could be detected a little to the right of the median line. On the following morning he had performed laparotomy. The anterior abdominal wall was found adherent to the mass referred to, and when the adhesions were separated a considerable quantity of blood and clots escaped. Owing to the profuse hemorrhage it became necessary quickly to clamp the broad ligament. During the manipulations the mass ruptured and discharged a fœtus. The sac was enucleated and the ovarian arteries were ligated. A saline infusion was at once given, and she rallied temporarily, but succumbed later, owing to the extreme anæmia and exhaustion. Dr. Quinn said that in another case of this kind he would prefer to open the anterior and posterior vaginal cul-de-sacs at the outset, and secure the uterine aretries in order to avoid such profuse loss of blood.

DR. HENRY J. BOLDT asked what were the grounds for considering this an abdominal pregnancy. Such a condition was extremely rare—indeed, its very existence was absolutely denied by many.

DR. QUINN replied that the uterus could be seized close up to the broad ligament without any separation whatever, and the tube could be felt distinctly coiled around the uterus, and it could be traced into the gestation mass.

DR. J. BLAKE WHITE remarked that the history emphasized the difficulties experienced in making the diagnosis sufficiently early. He recalled having seen some years ago a case of abdominal pregnancy with Dr. A. F. Currier. During life the case had not been looked upon as one of abdominal pregnancy, but the post-mortem revealed the true condition. There was also found at the autopsy not only an acute peritonitis but a chronic peritonitis, with extensive adhesions. When he had seen the patient, about twenty-four hours before death, there had been no evidence of collapse and she had had no fever. The absence of the rational symptoms of peritonitis in this case was, in itself, a matter of considerable interest.

DR. A. E. GALLANT asked what was the cause of the rapid and extreme emaciation in the case reported by Dr. Quinn. He thought the ectopic gestation alone would hardly account for the emaciation.

DR. QUINN replied that the only explanation for the emaciation was the frequently repeated small hemorrhages, extending over a considerable period of time.

The Treatment of the Paroxysm in Dysmenorrhœa.—DR. W. R. DALTON presented a brief communication on this subject. He said that the first duty of the physician when called to a case of dysmenorrhœa was to relieve the pain, and then to study out the cause at his leisure. He had found that some of coal-tar products were very efficient remedies in relieving the distress in a number of these cases.

A Belief that So-Called Displacements of the Uterus are Not Pathological.—DR. FREDERICK P. HAMMOND presented a paper with this title. He believed that any position of the uterus in the pelvic cavity was correct in which the organ was maintained at the proper level. Cases were not infrequently seen in which the uterus normally lay more or less posteriorly. Mackenrodt, after very careful anatomical studies, had stated that the pelvic fascia kept *in situ* the pelvic viscera, and, while he laid perhaps too much stress upon the pelvic fascia in this connection, it was a factor which was not usually given sufficient attention. The speaker said that, according to his own observation, he could not believe there was such a thing as uncomplicated displacement of the uterus—except prolapse—which deserved any attention. Skene said that flexions were not displacements but pathological conditions of the organ, and many writers claimed that flexions were the result of an unequal growth or an arrested development in the uterine wall. Personally he could not accept this view, for it was almost the rule for the contour of the uterus in multiparæ to exhibit wide variations. Dysmenorrhœa and sterility were attributed to obstruction or stenosis at the point of flexion, *i.e.*, at the internal os. If internal flexion was the cause of the stenosis, no relief would come except by straightening out the flexion, yet it was well known that relief often followed divulsion of the os without other measures. According to some statistics quoted by Hart and Barbour, about half the cases of dysmenorrhœa were associated with anteflexion, yet, in another series referred to by the same authors, forty-six out of one hundred and thirty-eight cases of dysmenorrhœa did not exhibit any well-marked anteflexion. Again, J. Reeves Jackson had stated that he had known of cases in which the obstruction was so acute as to prevent the introduction of the uterine sound; yet in these cases conception occurred shortly after marriage. It was not claimed that the dysmenorrhœa and sterility were so frequent in retroflexion as in anteflexion—indeed, those having retroversion were more than usually prolific, even when there was a profuse cervical catarrh. The most probable cause of retroversion was a short posterior vaginal wall, acting in conjunction with the utero-sacral and vesical ligaments. The retroflexion pessary had been supposed to act by leverage, but, as a matter of fact, this instrument raised the organ into such a position that gravity caused it to fall forward. While admitting that many factors were at work to throw the uterus backward, Dr. Hammond maintained that these conditions were all physiological. Of four hundred and twelve patients examined by him, full notes having been kept, four only were recorded as having displacement; in all these there was a varying degree of prolapse. In ten cases only was the angle of flexion or version very marked, and in one the organ was situated decidedly posteriorly. The writer laid much stress on the erroneous deductions resulting from the unskilled use of the sound, a criticism which he asserted applied even to many otherwise experienced and skilful practitioners. Another source of error was the use of too large an instrument at first. Regarding stenosis and dysmenorrhœa, it should be noted that fluid blood passed readily through the capillaries; hence it must be able to pass readily through the os, no matter how great the stenosis. No matter what the position of the uterus, if there was parametritis or perimetritis, there would be symptoms. In his opinion, the use of strong antiseptics post partum was a very prolific cause of parametritis.

DR. BOLDT said that the belief advanced in the paper that there were no malpositions of the uterus was

an old subject of contention. Years ago the normal position of the uterus was looked upon as one of anterior version. We can now speak only of the physiological position of the uterus—not of the normal position. Schultze claimed that there must be a rigidity of the angle of flexion to make a flexion pathological. Such cases were occasionally met with by all. The fixation of the cervix was produced by plastic inflammation surrounding the cervix, and hence the condition was pathological. Retroversions and anteversions were only the beginnings of flexions. Still later the flexion would be found to be associated with more or less descent. For these reasons it seemed to him that the condition was undoubtedly a pathological one. It was claimed by some that if these secondary inflammatory manifestations were relieved the patients recovered. It was true that they would be well symptomatically, but for a time only. If these displacements were not pathological, he could not understand how the restoration of the position of the uterus could bring about relief of tachycardia or of melancholia, yet such relief was matter of record. These clinical reasons convinced him that other displacements of the uterus than prolapse must be looked upon as pathological.

Dr. J. J. E. Maher cited a number of familiar examples in gynæcological practice as instances of the difficulties that must be encountered by those who took the position that most displacements of the uterus were physiological.

Dr. George Tucker Harrison said that he was in accord with many of the views expressed in the paper, but not with all. The medical profession owed a debt of gratitude to Schultze of Jena for having demonstrated that the physiological position of the uterus was that of anteversio-flexion, and that it had a range of variation dependent upon the degree of distention of the bladder and rectum. But he would insist that retroversion and retroflexion were always abnormal, and always led to some complications, and hence needed treatment. When the uterus was displaced posteriorly the vessels were compressed, and, as a result of the stasis, there were catarrhal inflammation and frequently more or less ovaritis. Again, with the uterus in the backward position, the two folds of the peritoneum came in contact, and adhesive inflammation (perimetritis) was liable to result. Dr. Harrison said that he was astonished to find that the reader of the paper was opposed to the mechanical theory of the causation of dysmenorrhœa. In what other way could one account for the terrible pain associated with the expulsion of clots from the uterus?

Dr. David P. Austin said that there were certain cases met with in which it was difficult to determine what was cause and what effect. In many cases of constipation, associated with retroversion, for example, it was difficult to say whether the retroversion caused the constipation, or the loaded rectum had by pressure resulted in the backward displacement of the uterus. He had at present under his care a case in which an extreme posterior displacement of the uterus had been rectified by unloading the lower bowel.

Dr. Hammond closed the discussion. He said it should be borne in mind that in many cases, in which marked benefit had apparently followed the use of a pessary, the haphazard insertion of a tampon or almost any local treatment, through its mental impression, exerted a beneficial influence on the patient. Regarding dysmenorrhœa, he said that it was often stated that the pain was due to the damming up of the fluid blood within the uterus. To this he had taken exception, because the fluid blood could easily pass through even a pin-hole os. Clotting did not normally occur inside of the uterus, and hence he had omitted this from present consideration. He did not believe that symptoms arose from displacements until adhesions took place.

Tubal Gestation.—Dr. A. B. Tucker presented a specimen from a case of tubal gestation occurring in a woman, twenty-five years of age, who had been married seven years. She had skipped one menstrual period, and then had been attacked by severe abdominal cramps. Examination showed a freely movable uterus, which could not be retained in position. A mass was found behind it, and on abdominal section this was discovered to have been produced by the rupture of a tubal gestation.

Clinical Department.

THE SYNDROME OF KATATONIA OCCURRING IN A CASE OF TERMINAL DEMENTIA.

By M. L. PERRY, M.D.,

MORRIS PLAIN, N. J.,

ASSISTANT PHYSICIAN AT THE NEW JERSEY STATE HOSPITAL.

In view of the difference of opinion among alienists as to the classification of cases presenting the symptom complex known as katatonia, the following case seems of sufficient interest to justify its publication.

S. O——, female, aged thirty-four, was admitted to this institution, May 31, 1895, with a history of having been in poor physical condition for two years and insane for the past six months. This was the first attack of mental disease. The family history was good, with the exception that a maternal uncle had died insane. The history of mental symptoms previous to admission was that of a slowly developing state of mental depression, with various delusions of a depressive character. At the time of admission the patient was found to be in poor general health, quite anæmic, and with deranged secretions. She was about seven months pregnant. Her mental state was that of mild depression, with some dulness and confusion. She was not inclined to talk, but would answer questions readily. She took little interest in her surroundings and appeared entirely unable to comprehend her condition. Six hours after admission premature labor set in, and she was delivered of a child weighing only three pounds. The labor was uncomplicated, as was also the puerperal period.

After confinement her general health improved very much, but no marked change could be noted in her mental state. Her perceptive powers became somewhat more acute and she would enter into conversation more readily, but was incapable of exercising any but the most superficial mental action. Her emotional state gradually changed from depression to one of marked indifference. In the course of a few months all the mental processes appeared to be dulled and enfeebled. Even the maternal instinct, one of the most acute and deeply rooted of the mental faculties, was so obtunded that she took little or no care of or interest in her child, although she recognized fully that it was her own. As dementia advanced, with its consequent relief from the worry and mental strain incident to states of depression, there was constant improvement physically until her general health was quite good.

This condition continued for almost two years, or until October, 1897. About the first of this month it was noticed that she was more depressed than usual and indulged in frequent fits of crying. She occasionally became excited for a few hours, but was easily controlled. There was no mental exaltation at any time.

On the 17th of October she went to bed complaining of nausea, with severe headache, and vomited

some during the day. There was complete anorexia. The temperature was normal, pulse slightly accelerated, and heart action irritable. One of the coal-tar preparations was given, which relieved the headache. She felt somewhat better next day, but still depressed and stupid. She complained in the afternoon of severe headache again, but could not give a clear account of her symptoms. There was no rise of temperature, but the pulse became quite rapid—120 a minute and irregular. The bowels, which had been fairly regular, were moved by means of small doses of calomel.

On the 19th she was dull and stupid, still complaining of headache, but was unable to locate the exact seat of the pain. She complained of her eyes hurting. The conjunctivæ were congested and there was some photophobia. The pupils were normal. The symptoms were of such an obscure nature that for the next few days an expectant and tentative line of treatment was pursued. In the mean time she became more and more stupid, but this symptom did not progress regularly. At times she would brighten up and talk as well as usual.

On the 22d, about a week after she had begun to complain, the mental hebetude was very pronounced. She seemed entirely indifferent to everything and would not take food unless fed with a spoon. In the afternoon she commenced to talk to herself and soon began to verbigerate. At first she would repeat the entire alphabet and count until several hundred were reached, when she would begin anew. After a time she would repeat combinations of letters and numbers—as 1, 2, 3, 4, s, o, p, q—for hours. Her temperature at this time was 99° F.; pulse, 100, regular, with tension increased. The urine was about normal in amount and acid in reaction: specific gravity, 1.016; it contained no albumin. The bowels were somewhat constipated, but were moved freely by a cathartic.

October 23d, she was quite stupid and would not talk; she had to be fed with a spoon. She was decidedly cataleptic, and would remain perfectly still, with eyes tightly closed, the head flexed upon the breast, and the hands clenched, until disturbed, when she would remain in any position in which she was placed. Resistance to movements was marked. The tendon reflexes were exaggerated. Sensation was almost abolished. Temperature, 99.6° F.; pulse, of high tension and accelerated, with the rhythm disturbed. After a time she began to verbigerate again, repeating the same combination—1, 2, 3, 4, s, o, p, q. This condition continued to be more or less pronounced for the next ten days. The degree to which the symptoms were present varied very much from day to day. Sometimes the patient would brighten up and talk fairly well, and again would lapse into a state of stupor with marked verbigeration and catalepsy, from which she could not be aroused. At these times she would pay no attention to anything that was said to her and appeared to take no notice whatever of anything that was done in her presence. The temperature at no time was above 99.6° F., and more often was between 98.5° and 99° F. The pulse was of high tension and full throughout, and varied in rate from 90 to 115. The urine was examined at several times, with a result similar to that obtained in the first examination, except on one occasion, when a few hyaline casts were found.

The bowels were kept regular and free purgation was resorted to, but without apparent effect on the mental state. The tension of the pulse was reduced by nitroglycerin, one-fiftieth grain every two hours until four doses had been taken and a marked dicrotism produced, but with no effect whatever on the patient's general condition. Tincture of aconite in small doses frequently repeated seemed to have a better effect. At the end of about a month from the beginning of the attack the patient began to improve, and in the course of a few weeks more had entirely recovered from it and was in the same condition as she had been previous to its development.

The points of special interest in the case may be summed up as follows:

First, the sudden development of a pronounced symptom complex of katatonia in a patient who throughout the course of a mental disease of three years' duration had never shown a single symptom suggestive of such a condition prior to the attack under consideration.

Second, the development of a well-marked syndrome of katatonia in a patient who had passed through the active stages of insanity, and who for a period of two years had been a typical case of dementia following a state of mental depression.

Third, the short duration and rapid subsidence of the attack. From the time she began to complain until the re-establishment of her usual mental state was not more than six weeks.

Fourth, the fact that nitroglycerin, a drug recommended by some good authorities, was given until its full effect upon the circulation was obtained, without producing any change whatever in the patient's general condition.

Fifth, the bearing which the case has upon the proper classification of cases presenting the symptoms of katatonia. Since the time when Kahlbaum first described this group of symptoms and suggested to the profession that it be given a distinct place in the classification of mental diseases, under the name of katatonia, it has been the source of much discussion and difference of opinion. Many alienists have held that the condition designated as katatonia is merely a complication liable to develop in the course of some well-recognized forms of insanity, and is not of sufficient importance to be classed as a clinical entity. The trend of opinion at the present time seems to be in this direction, and the case here reported would certainly sustain such a view.

REPORT OF A CASE OF LONG-CONTINUED ABNORMALLY LOW TEMPERATURE.

By JOHN HEY WILLIAMS, M.D.,

ASHEVILLE, N. C.,

SURGEON-GENERAL, NORTH CAROLINA.

April 4, 1896. Mrs. H. P. A——, primipara, was delivered of an apparently healthy male child, weighing nine and one-half pounds; the labor was normal in all respects. The mother made a prompt and uneventful recovery, although she is distinctly tuberculous and has been under my care for the past two years. The father has a bad family history. The babe was vigorous and well developed. On account of the pronounced general tuberculous condition of the mother the child was put on artificial food from the first. It thrived and did apparently well until June 1st, when some slight digestive trouble appeared, which yielded to careful regulation of diet and digestive aids. There were occasional outbreaks of digestive trouble during July. From the 1st of August until the 14th the child appeared to be in good condition. On that date I was called to see the child. I found well-marked febrile movement, great restlessness, turning of the head from side to side, occasional vomiting, slightly relaxed bowels, unequally dilated pupils. On the 15th of August the cerebral symptoms were more marked—eyes wide open and staring, pupils dilated, with some slight retraction of the head. On

the 16th there were occasional slight convulsive movements, exaggerated reflexes, the temperature reaching its highest point, 104.2° F. The convulsive movements were controlled by warm baths with bromides and hyoscyamus. The temperature remained high, varying from 102° to 104° F., with an occasional convulsive movement, till August 20th, when there was an apparent amelioration of the symptoms, the temperature dropping during the day to the normal; but the child was inert, with expanded pupils, and poor reflexes, and in a state of stupor. It took food freely when the nipple was placed in its mouth; the bowels were normal, and the bladder was evacuated normally. The temperature gradually declined during the night of the 20th, reaching 96° F. in the rectum on the morning of the 21st. The pulse was 126; respiration, 14. The temperature gradually farther declined during the day until it had reached 92° F. On the evening of the 21st the respiration was 12; the body was cold and dry; the reflexes were abolished except for a slight movement of the right leg when the sole of the foot was tickled. On the morning of the 22d the temperature was so low that I could not get a registration with my thermometer, which was not graduated below 92° F.; respiration, 10; pulse, 100; body cold and dry; no reflexes. The child continued to take food, though slowly. I found a thermometer which was graduated down to 90° F., with a long stem, and was able to protract the graduation down to 87° F. On the evening of the 22d I found the temperature 92° F.; respiration, 10; pulse, 100. The child still took food slowly, but in smaller quantities. The functions of the bowels and bladder were still performed, but at longer intervals. It lay perfectly quiet in whatever position it was placed, with no apparent rigidity and presenting the appearance of a hibernating animal. On the morning of the 23d the temperature had dropped still farther, the thermomenter registering 89° F., rectal; respiration, 10; pulse, 96. The general condition remained the same throughout the day, except that the temperature gradually declined until it registered 88° F. at 7 P.M. On the morning of the 24th the temperature had dropped still farther, and it did not rise above 87° F., the lowest limit of the thermometer, below which of course I could make no observation. The body felt like a corpse, appearing to have the temperature of the surrounding atmosphere. The child still swallowed food when it was placed in his mouth, but swallowed very slowly and with no apparent difficulty. Respiration, 9, slightly Cheyne-Stokes in character, and continuing so but becoming more pronounced during the day. This condition persisted throughout the 25th, 26th, 27th, and 28th. On the morning of the 29th the temperature had risen to 90° F.; the breathing was pronouncedly Cheyne-Stokes; the interval of suspension of breathing was from thirty to forty seconds; pulse, 90; food was swallowed no longer. The bowels and bladder were evacuated about once in twelve hours. During the 30th and the 31st his condition remained about the same, except that the respirations dropped to 6, pronouncedly Cheyne-Stokes; the temperature, rising during the night of the 31st, reached 94° F. on the morning of September 1st, when the flickering candle went out.

The case was one of very great interest to me—so much so that I was unusually careful in my record. I am in possession of no literature bearing on such a low temperature continued for such a time, and report the case that I may possibly learn the experience of others. It is so contrary to the usual exhibition of tuberculous meningitis—I had so diagnosed it—that I can form no rational idea of the processes involved, except that there was a complete suspension of metabolism.

53 Haywood Street.

NAPHTHALIN POISONING.

By J. A. OTTE, M.D.,

ASHEVILLE, CHINA.

On May 5, 1897, wishing to prescribe naphthalin to one of my patients, I obtained eight grains of the drug from one of our local apothecaries. The bottle from which it was taken was clearly marked "Naphthalin. Dose, 5–15 grains." The drug was carefully weighed in my presence. It was in the form of white crystalline scales, and seemed pure; but, having some doubts on the subject, I decided to take a dose myself before administering it to my patient—a very weak, anæmic woman, suffering from chronic enteritis. I took the eight grains in a wafer at about 12:15 P.M. Soon after reaching home (at one o'clock) I was seized with severe colicky pains in the abdomen, followed almost immediately by diarrhœa, tenesmus, and strangury. The motions were very numerous and small. At first they were simply fæcal, but finally were mixed with a great deal of mucus. The pain on micturition was most distressing. Thinking that I was suffering from an attack of dysentery, I took one-half ounce of castor oil and washed out the rectum with simple water. At three o'clock the discharge from the bowel suddenly ceased. In spite of this, the abdominal pain continued, gradually changing into a continuous dull ache all over the abdomen. After a short time the pain became most severe in the hypochondriac regions, and thence radiated toward the bladder and back.

At 4 P.M. vomiting set in, and continued at short intervals until six o'clock of the following day, when it ceased after I swallowed several small pieces of ice. During all this time it was impossible to retain anything, not even a mouthful of water. The vomited matters consisted simply of the contents of the stomach, toward the last slightly streaked with blood.

At five o'clock Dr. McDougall gave a hypodermic of one-third of a grain of sulphate of morphine. After this the pain became somewhat lighter, but still prevented sleep.

At 3 A.M. of the 6th (fourteen hours after I took the drug) the pain suddenly became most agonizing. It seemed as if a red-hot iron was plunged into the kidneys with every heart beat. This severe pain lasted some twenty minutes. During this paroxysm the pulse was very slow, and almost imperceptible at the wrist. The urine passed shortly after this paroxysm was apparently normal in quantity; reddish-brown, acid; specific gravity, 1.014; and contained about twenty-five volume per cent. of albumin (estimated after standing twelve hours). It also contained a few small blood clots; there was an abundance of granular casts, urates, and mucus. The diagnosis was now made of probable poisoning by naphthalin, causing a temporary inflammation of the whole of the digestive tract, followed by acute nephritis.

A hypodermic of one-third of a grain of morphine was promptly followed by considerable relief. Further relief was obtained with three leeches applied to the lumbar region over the right kidney, which after 3:30 A.M. was the more painful. At 6 A.M. the pulse was 45 and weak. The temperature was normal. The temperature never rose above normal.

May 7th, spent a restless night; in spite of this, the improvement was marked, the pain in the kidneys nearly gone. During the afternoon I suffered from severe hemicrania. The urine was apparently normal in quantity; color, brownish-red; acid; specific gravity, 1.016; albumin about ten volume per cent.; granular casts, urates, and mucus decidedly less; no blood clots. At noon the temperature was 98° F., and the pulse 56. Still felt very weak.

May 8th, spent another restless night; pain scarcely perceptible, appetite good. Urine normal in color;

acid; specific gravity, 1.020; only a trace of albumin; no casts. The urine contained two or three fibrinous clots looking like sago granules. At noon the pulse was 46 and weak; temperature, 98.2° F.

May 9th, except for a feeling of weakness, the recovery was complete. The urine was normal in color; neutral; specific gravity, 1.018; no albumin or casts. Pulse at noon, 68; temperature, 98.2° F.

I would have reported my case before, but have delayed doing so until I could also send the report of a chemist on a portion of the drug which I sent to England. Below I append the report:

"I have made a most critical examination of the above sample, both as regards its physical and chemical characters. The sample fully answers all the tests that it should, and in my opinion is normal in every respect. It is rather above the average pharmaceutical degree of purity, it is quite free from quinoline bases, and contains only the merest trace of phenols. [Signed] "W. CHATTAWAY, F.I.C., "*Chemist to the Society of Apothecaries, Public Analyst for the Borough of Colchester and for the Parish of Hammersmith.*"

In a private letter received from the same gentleman occurred the following paragraph: "I am not a medical man, but I would throw out the suggestion that in certain medical circles it is recognized that bodies of this character, particularly including the terpins and naphthalins, are liable to produce nephritis, depending of course on the idiosyncrasy of those to whom the drug is administered."

Surgical Suggestions

Gonorrhœal Urethritis.—

℞ Antipyrin..... 10
Tr. ferri chloridi..... 10
Trit. bene et adde:
Aquæ dest.....q.s. ad 150–250

First clean the urethra by injecting from six to twelve ounces of boiled water. Then inject three or four syringefuls of the above, using a six-ounce syringe (Ultzmann) with a Mercier (coudé) catheter.—J. G. MÖHLAU.

To Lubricate Catheters.—

℞ Sterilized powdered soap,
Sterilized glycerin,
Sterilized water.....āā 11
Resorcin..... 1
M.

—GUIARD.

Boils.—

℞ Acid. carbol..... gr. v.–x.
Ext. ergot..... ℥ i.–ij.
Pulv. amyli..... ℥ ij.
Zinci oxidi..... ℥ ij.
Rosæ aquæ ung..... ℥ viij.
M. S. Apply locally.

—L. DUNCAN BULKLEY.

Prevention of Post-Partum Hemorrhage.—

℞ Liq. strychninæ (one per cent.)..... ℥ i.
Fl. ext. ergotæ..... ℥ iij.
Inf. ergotæ.....q.s. ad ℥ vi.
M. S. One-half ounce t.i.d.

This medicine is begun on the thirty-fifth week of gestation. The following conclusions are drawn: 1. When administered previous to the termination of pregnancy in the case of a woman in whom a tendency to post-partum hemorrhage is known to exist, it tends in a marked degree to prevent its occurrence. 2. In ordinary doses it does not produce any injurious effect on either mother or child, and it seems to delay the commencement of labor. 3. It tends to make the involution of the uterus more perfect, and lessens the chance of the occurrence of subsequent uterine troubles. 4. It will not bring on premature labor or induce abortion unless uterine action has previously been set going. 5. In threatened abortion it seems to act as a uterine tonic, and in some cases tends to avert a miscarriage, provided the ovum is not blighted. 6. If the ovum is blighted, and especially if it is detached, ergot usually hastens its expulsion. Ergot does not originate uterine action, but stimulates the uterine fibres when once they have begun of their own accord to contract.—ALTHILL, *British Medical Journal*, March 9th.

Cyanide of Mercury for the Sterilization of Surgical Instruments.—The following solution is recommended as a sterilizing fluid:

Cyanide of mercury..... 1 to 3 gm.
Sodium borate (water free) or
Sodium carbonate..... 5 gm.
Distilled water..... 1 litre.

It may also be employed for disinfecting the hands. Cyanide of mercury can be used as a substitute for sublimate; it is not more poisonous, is as strongly antiseptic, and has the advantage of not acting on albuminoid substances.—DENIGIS, *Rép. de Pharm.*, 1897.

Fæcal Impaction.—If firm pressure be made with the finger tips against the mass of fæces, and the fingers are then slowly and carefully withdrawn, a peculiar sensation is perceived, a sensation the same as that received when the fingers smeared with grease are pressed against the opposite palm and then slowly withdrawn. To obtain this sensation, the mucous membrane of the intestine must be somewhat dry, the fæcal tumor of such a character as to dent upon pressure, and there must be gas enough present to cause the intestinal wall to resume its former position as soon as the pressure is relieved.—GERSUNY.

Scarification.—For lupus and similar affections, Vidal's little instrument, modified until now its blade is twenty-two millimetres long and about three millimetres broad, admits of extreme precision in operation, and is considered by its originator decidedly superior to multiple-bladed instruments and those which cut obliquely through the tissues, taking the tops off the papillæ instead of dividing them longitudinally.

Cold glandular abscess in the cervical region, while usually followed by good results from operation, has the serious drawback of preventing a satisfactory cicatrix in the beginning, which secondarily becomes cheloidal. This must be remembered every time the question of operation in young subjects of lymphatic constitution comes up, so that parents may be warned of such a possibility.—DUPLAY.

Appendicitis.—Never give opium or morphine in cases of appendicitis, except in case of abdominal shock from rupture of the appendix or abscess. During an attack of appendicitis a sudden cessation of symptoms is always a bad sign.—PARKER SYMS.

I have found the tip of the appendix almost entirely separated from the rest of the structure, and obtaining its nourishment from its new attachment.—J. F. W. ROSS.

Large Effusions into the Knee-Joint.—Dums (*Centralblatt für Chirurgie*, September 18, 1897) recommends that the treatment of this condition should be the removal of the fluid from the joint, followed by the application of a firm bandage and the fixing of the limb in an immovable apparatus in an extended posi-

tion. At the end of a week remove the bandage and make a few passive motions, and then apply a starch bandage. In the course of another week the patient may go about on crutches. From this time on a gradually increasing amount of passive and active motion is allowed, and at the end of six weeks a complete cure may be expected. This may appear to be a tedious treatment, but relapses are fewer than in cases in which the older methods are followed.

To Clean Rusty Instruments.—Fill a suitable vessel with saturated solution of stannous chloride (chloride of tin) in distilled water. Immerse the rusty instruments and let them remain over night. Rub dry with chamois after rinsing in running water, and they will be of a bright silvery whiteness.—Brodie, *Journal of the British Dental Association.*

Pressure Neuritis.—H. T. Pershing reports cases of pressure neuritis caused during surgical operations and due to the placing of the extremities upon hard, pointed, or angular surfaces. In most cases the paralysis was of short duration.—*Medical News*, September 11, 1897.

Lupus.—Dehydrated dried crystals of permanganate of potassium are applied in a layer, three to five millimetres in thickness, over the surface of the lupus. If it is deepiy ulcerated with undermined edges, curette first several times a day and apply the same powder. In all cases a layer of medicated cotton is placed on the patch to keep the powder in place, to absorb the secretions, and to eliminate material.—Kachanovsky.

Therapeutic Hints.

Drops for Atonic Dyspepsia.—

℞ Tincture of nux vomica..... ʒ iiss.
Resorcin ..... gr. vij.
Mix and take five or ten drops three times a day.
—*Therapeutic Gazette.*

Poisoning by Nitrobenzol.—A. Boas reports a fatal case of nitrobenzol poisoning. The blood, though of a tar-like color, presented, strange to say, a normal appearance microscopically. The spectroscopic examination was negative. The urine contained a reducing-substance, the same which Ewald first found in these cases. On the fourth day a decubitus appeared, which became gradually worse. Despite opinions to the contrary, Boas says that he observed most excellent results from the use of alcohol.—*Deutsche medicinische Wochenschrift*, No. 51, 1897.

To Remove Picric-Acid Stains.—To remove the stains from animal tissue, rub the part, previously moistened, with carbonate of lithium. The color soon disappears. Stained linen is best treated by immersion in water containing the carbonate in suspension.—Prieur, *Rép. de Pharm.*

Acute Poisoning by Gas.—Generate steam and let the patient inhale it. A gasoline stove, a tea kettle, and a section of garden hose are sufficient for the purpose. Hold the end of the hose about one foot from the patient's mouth, and spread the steam by interposing a fan or piece of paper.—William Burton.

To Disguise a Bitter Drug.—A plant grows in Assam the botanical name of which is Gymnema sylvestre, which has the peculiar property, when chewed, of temporarily neutralizing the sense of taste as regards sweet and bitter things, while that for sour and saline substances remains unaltered. The Hindus claim that the plant is an antidote to snake bite. However that may be, it is believed that the plant might be advantageously introduced in our pharmacopœia as a means of disguising the bitterness of quinine and other disagreeable medicines.—*Dunglison's College and Clinical Record*, January, 1898.

Scleroderma.—A. Philippson reports a case of scleroderma which was entirely cured with salol in daily doses of two or three grains.—*Deutsche medicinische Wochenschrift*, No. 33, 1897.

Treatment of the Insomnia of Neurasthenia.—First sponge off the patient with cool water; then quickly wrap him in a blanket which has been wrung out of hot water. Outside of this place a dry blanket, and about this hot bottles. In a few minutes the patient breaks out into a profuse sweat; when this has continued five or ten minutes, place the patient between warm blankets and rub him off with a towel, and permit him then to go to sleep.—D'Aulnay.

Epistaxis.—Lemon juice applied locally.—Fruitnight.

Eye Symptoms in the Parturient Woman.—Disturbances of the retina and optic nerve occur in each trimester of pregnancy. They may be manifested by dimness of vision, coming on at the fourth month; by double vision, appearing in the third trimester; and by total loss of sight in the last month of pregnancy, and by all the symptoms attending neuro-retinitis as early as the seventh month of pregnancy.—K. K. Wheelock, *Columbus Medical Journal*, September 28, 1897.

In septic conditions the patient is often very uncomfortable, by reason of dryness of the tongue. A bit of ordinary chewing-gum will usually start the oral secretions and in a very short time give relief.—*Canadian Lancet.*

In using forceps, ether is distinctly to be preferred as an anæsthetic; here the obstetrician desires to further uterine contraction in every way. The delivery of the patient is often prolonged, and if chloroform is given to complete anæsthesia the uterus will often relax and the obstetrician will push the child's head away from the brim of the pelvis in his efforts to apply the forceps. This is especially true in cases in which the high application of the forceps must be practised.—Edward P. Davis.

Tuberculosis.—Cinnamic acid in five-per-cent. emulsion. Give one and one-half minims by injection in the gluteal region, increasing the dose day by day.—Heusser.

Asthma.—

℞ Morphin. sulph ..... gr. ½–½
Strychnin. sulph..... gr. $\frac{1}{60}$–$\frac{1}{40}$
Hyoscin. hydrobrom..... gr. $\frac{1}{200}$
M. S. Give hypodermatically at bedtime.
—S. Solis Cohen.

Malaria in Children.—

℞ Tr. eucalypt. globul..... ..... 8 parts.
Spt. vini diluti..... 8 "
Quininæ muriat..... 2 "
Chinoidini..... 1.25–2 "
Acid. muriat. dil..... .....q.s. ad solutio.
M. S. Gtt. xx.–xl. five times daily.
—Zukermann.

Cancer of Stomach.—To increase the appetite, bark of white condurango, 15 parts; water, 250 parts. Reduce by boiling to 150 parts, filter, and add syrup. A soupspoonful is to be taken a quarter of an hour before meals.

To favor digestion, muriate of ammonium, 0.15 gm.; bicarbonate of sodium, 0.26 gm.; Dover's powder, 0.10 gm. To be taken ten minutes before meals.—ROBIN.

Sciatica.—Copaiba, forty or fifty drops a day in divided doses.—GLORIEUX.

Migraine.—Fluid extract of gelsemium and of cannabis indica, three drops t.i.d.; increase the dosage day by day till physiological effects are produced.—ESHNER.

Irritating Coughs.—

℞ Phenacetin ..... gr. iiss.
Ext. glycyrrhizæ ..... gr. ij.
Codeini ..... gr. ½
Sacchar. alb ..... q.s.
M. S. For one dose.

—G. A. TOLMAN.

Ulcero-Syphilides.—

℞ Hydrarg. bichloridi ..... gr. viij.
Ammonii muriat ..... gr. xij.
Syr. aurantii cort.,
Aquæ destillat ..... āā ℥ iv.
M. S. A teaspoonful in water after each meal.

Later on and in more advanced cases the mixed treatment will be found of benefit. A good working formula is the following:

℞ Hydrarg. bichloridi ..... gr. iv.
Potassii iodidi ..... ℥ i.
Liq. pepsini,
Aquæ destillat ..... āā ℥ ij.
M. S. A teaspoonful in a glass of milk after each meal.

—O. DUMESNIL, *Tri-State Med. Jour.*, December, 1897.

Hemorrhages of Typhoid Fever.—

℞ Acidi tannici ..... gr. iij.
Tincturæ opii ..... ♏ x.
Extracti ergotæ fluidi,
Spiritus terebinthinæ rectificati ..... āā ♏ xv.
Spiritus chloroformi ..... ♏ xx.
Mucilaginis acaciæ ..... ℥ ij.
Aquæ menthæ piperitæ ..... ℥ ss.
M. S. Teaspoonful every four hours.

—F. S. NEVLING, *Penn. Med. Jour.*, November, 1897.

Ulcerations of the Nasal Septum.—

℞ Fld. ext. calendula ..... ℥ ij.
Lanolin,
Albolin ..... āā ℥ i.
M. S. Apply.

—O. B. DOUGLAS.

Rosacea.—

℞ Ichthyol ..... gr. xv.–lxxv.
Resorcin ..... gr. xv.–xlv.
Lanolin ..... ℥ viss.
Olive oil ..... ℥ iiss.
Distilled water ..... q.s. ad ℥ iss.
M. The proportions of ichthyol and resorcin may be gradually increased according to the tolerance of the patient.

—JUDASSOHN.

Colic Due to Intestinal Acidity.—Tincture of asafœtida combined with milk of magnesium.—*Pediatrics.*

Seminal Emissions.—Thuja, in doses of from five to seven drops.—ROBERTS.

Pulex Penetrans (Sand Flea).—

℞ Olei caryophylli ..... gr. v.
Unguenti petrolati ..... ℥ i.
M. S. Rub well into the feet between the toes night and morning

—A. L. BENNETT.

Chronic Rhinopharyngitis.—

℞ Menthol 1
Oil of sweet almonds, or
Liquid vaseline 10
M. S. Apply with a brush.

—FOUGERAY.

Asthma.—

℞ Tr. opium ..... ℥ i.
Sulphuric ether ..... ℥ ij.
M. S. Gtt. l. every half-hour till the patient is relieved.

—*Journal de Médecine de Paris*, April 14, 1897.

Hoarseness in Singers or Speakers.—

℞ Cocain. hydrochlor. ..... gr. xv.
Strych. sulph. ..... gr. ¾
Aq. destillat. ..... gr. 1,500
M. S. Spray throat.

And:

℞ Cocain. hydrochlor. ..... gr. ¾
Tr. aconiti ..... ♏ x.
White sugar and marshmallow ..... q.s.
Ft. pastillas No. lxxx. S. To dissolve in the mouth.

—BOTEY.

Puerperal eclampsia is an albuminuric auto-intoxication. The indications for treatment are the quieting of spasms and the elimination of the intoxicant. Spasm is best relieved by chloroform anæsthesia and the free use of chloral hydrate. Elimination is best and quickest and safest effected by venesection according to the patient's strength, and hourly doses of Clutterbuck's elaterium, one-fourth grain at a time, till there are free stools. If labor is in progress, delivery should take place with the forceps as soon as the os is sufficiently dilated; but if dilatation is unduly delayed it must be forced by means of the fingers, a Barnes dilator, or by some other equally good means.—J. B. TAYLOR, *Columbus Medical Journal*, November 23, 1897.

Acute Rheumatism.—Strontium salicylate is less irritating to the stomach than the sodium salt, and it does not produce salicylism. Order it in powder form to be dissolved in hot water.—ESHNER.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SPECIAL SESSION OF THE MEDICAL COUNCIL: THE NEW PRESIDENT, THE MIDWIVES QUESTION, THE CROWN VACANCY — THE NEW PHARMACOPŒIA — MEDICAL SOCIETY'S CLINICAL EVENING—SMALL-POX—TYPHUS IN LONDON—VACCINATION—SIR S. WILKS—COLLEGE OF PHYSICIANS ON ARMY SERVICE—NEW DIRECTOR OF NAVAL MEDICAL DEPARTMENT—A THREATENED SCANDAL—RECENT DEATHS.

LONDON, April 8, 1898.

As the special session of the General Medical Council opened on Tuesday, the first business was the election of a president in succession to the late Sir R. Quain. The council unanimously chose Sir William Turner, whose reputation will be well known to you. Outside there had been some talk of a difficulty arising because the eminent professor resided in Edinburgh, but I do not see any necessity of the president being in London. It is certainly not desirable to leave too much to be done by the president or for him to interfere with ordinary details. Indeed, the late R. Quain, in his anxiety to fulfil his duties to the utmost, assumed almost too much for even his long experience, and his successor will not be allowed quite so free a hand.

Sir William Turner, having been elected, took the chair, thanked his colleagues for their confidence, and paid a warm tribute to his predecessor. A vote of condolence with the family of Sir R. Quain was in due course adopted by the council.

The most important business of the session is the reply to be given to the government, which has requested the council to state its views on the regis-

tration-of-midwives bill. This bill will shortly come on for second reading in the house of commons, and is of such a dangerous character to the profession that Dr. McVail proposed that it should not be considered in committee, but that the government should be informed that the public safety requires that no one should be recognized as a practitioner in one branch unless qualified in medicine, surgery, and midwifery, as required by the acts—the medical register being open to men and women alike.

There was evidently a strong feeling against the bill, and it was declared that, whatever England might submit to, neither Ireland nor Scotland would suffer the provisions to be extended to them. In both the existing arrangements work satisfactorily. It was thought, however, that it would be better to discuss the clauses of the bill, and this accordingly was done, the length of the discussion thus entered upon necessitating an adjournment. The bill is really the same as that of last year. It proposes to register all midwives who have been in practice prior to its passing, and then those who have been to some extent trained or examined Thus there would be an inferior order of legally qualified practitioners, including all the ignorant women who have been present with a neighbor in labor and choose to call themselves midwives. The report of the committee which had been appointed by the council was so moderate in tone, and showed so clearly what might be the result, that I think Dr. McVail's proposal might well have been accepted. As he said in his speech, the only people who desired this bill were "a handful of wealthy philanthropists, some members of an obstetric diploma-selling society, antivaccinators, antivivisectionists, anticontagionists—in fact, all the anti-common-sense people of the community."

Outside the council the question is a burning one and has been argued in various ways since the bill of last year. No little indignation is felt by general practitioners at the way in which Dr. Cullingworth and other members of the Obstetrical Society are ready to sacrifice the rank and file to their own whims. Consultants are ready enough to declare they never wish to attend a natural labor, and for that reason are ready to hand over the lying-in room and the infant to a new order of midwives. They should beware of Nemesis. Perhaps the rank and file may yet refuse to consult with them on dangerous complications. It would be easy to ask, how can they know anything about abnormalities if they never see normal cases? Dr. Cullingworth confesses that his midwife would have "some limited responsibility," and that to call her a nurse "is to confound one who has independent charge with one who has not;" and again, "her functions include a certain amount of attendance on both mother and child during the lying-in period." Clearly, then, he is prepared to take the bread from the mouths of the general practitioners and to give it to the ignorant Gamps who have done so much mischief and would at once register themselves as qualified midwives.

The death of Sir R. Quain leaves a vacancy in the council to be filled by the crown. The dentists are agitating that they ought to be represented, and there are a number of dental surgeons who are also fully qualified medical men; so the claim is a fair one, especially as the dentists contribute to the funds of the council and are subject to its authority. The general practitioners are also desirous of seeing one of their order appointed—but it may be said they have already the direct representatives, as they could, if they pleased, elect all from their own ranks. Hitherto they have not chosen to do so simply because they were general practitioners.

The new Pharmacopœia is ready, and copies have been given to some of the journals, but it cannot be sold until the treasury has fixed the price. One of the journals has extracted the lists of additions and omissions—both rather lengthy and by themselves of little interest.

On Monday the Medical Society had a clinical evening. There was a woman, aged thirty-three, who had been relieved from neuralgia by the injection of osmic acid (one-per-cent. aqueous solution) into the infra-orbital nerve. Removal of the Gasserian ganglion had been contemplated, but was now unnecessary. It was suggested that the nerve fibres were destroyed by the acid; on the other hand, one speaker doubted whether the neurilemma had been penetrated, and attributed the effect to traumatism.

A woman, aged fifty, was shown with multiple venous angiomata. Also a man, aged thirty, in whom Coley's fluid had been tried with much benefit for an inoperable tumor.

Dr. Maguire showed a man, aged twenty-seven, with asystolic murmur audible over nearly all the chest, but clearest along the line of the interventricular septum, and he thought it was due to a deficiency of the septum. The patient had often been "blue" when a child, but this had passed off, and Dr. Maguire suggested as an explanation that pressure in the left ventricle was now so much greater than in the right that any admixture of blood would take place in the right. He had seen a case in which there were no symptoms for eight years, when the child suddenly became cyanosed and died. At the post-mortem the opening was so large that practically there was only one ventricle, with stenosis of the pulmonary artery. There had been no bruit in the case.

The daily tale of new cases of small-pox at Middlesborough has varied during the week between three and eleven. Yesterday eleven new cases were notified.

An outbreak of typhus in London was reported to the Kensington Vestry on Wednesday by Dr. T. O. Dudfield, the M. O. H. It was confined to one dirty and overcrowded flat and fourteen cases are recorded, but probably some others may have occurred, as at first the nature of the outbreak was not suspected. Three persons died, one being a young doctor who had attended some of the patients, and his own death in hospital caused the medical superintendent to inform Dr. Dudfield of the nature of his case. It seems there has been no death from typhus in Kensington since 1883. There are plenty of doctors in London who have never seen a case of typhus.

The Epidemiological Society has addressed the government on the vaccination question, expressing regret that the royal commissioners did not see their way to recommend legislation which would place revaccination on the same basis as the primary vaccination.

Sir S. Wilks was on Monday re-elected president of the Royal College of Physicians.

Sir William Priestley proposed that the College of Physicians should represent to the government that the concession of titles to the army medical officers should not stop at the rank of colonel, as proposed by the war office. The motion was warmly seconded by Sir Joseph Fayrer, and carried.

Sir Henry Norbury, K.C.B., is the new director-general of the naval medical department.

Another hospital scandal is threatened. The honorary medical staff of the Royal Hospital at Winchester has resigned in a body. Another chance for the men who only care to push themselves!

The death of Surgeon-General W. S. Murray is reported, aged sixty-seven. He had served mostly in India. Surgeon-Colonel Shepherd, R.O., died on the 30th ult., aged eighty-three; and Dr. John Watson, of Kensington, on the 28th, in his eighty-fourth year.

INSTRUCTION OF DEAF-MUTES.

To the Editor of the Medical Record.

Sir: Your article of April 2d, on the "Training of the Deaf," has come to my notice. While much of the information given is correct, I find two or three errors which need to be pointed out to your readers.

The idea that any deaf-mutes are educated by the "sign language," as suggested at several points, is misleading.

There is no "sign-language method."

The manual method makes use of the language of gestures to a greater or less extent, according to the capacity and needs of the pupil; but one of the important aims under this method, as under the oral, is to bring deaf children into the facile use of their vernacular. And this aim is attained quite as readily under one method as under the other.

Near the end of your article the following statement occurs: "In Europe the teaching by articulation and lip reading prevails, while in this country the sign and manual language is still the method of instruction chiefly relied on."

How far this is from the truth will be seen when I say that teaching speech to the deaf was systematically entered upon in this country more than thirty years ago, and it is now taught in every one of the State schools for the deaf and in this institution.

The paragraph in your article immediately following represents me as approving the "sign and manual language method," and speaks of a report of mine, written some time ago, from which a quotation is made. In that report, which it is true was made thirty years ago, I recommended the general teaching of speech to the deaf, and I am happy to note that my recommendations have been fully and widely accepted and acted on.

I inclose you in to-day's mail a copy of our fortieth annual report, in which you will find an account of a very recent visit I have made to Europe, and will note that the combined system, now generally prevailing in this country, has the earnest approval of the educated deaf themselves all over Europe.

E. M. Gallaudet, M.D.

Washington, D. C.

A FEW IMPRESSIONS AT A DISPENSARY IN CHINA.

To the Editor of the Medical Record.

Sir: The vitality of the Chinese has impressed me, I think, more than anything else, and this has been especially evident in cases of carbuncle. We have treated about one hundred cases since we opened our dispensary, and not one case has been fatal. And these were not hospital patients, but those who came daily to the clinic, and often too poor to have sufficient food. One woman had erysipelas of the neck and face in the course of her carbuncle, but made a good recovery. One of the largest carbuncles measured nine by four inches, but there was one this winter larger, that I failed to measure. The neck and back are the most common seats, but we find them on legs and arms not infrequently. Some may be interested in our treatment, though I ascribe our success, not to that, but to the Chinese natural vitality. Not one has been lanced. We burn the most prominent part with pure carbolic once daily, then apply on absorbent cotton a mixture of one part each of spirits of camphor and spirits of turpentine to four or five parts of glycerin, cover with oil paper, and hold well in place with several strips of adhesive plaster. We aid the separating slough with scissors or forceps. After the slough comes away iodoform and boracic acid, one to seven, are applied. Internally we give six or ten grains of cinchonine muriate daily. The above-mentioned mixture acts like magic on frost bites. We also use it as an application to ulcers and a dressing for boils.

Another patient, whose recovery surprised us very much, was a man so anæmic he had general dropsy and could scarcely walk. We hesitated about trying to do anything for him, but decided quinine would do him no harm. Quinine did him so much good we put him on what we call our "spleen pill," because we treat so many with enlarged spleens. It is quinine, iron, arsenic, and strychnine. In a short while he was all right, and the only food he had was a cake made of whole-wheat flour, and turnips.

One more example: A woman with an abscess extending from the lower dorsal to the sacrum and into the abdominal muscles, to within a few inches of the umbilicus. It looked like an upturned washpan. She was also pregnant four or five months. She could neither sit nor lie down, but stayed in the knee-chest position. She had eaten and slept very little for a month, so was in a most hopeless condition. I lanced the abscess, and she got perfectly well; she did not miscarry.

Another impression is the absence of rickets. I have not seen one case after six years in China. This is only my experience; I have not heard other physicians discuss the matter. Many of the children are fed on rice and nothing else from two or three months on; cow's milk is never used for children. One explanation for this is that it is because of the air they get. The door of a Chinese house stands open all the year, as they do not heat their houses and depend upon the door for light. To keep baby warm he is encased in wadded clothes and given a sun bath.

I have been noticing epileptics more closely since the Craig Colony was started. There are no asylums here for epileptics or insane either, so we see the former under conditions similar to those of the Craig Colony. They have a happier and more intelligent expression than those I saw in asylums in the United States, but their attacks seem just as frequent, and even more so, because they have no treatment. I know one woman whom marriage cured, and another in whom marriage intensified the disease very much.

Another impression is that all the Chinese skin troubles are not described in books on dermatology. I have found two that I cannot diagnose, but will not describe them at this time, as I have not gotten all the points yet.

The Chinaman has a well-deserved reputation for tricks. It does not take long to be impressed that he carries that propensity to the clinic. He will come for treatment to get the bottle you put his medicine in; he will sell your medicine to others; he will bring the prescription you gave himself or child and get more medicine, when he wants it for a friend with perhaps a different disease; or he sells his prescription for the large sum of fifteen cash, about one cent, to a friend, etc.

We find potassium permanganate a grand success in opium poisoning. If called early we give nothing else, as it always produces emesis. Out of fifty patients treated the past year not one died, if he could be aroused sufficiently to swallow the remedy. These cases are treated by one of our missionaries who is not a physician, so our experience with the hypodermic use of permanganate is limited.

Annie H. Patterson, M.D.

Chinkiang, China.

Gonorrhœa in Women.—Permanganate-of-potassium irrigations; the strength should be 1 to 1,000 or 1 to 2,000; the quantity should be at least one litre; the frequency should be every day.—Cumston.

THE O'DWYER AND FISCHER TUBES.

To the Editor of the Medical Record.

Sir: In a communication to the Medical Record of April 9th, Dr. Edwin Rosenthal, of Philadelphia, states that "in justice to the living as well as to the dead" the invention of the hard-rubber intubation tube should be credited to Dr. Louis Fischer and not to the late Dr. O'Dwyer. If Dr. Rosenthal had known Dr. O'Dwyer and his work, he would have recognized that nothing was forced upon the medical profession or heralded as an invention. Dr. O'Dwyer had used hard-rubber tubes for ten years before his death, but he did not consider the smaller sizes of tubes safe unless they were reinforced by a metal lining. These reinforced tubes were being made by Mr. Ermold, the instrument maker of this city, when Dr. O'Dwyer read his paper on "Retained Intubation Tubes," before the American Pediatric Society in Washington, May 6, 1897.

Dr. O'Dwyer's investigations and models were on anatomical lines, and his reputation can never be discredited by any claim made in behalf of Dr. Fischer's tubes.

Medical Items.

Pure Water Supply and Public Health.—In a recent article by Lieut.-Col. Charles Smart, deputy surgeon-general, U.S.A., dealing with the question of pure water supply as regards public health, he says: "London has had filtered water for sixty years. I have before me its typhoid-fever death rates for the years 1869 to 1894, taken from the reports in the library of the surgeon-general's office. The mean annual rate for the last ten years was 14.4; the extremes, 10.2 and 16.9. And the rates for the whole of England and Wales, although larger than those of London, show that much care is given to the purity of water supplies. The mean annual rate for the last decade on my list is 17.6, with the extremes 13.7 and 22.9. I have the Berlin rates from 1854. Before this city began to pay attention to the purity of its supply, the rates ran from 60 to 100. The highest rate was 18.4 in 1889; the rate in 1894 was 4 per 100,000. I have the Vienna rates from 1867. The highest rate was 181.8 in 1871. A pure water was obtained in 1874, and the rate fell immediately. During the past ten years it has been less than 10 annually. In 1894 the rate of Hamburg was 6; of Rotterdam, 4.8. In Warsaw, where purification was effected in 1887, the typhoid rate was 60 to 105 annually during the period 1879–86, and 18 to 30 subsequently. I could give columns of such statistics, all showing that the deaths from typhoid fever are lessened in proportion to the care taken in providing a pure water supply.

The Importance of Public Baths.—Some interesting statistics are given by Walter Channing, regarding the municipal public baths of Brookline, Mass. The baths were opened in January, 1897, and at the time Mr. Channing's article was written, about the middle of May, there had used the baths 17,089 bathers, or an average of 451 daily. A somewhat curious difference was noted between the number of males and females—the bathers during the last six weeks, for instance, being divided as follows: Men and boys, 3,813; women and girls, only 1,080. When the baths were first opened, the policy was to have as many free days as possible, but it was found quite impossible to keep order even with the aid of a police officer. Under a new arrangement by which a fee of five cents was charged, a great improvement was manifested. Instead of the fees decreasing the number of bathers, there was a constant and steady increase. Aside from the value which this bath has as a swimming-school and healthy recreation ground for the children, its successful continuance cannot fail to have a most beneficial effect on the general personal cleanliness and sanitation of the town—a clean individual being much less patient with nasty streets and houses and neighbors than a dirty one. The importance of the public bath does not seem to be generally appreciated in this country. It is, when properly handled, one of the most powerful and far-reaching of the municipalities' institutions for promoting cleanliness, both mental and physical, and good citizenship. In several of the European states where this fact has been appreciated, the public baths of the cities and towns are among their most important institutions.

Position of the Medical Profession in Victoria.—The Australian correspondent of *The Lancet* writes that the retiring president of the medical society of Victoria, Mr. I. T. Brett, took as the subject of his address the position of the medical profession in Victoria and its relation to the general public. He stated that statistics showed unmistakably that the medical profession was increasing in numbers vastly out of proportion to the general population, and he considered the outlook for the ever-increasing accessions to the profession a poor one—a bare subsistence and that hardly striven for. One reason for this view apart from the overcrowding of the profession was the continued encroachments of the friendly societies. Patients who ought to pay proper fees join these societies, while the class for which they were intended crowd the hospitals. Reference was also made to quackery, which had lately attained vast proportions in Victoria, and Mr. Brett thought it was the duty of the profession to inform the general public that they were being deceived and duped, although such action might be misinterpreted and ascribed to jealousy and unworthy motives. The treatment of medical witnesses in courts of law also came in for adverse comment. According to Mr. Brett the medical practitioner is called an expert and treated as a criminal, and counsel have not hesitated to impute to him venality and untruthfulness. His rightful place in many cases would be not in the witness box but on the bench as a medical assessor.

Cesare Lombroso.—Cesare Lombroso, the most prominent exponent of criminal anthropology, is a Hebrew by birth, and was born at Turin in 1836. As a mere lad he loved to write and composed with the same facility and rapidity that distinguishes him to this day—novels, poems, tragedies, treatises on archæological, physiological, and already on sociological subjects, those dating from his student days being actually published, so much talent did they show. Medicine was the study to which he devoted himself, and his first independent researches were directed to examining into the causes that produce the idiotism and the pellagra that exist, unfortunately, so largely in Lombardy and Liguria. His treatise on this theme attracted the attention of no less a person than Professor Virchow. After fighting for the independence of Italy in 1859, he was appointed professor of psychiatry at Pavia, where he founded a psychiatric museum. From Pavia he passed to Pesaro as director of the governmental madhouse, and thence to Turin as professor of forensic medicine, a position he still retains. It was in his native Turin that he began those original studies destined to make his name famous over all the globe. Endowed by nature with a strong intelligence, a robust will, a keen intel-

lectual curiosity, he was indifferent to the incredulous smiles and sarcasms that greeted his first efforts at solving problems, hitherto held insoluble. Very bitter, very hard were his struggles—how hard only those can appreciate who have talked with Lombroso in intimacy and have noted the pained scorn with which he speaks of his adversaries—adversaries some of whom are not silenced to this hour. But his science, his studies conquered, which, if not always complete, yet are always serious; wherefore criminal anthropology, a mere infant some thirty years ago, may to-day be said to be adult; a raw empiric but a while ago, to-day a science, young if you will, but vital and destined to overturn the facile, fantastic monuments erected by so many penalists. The work with which Lombroso will go down to posterity is a huge book, huge in every sense of the word, in which criminal man is studied on a scientific basis. We refer to the "Uomo Delinquente," of which its author has published most recently a new revised and enlarged edition, wrestling with new facts, new observations, and new deductions. —*Appleton's Popular Science Monthly.*

Non-Medicinal Methods of Treatment.—In his opening address before the last congress for internal medicine, Professor von Leyden gave expression to the following views: "To-day we are conscious at the bedside that we have not simply to treat the disease, but chief of all the patient himself, and that he is indifferent to nothing, not even the slightest thing; nothing is adjusted at the bedside in the right way of itself; the physician has to see to everything, and not infrequently the so-called simple remedies are the ones which possess the power to hold together the delicate thread of life and again to fortify it. Medicine of to-day no longer rests upon a fixed system and no longer draws from a single source. Its remedies and methods have been multiplied and extended to an astonishing degree. What formerly appeared of secondary importance has now risen to a position of prominence. Numerous therapeutic measures arise to demand recognition. Our therapy is no longer exclusively based upon medicaments and prescriptions. We know that the task of the physician is not finished when he has written his prescription *lege artis*. He must make a more critical and thorough investigation of his patient's condition. We are convinced that many patients recover without medicine, and that many diseases are healed by other means."

Examination of Food.—The chemical examination of foods according to scientific rule is one of the municipal regulations of the city of Berlin. This examination in the month of September last included two hundred and two samples of edibles and drinkables, and of these fifty-seven were rejected as not up to the legal requirements. There were among the articles thus proven unfit, milk, butter, lard, flour, fresh eggs, sweet oil, lemon oil, chocolate, green tea, "medicinal" Hungarian wines, and denaturalized alcohol. Remarkable, in particular, was the large number of the butter samples which were found to be objectionable; that is, among twenty-five of these, two were pure margarine, twelve were mixed butter containing from twenty-five to seventy-five per cent. of margarine, and two were doubtful. The milk control extended over nearly fifteen hundred stores, and led to the detection of fifty-nine cases of adulteration.—*Sun.*

Disinfection of Linen in Paris.—The infection of a laundress in Paris during the course of her work has led to an inquiry into the ways in which laundries may serve to disseminate disease. Primarily the operations which are dangerous are those of sorting and steeping in cold water, particularly the former, in the course of which infected linen may obviously communicate its infection alike to the operator and to the room. The operation of soaking becomes dangerous when the dirty water is not run off into a sewer, a state of things which must necessarily often occur in the country. The remaining operations of laundry work are rather a source of security than of danger. The measure of the danger in the first two operations is not always confined to the infection of the operators and to such secondary infection as they may initiate. In the smaller laundries it frequently necessarily happens that the room in which the linen is sorted is used also for packing it up, and in this way there can be little doubt that reinfection of clean linen would readily occur. The bags used for conveying dirty linen from the customers' houses to the laundry may during the journey lie in contact with baskets of clean linen on their way to delivery. The risks in each of these cases are no doubt slight, but their reality can hardly be contested; and when there are added to them the risks of infectious sickness in the laundry establishment itself, the wisdom of taking such precautions as may be practicable is obvious. M. Deschamps, who is inspector of epidemics in the Seine department, relates, for instance, a case of diphtheria which could be explained in no other way. The industry is one in which it is difficult to control the small establishments without almost making their work impossible. So far as practicable, the use of mechanical means of washing, and the provision of a separate room reserved entirely for the operation of sorting, which should be conducted in a moist atmosphere, are to be recommended. Boxes for dirty linen should be washed after each time of use, and all possible pressure should be brought to bear on persons in whose houses the disease occurs to permit their things to be disinfected before they are washed. Dr. Vallin points out that some prejudice would be liable to exist against disinfection if care were not taken to decompose with dilute permanganate or other liquid any stains which the process of disinfection by heat would otherwise fix.—*The Journal of State Medicine.*

Intubation.—Twenty-nine consecutive cases of intubation with twenty-seven recoveries were reported by Dr. Waxham before the Denver and Arapahoe Medical Society (*The Colorado Medical Journal*, February, 1898), giving the low mortality of 6.9 per cent. This low mortality was attributed to the use of the antitoxin. The doctor contended that if death occurred after intubation for diphtheritic croup from the extension of the disease, it was because the remedy was used either too late or in insufficient doses, or was of uncertain strength. Death from diphtheritic croup, he declared, should rarely occur.

Health Reports.—The following statistics concerning small-pox, cholera, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended April 23, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile	April 13th	1	
Arkansas, Pulaski County	April 7th to 14th	8	
District of Columbia, Washington	April 9th to 16th	1	
Kentucky, Louisville	April 16th	1	
Pennsylvania, Philadelphia	April 13th	2	

SMALL-POX—FOREIGN.

Bohemia, Prague	March 26th to April 2d	12	
England, Gibraltar	March 27th to April 3d	1	
Norway, Christiania	March 31st to April 6th	1	1
Russia, Odessa	March 26th to April 2d	6	1

SOME REMARKS ON HOSPITAL ABUSE.

By FREDERICK C. SHATTUCK, M.D.,

BOSTON, MASS.

Hospitals are so beneficent, and the lives of many of us are so bound up in them and their work, that we may at times fail to realize that they have any possibilities of evil, as regards either the public in general or our own profession.

With your permission I shall venture to lay before you a few thoughts which come into my mind on this question; some general subject pertaining to medicine seeming to be more suitable for the address with which it is my great privilege, thanks to your unmerited kindness to me, to open our session.

Though it is over four hundred years since this country was discovered, and more than two hundred and fifty years since real settlements by highly endowed members of the Anglo-Saxon race were effected, the first hospital was founded not much more than a century ago. Until approximately fifty years ago the population was relatively homogeneous, and then even the largest cities were small enough for the inhabitants to know each other and each other's affairs. There were few poor, and neighborly succor efficiently met illness and the distresses which so often follow in its train. Then began the great Irish immigration, followed by that from almost every overstocked European country; the older cities grew apace and new cities sprang up as the tide moved westward. The conditions of life changed with enormous rapidity, and every large city developed a class whose earnings or whose lack of thrift do not permit provision against the almost inevitable day when the breadwinner, afflicted with acute or chronic disease, can win no bread, while the requirements of himself and his family can be but little if at all diminished.

We all know from personal experience how wonderfully helpful the members of this class are to each other in trouble of all kinds; also that their helpfulness has clearly defined limits. The larger the class grows, the more imperfectly are its members acquainted with one another and with one another's special needs; and much less are they, as individuals, known to the easier classes. Thus organized and public must supplement private and individual help in time of need, and it is natural that the hospital should take a high if not the first place among the forms of help. We are all mortal; the vast majority of us are unsound somewhere; illness and disability come to many without any fault on their part. Health is an almost indispensable condition of support and usefulness. Its preservation, therefore, appeals directly alike to the head and heart of the community.

All the first hospitals in this country were founded by private individuals, public spirited, anxious to benefit their less fortunate fellow-mortals and fellow-citizens. But as cities grow large it is often found necessary for the taxpayers to aid and supplement private effort. We see, then, that the original cause for hospital foundation lay in charity—charity in its best and highest sense. Hospitals were designed to help those who could not help themselves; and it has been and is the pleasure as well as the duty of the medical profession to contribute its full share by rendering its services without direct pecuniary reward. But we should never forget that no physician can do conscientious work in a hospital without indirect reward, a portion of which is pretty sure to be pecuniary. The gain in knowledge, the stimulus to its acquirement, the development of the man and doctor alike, which the honest performance of hospital work surely bring, almost as surely lead to the better performance of private work, and hence to the demand for it. As hospital physicians we are, I think, sometimes inclined to strike a false balance between the sacrifice of time and strength which hospital work demands, and the return, which is none the less real because it is indirect and cannot be estimated with mathematical accuracy. Personally I believe that this natural return is ordinarily ample, and that any conscious and deliberate attempt on our part to enhance it can only be lowering to ourselves and unfair to the general body of the profession.

And just as there are indirect advantages flowing to physicians from hospitals, so also do they flow indirectly to the rich who endow and maintain them—in that the rich profit by the skill acquired by the staff and by the advance in scientific knowledge secured by the minute study of collected cases of disease. Virtue may be its own, but it is not necessarily its only, reward.

I repeat that the primary purpose of hospitals is charitable; hence their immediate benefits should be reserved for the poor, for those who are unable to pay for medical attendance. Poor and rich are of course relative terms, and not easy of exact definition. A person may be able to pay one fee, perhaps several fees; but totally unable to pay for prolonged attendance. Medical attendance, moreover, stands on quite a different footing from almost every other necessary of life. There are different grades of food and clothing, even of fuel and light, between which, within certain limits, one can choose without detriment to health, but with advantage to the pocket. The first cuts of meat are no more nutritious than the lower grades; and style alone may be the larger element in the cost of clothing, to say nothing of the choice of material. But the poorer a person is, the more purely dependent he and his are on his own exertions, the more important is it for him to have the best medical care attainable. Here economy may be the wildest extravagance. This is an aspect of hospital abuse which cannot be lost sight of. There is no clearly discernible line of cleavage, and therefore abstract justice cannot be done in every case as in most other branches of human activity substantial justice is the best we can hope, at present at least, to attain. Medical charity in hospitals and dispensaries should be freely extended to those who require it; denied to those who do not, and from ignorance or parsimony demand it. The community suffers if provision is insufficient or proper access is difficult. The commu-

[1] President's address delivered before the Association of American Physicians at its annual meeting in Washington, May, 1898.

nity also suffers if no questions are asked, the independence and self-respect of the laity being undermined, and the medical profession failing to receive returns which justly belong to it. Alike as citizens and professional men we should carefully scrutinize the claims of every new charitable medical institution, and refuse our aid and countenance unless satisfied that it is likely to meet a real need in the community.

The same care should be exercised with regard to abuse creeping into existing institutions. The matter lies really in the hands of our profession. If no physician would serve or aid in promoting a medical charity, so-called, founded mainly on sentimental or selfish considerations, such would soon cease to exist and the millennium would be at hand. There is too much reason to believe that hospitals and dispensaries are sometimes started purely in the selfish interest of members of our profession.

The second great function of hospitals—second in point-of-time evolution, though not, I believe, in point of importance—is the educational function, the advancement and dissemination of knowledge. On this function I need not dilate to this audience. It is, of course, more obvious to us than to the laity. But their attention is being more and more called to it. They are quick to see the truth and to recognize the powerful stimulus to the staff to do first-class work afforded by the critical eyes of bright students. The clinical teacher must study his cases carefully; compulsion acts more imperatively on him than on the hospital physician who is not also a clinical teacher. The necessities of teaching and the demand for much material from which to select have been used as an excuse for the abuse of hospitals and dispensaries, and to a certain extent such excuse may be valid. Students should become familiar with as wide a range of disease as possible. The didactic lecture in medicine and surgery is slowly but surely falling into the background, teaching becoming more and more clinical. Patients may be made to pay in their persons if not from their pockets. The student and clinical teacher demand material; the practitioner wants patients. When the student becomes a practitioner, his point of view changes. But he should not forget that he, when a student, probably gained in remunerative knowledge more than the equivalent of a few cases which, after he has gone into practice, seek advice at a hospital instead of paying his fees. Our direct losses loom up larger than our indirect gains. I do not mean to imply that a teaching-hospital is free from responsibility in regard to this matter. I merely want to indicate that there are two sides to this question, at the same time stating my conviction that very little injustice need be done if a due sense of responsibility is felt and influences action.

Complaint in the medical press of hospital out-patient departments and dispensaries seems to be endemic in England, and there has been of late an epidemic in this country; legislation on the subject has even been seriously considered. It is claimed that the doors of these institutions are thrown open so widely as to entail great hardships on many worthy members of the profession. That there is some ground for these complaints I fear there can be no question. For some eight years I did out-patient work in the Massachusetts General Hospital, and have no reason to believe that the conditions are materially different now from what they were at that time. The number of cases of deliberate intention to avoid payment for advice was, as I remember, small. Some residents of the city, apparently able to pay, came, seemingly without wrong intent, to get an opinion and see how far it coincided with that of their doctors. More came thus from the country, under the impression that the city must contain more wisdom, not knowing whom there to consult and not having told their regular advisers that they wanted further counsel. The reputation of the hospital, and sometimes the idea derived from the name, "Massachusetts General," that it is a State institution, to the benefits of which as taxpayers they had a right, determined their coming. Not infrequently patients would come, more commonly from out of town, either with their physician or with a letter from him asking for a consultation and perhaps a detailed opinion in writing—no light demand, considering the number of patients requiring attention.

For some years now at the Massachusetts General Hospital a paid medical officer has questioned applicants to the out-patient department as to their circumstances, and refused entrance to those who did not seem to him proper persons for free advice. It is also his duty to exclude such diseases as measles, scarlet fever, and the like from the waiting-rooms, in order that their spread may be limited. This is a plan which does not involve a hospital in great expense—$500 per annum at the Massachusetts General Hospital, with an average of about one hundred new patients a day—as the services do not require more than a couple of hours a day. It seems to me as efficient as any plan which has been suggested, and one which it is not unreasonable to expect all similar institutions to carry out.

There is another ground for complaint against hospitals, about which less has been said. I refer to the growing practice of attaching pay wards to hospitals, which, let me repeat once more, are founded and exist for charitable and educational purposes. Patients who pay from $20 to $50 per week for private rooms ordinarily serve neither of the above purposes, and provision for them here seems to me unfair and improper unless to a very limited extent. This is not a legitimate mode of providing revenue for the care of the sick poor. Our well-to-do citizens are amply able, and I am convinced more than willing, to provide for such cases through gifts, bequests, and taxes. The chances are strong that a hospital which cannot be maintained without the resort to this practice is in whole or in part unnecessary to the community in general, and should consequently, in whole or in part, close its doors until the community in which it is situated grows up to it. One great and well-known hospital derived $55,000 from this source last year. I am told that other great hospitals are making large investments in this field. I am perfectly well aware of the fact that strangers in the city fall ill in hotels, and that residents are for one reason or another sometimes so situated at their abodes that proper care is difficult or impossible to secure. I know what a boon it sometimes is to patient and physician alike to have access to a well-organized hospital. But this need not and should not be a charitable hospital. This class of cases is sufficiently large in every considerable city to maintain one or more hospitals or infirmaries—private, in that they are designed for private patients; public, in that any physician can send his patient thither and assume personal care of him, making such professional charges as his wisdom and conscience dictate. This is free trade in medicine. In a large hospital it is, from an administrative point of view, impossible to allow physicians other than members of the staff to care for patients within its walls. The small private hospital or infirmary can be made to yield a good return on the investment and no injustice is done to anybody. And it seems to me that injustice to somebody is inevitable when well-to-do patients are admitted to hospitals designed for the sick poor. If the staff is allowed to receive fees for attendance on such patients, its members are given an unfair advantage over those members of the profession without hospital appointments, and the hospital becomes a sort of medical trust. The indirect

benefits of hospital service are quite sufficient. If the members of the staff are not allowed to take fees, the well-to-do patient is injured by receiving gratis services for which he is able to pay and should pay; the time and skill of the attendant are diverted from the sick poor or from such use as he might wish to make of them; and the sum of professional earnings, now none too large, is unfairly diminished. Commercialism tends to degrade the medical profession, and, if well-to-do patients are to be cared for in our great hospitals, it seems to me that the evils of free are less than those of paid professional service.

The Massachusetts General Hospital has eight private rooms of the class I now allude to. Years ago the staff itself established the rule that no fees should be received for attendance on inmates of the hospital, and a printed notice to that effect is placed in each of the private rooms.

The hospital physician can keep his private hospital if he will, or he can, just like any other physician in the town, send his patients to an infirmary. The charitable and educational institution should not step in to save its staff the trouble of housekeeping and of providing and superintending nursing for patients in easy circumstances. It should not demand of its staff unrequited service save for the sick poor. It should not place any unnecessary obstacles in the way of full and free competition between members of our profession. To the exaction of the payment of a few dollars a week from patients who can afford it, who are treated in the ordinary wards, and who can be used for teaching if suitable cases, I can see no valid objection. The self-respect of the patient is maintained by rendering some return for much-needed care, which his circumstances preclude his securing at home, and no just ground for complaint is afforded practising physicians unattached to hospitals.

In this whole question we have a responsibility which we cannot escape. The more fortunate a man is, the more mindful should he be of the rights of others, especially of his professional brethren. The staff of the hospital or dispensary should co-operate fully with the trustees, giving them the full benefit of their more intimate knowledge of all professional matters, and always remember the broad therapeutic principle—"*Ne quid noceat.*"

CHANGEFUL PERSONALITY: A STUDY ON THE RELATION OF THE EMOTIONS AND THE MEMORY.

By J. LEONARD CORNING, A.M., M.D.,

NEW YORK.

In a paper on certain of the less cultivated phases of psychology,[1] notably those dealing with the genesis of feeling, read at a meeting of the New York Neurological Society several years ago, I was at some pains to demonstrate the precedence, both biological and psychological, rightfully belonging to the emotional or affective faculties. To add force to the argument, I was fortunate in being able to quote extensively from a paper by Mr. Lester Ward, a botanist and sociologist of renown, whose studies on cross-fertilization in plants and on allied matters have enabled him to adduce certain facts of great corroborative importance in connection with the evolutionary priority of the emotions. As a corollary to the main argument, the important relation of the feelings to the will was accentuated, and a plea entered for their more scientific management in hysteria and depressive states of the simpler kind. The present paper differs from its predecessor in this—that it embodies an attempt to show from the history of a case, rather rare and vastly interesting, how great is the significance of the feelings as cohesive factors in the recording segregation and revival of a multitude of mental impressions. The manifestations about to be described occurred in a married woman who was a sufferer from traumatic hysteria, and who, even in her relatively normal state, disclosed a somewhat low grade of intelligence. Cases of a somewhat similar type, described by Dufoy, Azam, and others, have evoked a suggestive commentary from Alfred Binet, the accomplished director of the laboratory of physiological psychology at the Sorbonne, with whose interpretation, however, I am not always able to agree.

Ignoring for the moment the purely historical side of the question, whose discussion would demand more time and space than I am able to give it, let me say at once that the case is an instance of what is variously known as "multiple personality," "alteration of personality," the "double ego," "day somnambulism," or "vigilambulism." What renders the affection of pressing interest is the fact that the patient, besides her normal life, leads one, two, three, or even more additional existences, of which she has no memory in her normal state. On the other hand, certain of the normal memories are revived during these pathological states; and later I shall endeavor to show upon what principle this selection of memories depends. The disorder, then, is truly well named, for the personality of the subject undergoes disintegration—is split up, not figuratively but actually, into distinct fields of consciousness, the cleavage between each of these states being marked by a strange lapse of memory, following and contingent, as I believe, upon an abrupt and striking change of the affective faculties.

When I speak of a chasm or cleavage between these states, I mean—most wonderful to relate—that each state has a separate memory of its own, a memory which does not embrace an iota of the neighboring morbid states, and whose restricted scope causes a disruption, a dismemberment of the normal field of consciousness: so that certain experiences and tendencies, receiving, as I believe, a gregarious impulse from the dominant mood, flock together in one autonomous group; while others, ruled, as it were, by a different mood, form still other and different aggregations. Thus, to yield to the lure of a bit of metaphor, consciousness, dismembered by an inscrutable upheaval, parts with its solidarity—is split into islands, between whose shores, bridged by no span of memory, blend the surges and the mists in an unfathomable obscurity.

With these elementary conceptions well-seated in thought, the full understanding of the following case, which occurred some years ago in the practice of the author, will present, I think, little difficulty even for those but slightly inclined to things psychological.

Till her fourth year Mrs. L. E—— exhibited every token of perfect bodily and mental health. About the latter part of the fourth or the beginning of the fifth year, however, she fell ill of meningitis. During the greater part of the time she remained unconscious, and when, at length, recovery took place, it was seen that her mental condition had suffered pronounced deterioration. Formerly cheerful and affable, she was now become fretful, self-centred, and wilful. If thwarted ever so slightly, she would burst into violent fits of anger, putting a sharp edge on her resentment with invective and not infrequently with blows. Though possessed of cunning, she is without judgment in the larger sense, being quite incapable of giving effect to her desires by even a moderate degree of prevision and rational persistency.

As she grew older, she disclosed such fickleness as to awaken astonishment throughout her youthful

[1] "Considerations on the Genesis of the Feelings," etc., MEDICAL RECORD, March 31, 1894.

acquaintance. No friendship was of long duration; she flitted from one schoolmate to another, bringing tokens of devotion—little gifts of bonbons, offered in a fit of querulous ardor. These ties, formed with all the extravagant precipitancy of melodrama, melted as quickly as the sweetmeat symbolism that foreshadowed their accomplishment. A word, a look, a gesture were sufficient to break these brittle attachments. Sometimes a gradual coldness preceded the end; but more frequently a violent explosion of temper caused the rupture. These outbursts were not those of ordinary childhood; on the contrary, their causeless vehemence bore the stamp of such unnaturalness that she was at first dreaded and ultimately shunned by all her schoolmates. Though stubborn and artful in matters touching her real or fancied interests, her will was feeble when attainment involved the inhibition of personal inclination. In her studies, therefore, quite irrespective of any obvious dulness of apprehension, she was strikingly deficient. A pronounced enfeeblement of the power of attention was no less baneful in its influence upon her attempts at acquisition. When taxed with her lack of attention, she complained that study caused a feeling of heaviness in her head, and when persistently urged to renewed efforts she became peevish, taciturn, and morose. This, so far as I have been able to ascertain it, is the story of her school days. Her history for the succeeding twenty-five years reveals substantially the same concourse of tendencies—tendencies which were little if at all modified by her marriage, which occurred in her thirty-fourth year. With the coming of the menopause, however, there was a change. This crisis, which occurred in her fortieth year, proved a severe ordeal; yet, thanks to skilful pilotage, she passed through it without manifest detriment, her mental condition remaining little if at all worse than before. For the sake of convenient discussion, I shall symbolize this, her relatively normal state, by the letter A.

We now come to the turning-point in the case—an accident. One day, while she was driving, the horses became restive, and, springing suddenly forward, imparted a lurch to the vehicle, that threw her, or, as she expresses it, "rolled" her over the back of the rear seat—a low affair—so that she fell all of a heap. The fall was not a high one, for the vehicle was but a phaeton, and no bones were broken. Unfortunately, however, the back of her head had struck with some violence; so that, although but slightly dazed and at no time unconscious, she complained of considerable occipital pain for weeks afterward. Nor will it cause surprise that, three or four months after the accident, she developed symptoms of traumatic hysteria, that common but troublesome sequence of moderate concussion. But if this were all, if nothing further had come of it, there had been no excuse for this writing. Let me say, then, to come quickly to the point, that merged with these hysterical symptoms, and under certain circumstances alternating with them, came a series of mental disturbances of unique interest, from both a clinical and a medico-legal viewpoint.

During my first interview with her, at this time, she appeared very restless, moving about constantly, and giving utterance meanwhile to an endless series of complaints. These she reiterated without ceasing, scarce pausing in the tirade to answer a question or take breath: "I am abandoned by everybody; I shall never recover; they want me to die," were some of the phrases she repeated over and over, to the discomfort of the ears of every one. She did not explicitly threaten to make an attack on her life, but spoke of suicide as something to be desired, since "the dead alone are happy." The expression of her face was characteristic: the eyes were wide open, the features were pinched and drawn, and the general expression was so dejected as to make it appear, at first view, that she suffered from melancholia agitata. She had been harried for long by insomnia and had taken various sedatives, but without manifest relief. Nevertheless, I prescribed a hypnotic, enjoining a repetition of the dose should she fail to fall asleep within the hour.

Next morning I received word that she had had at least seven hours of unconscious rest and was feeling "much brighter." An hour later she came of her own motion to my office, and truly the change I beheld was the most wonderful imaginable. Her face had taken on a contented, not to say joyous expression; she had parted with her plaints, her suspicion, and her depression; she no longer spoke of the desirability of death—her talk went rather to the felicities and privileges of living. I began to speak to her of her condition of the day before, and to congratulate myself half-playfully on the auspicious sequence of my efforts to relieve her. As she listened, her face changed; her eyes opened, and, in a twinkling, incredulity the most complete held possession of every feature.

"Last night, last night?" she questioned. "Why, I was asleep. And you, doctor, must have been dreaming, for I never saw you or took any medicine from you."

Presently, as if to ease the situation, she explained that "peoples' memories were dull," and that physicians were certainly excusable if in this respect they made "no better showing than the rest." Clearly, then, not only had she forgotten all the occurrences of the night before, but she was completely unaware that the fault lay with her.

This, the condition of depression, I shall call B: it persisted for nearly a week; and, frankly speaking, I had begun to regard it as the fundamental note of the case, when, arriving early one morning, I was astonished to find her up and about. But this, though at variance with her common habit, gave but small hint of the larger surprise in store. Indeed, even as I looked, she began to pace to and fro, in a kind of fever of locomotion, upsetting the furniture, bringing the bric-a-brac to grief, and behaving generally with such tumultuous disregard of the common maxims of decorum as to suggest at first glance the onset of an attack of acute mania. But, despite the flood of joyous chatter that accompanied this motor storm, there was, strictly speaking, nothing incoherent, nothing of delirium in her speech, which, though swollen and reflecting very exactly her native puerility of mind, maintained throughout a kind of maudlin consistency.

"Oh! doctor, I am feeling as though I could lift the town; I shall do something fine to-day—I shall buy a dress for Phœbe; go to the theatre—and the doll shall have a new dress. To-morrow, church!"

Speaking thus, she ran toward the door, declaring that she would go for a walk, although she had not yet breakfasted. By dint of persuasion, she was induced to remain till coffee was served. Of this she drank a cup, but of food she took little, making off at once, to wander aimlessly among the shops or bestow her largess wastefully on every beggar she met. The expression of her face at this time, benign and somewhat exalted, proclaimed the inner revel of "subdued delightfulness." To serve the ends of subsequent discussion, we may call this state C.

For nearly two weeks Mrs. L. E—— remained in the state last described; then suddenly, as if yielding to the sway of some hidden sorcery, her feelings underwent a change. She became fretful; found fault with everything that was done for her; complained that all her goings and comings were noted by those inimical to her; and kept all about her in a perpetual fever of annoyance. Suspicion, groundless and grotesque, constituted, in fact, the fundamental note of this new transformation. She exhibited, moreover, the

most astonishing vagaries of memory. Certain of the impressions hoarded during her relatively normal condition (A) were readily revived; while those gathered during this, her last transformation, which I shall designate as D, possessed a vividness truly astonishing. On the other hand, the memories of B and C were not revived during D, either spontaneously or yet by direct or indirect questioning. Here, as formerly, there was no delirium; she went about, conversing of her affairs according to her wont; attending to such small matters of business as demanded her attention; behaving, in short, with as much logical consistency as she ever did. In her disposition, however, all was changed. Such small adjuncts of tenderness as were visible in A, her comparatively healthy state, and exaggerated in C, her exalted state, she had now parted from completely. A rancorous suspicion now dominated everything she did; and in the place of that idle chatter, that ultimate sublimate of emptiness, so prominent in C, had come an era of slanting looks and malevolent planning.

In this state she remained several days—five or six at least, if my memory serves—to lapse in the end into what seemed to me a kind of amalgamate, half A and half B.

Diagnosis.—And here you may ask, and I think justly, "By what road must one go to win to a correct diagnosis? How is the thing to be achieved?" To say truth, the problem, though somewhat intricate, is not so difficult of solution as may appear at first glance. Indeed, the old adage, "*Nulla dies sine linea*," if intelligently applied, cannot fail to yield a significant and adequate return. To be sure, the note taking, at first desultory and unguided, may represent in the aggregate nothing more than an enigmatical hodge-podge, a kind of verbal ragout of hopeless irrelevancy. Gradually, however—and more especially if the moods as well as the sayings of the patient be noted—a species of provisional order emerges from the wordy chaos. Certain ideas are perceived to be indissolubly attached to their emotional analogue; and the memorial pabulum for them, or much of it, is quickly seen to be derived from the subject's normal state. During the persistence of the morbid emotional state, however, other experiences are added. These, as far as possible, should be most carefully noted; for, with the disappearance of the morbid emotional state and the return of the subject to her relatively normal condition, it becomes an easy matter to prove that of these memories, hoarded during her unnatural mood, she now retains not a vestige of recollection.

Thus, by noting what is said, done, and recollected during each morbid change of feeling, it becomes possible, by a species of mental subtraction, to determine pretty exactly the limits of the different fields of consciousness. These precipitate and wholly unnatural changes in the subject's affective life constitute, indeed, the most infallible warnings of the impending disorders of memory. From the facial expression, conversation, and demeanor of the patient, it should, moreover, be easy to gather evidence sufficient to determine that an emotional change of this kind has taken place. Thus, thanks to memoranda and diligence in questioning, it is possible to arrive at a satisfactory synthesis.

Addenda and Commentary.—On reviewing this case, remarkable alike in its immediate and collateral bearing, one cannot repress the suspicion that the phenomena are ultimately traceable to a distinct physiological cause. There, engrafted in the early history, is the lesion—meningitis—followed by a distinct and permanent change in the disposition of the subject—surely predisposition in plenty; then, years afterward, the blow on the head, with the quick appearance of hysterical symptoms, the latter apparently but little if at all enhanced by the ordeal of the climacteric. Here, obviously, is the immediate incitement of the trouble.

But what adds, in my opinion, the ultimate of probability to this interpretation is the fact—not sufficiently accentuated in the history—that just previous to a change of personality, and notably so before the change from A to B and from B to C, the patient complained of various paræsthesiæ—tingling and numbness before B, I remember, and marked hyperæsthesia before C, the relatively exalted state.

Yet, just as in the psychosis of epilepsy the motor disturbances give place to the mental ones, so here the sensory anomalies make room for their psychical prototypes: the anæsthesia goes off at the coming of melancholy, the hyperæsthesia gives back before the spirit of gleefulness.

Moreover, from such observation and analysis as I have been able to bring to the elucidation of this case, I cannot repress the conviction that, primarily at least, we have to do with an affection of the emotions, or rather of their underlying mechanism—a mechanism as yet but crudely understood, I regret to say, by either anatomists or physiologists. For long it has been the custom to lay a superlative, ay, almost an exclusive stress upon ideal association as the cohesive element in memorizing. When, however, we come to a full appreciation of how vast hosts of impressions are enmeshed and held together by the frail gossamer of mood, and how often their subsequent revival is contingent upon the reproduction of that mood, it is no longer difficult to understand how a breach in this diaphanous web of feeling inevitably entails the elimination from consciousness of legions of dependent memories. And again, just as in absent-mindedness—which is truly nothing more than the extreme of focalization in thinking—only ideas germane to the ruling trend of thought are admitted to the field of consciousness, so here, too, only such ideas and memories as coincide with the dominant note of feeling find conscious recognition. All memories falling short of this requirement are barred; while those whose content allies them with identical or close-related moods enter freely, thanks to an innate open sesame.

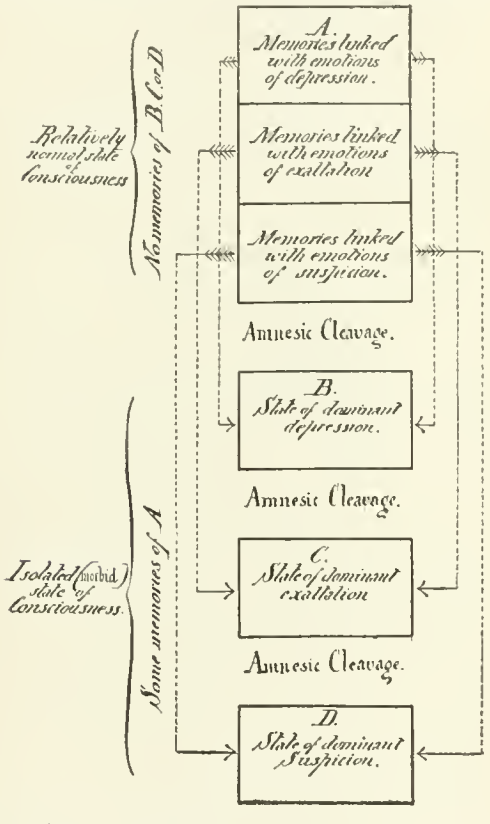
This explains, it seems to me, the intrusion into the morbid and mutually unrelated states B, C, and D, of memories proceeding obviously enough from A, the relatively normal state. Besides, on close scrutiny of the memories thence derived, it appears that only those of a sombre hue are remembered during B, only those of an exalted kind during C, while to D alone are linked the more sinister remembrances. Here, in this truly wonderful phenomenon, we have the capstone of the argument.

Indeed, if interpretation of the phenomena were all, the unravelling of the skein of psychological intricacy the ultimate goal, we might rest now, perhaps, with some confidence, with some sense of sufficiency of the explanation already unfolded. But there is the spirit of the *vis medicatrix*, that haunting wistfulness to make better, to be ever up and doing. And, as heirs of this altruistic bias, you will ask no doubt, "Is anything to be done for these unfortunates?" Yes, and no. On the one hand, it is certainly possible—and I have verified the possibility on more than one occasion—to change one emotional state into another, not by hypnotism, which in my experience is quite uncertain, but by the adroit use of stimulants followed by, or rather coupled with the use of certain sensory appeals, notably those of sight and hearing. Of this I hope to speak at length hereafter. But, on the other hand—to my infinite disappointment, be it said—it is not possible, or through my own management, at least, it has not been possible, to perpetuate the change from a baneful to a relatively normal emotional state. In

short, I have been able to change the mood B to A for several hours, and on one occasion for several days; but, just as hope was at high tide, there came a relapse, not necessarily to B, but to some one of the morbid states, with the consequent discouragement of all concerned.

Disappointing as seems the issue when viewed from a purely practical standpoint, it is freighted none the less with a physiological meaning not to be mistaken. Indeed, the fact that remedies which conspicuously kindle the emotions are capable of altering even evanescently these abnormally fixed moods, with the consequent change in the whole series of dependent memories, goes far to sustain the position maintained throughout this paper touching the very great dependence of ideational memories upon the imperative moods with which they are allied.

In conclusion, I have tried to make plain this principle of the emotional linking of the memories by a simple diagram; and if, on the whole, I have made



myself fairly understood, I shall feel in part reconciled to this quick relinquishment of a great subject, vexed only that I have not been able to provide a more complete illumination.

53 West Thirty-Eighth Street.

Multilocular Putrid Pleurisy without Gangrene.—Dr. E. Boinet (*Le Progrès Médical*, January 1, 1898) has reported a case of putrid multilocular pleurisy without gangrene of the lung or of the pleura, with pneumothorax accompanied by gaseous exhalation. M. Widal has already described such a case. A man, forty-two years of age, developed on the left side a pneumothorax without apparent cause. His general condition was bad; the fetidity of the pus obtained by an exploratory puncture decided them to practise an operation for empyema; an incision of ten centimetres gave an issue of gas and of pus having a very repulsive odor. The patient died in spite of all disinfecting irrigations. The autopsy showed that at the side of the cavity opened two other cells existed, which were filled with pus and gas; one of these compressed the heart. There was no trace of gangrene either in the pleura or in the lung.

THE SURGERY OF THE PREPUCE AND MEATUS.[1]

By B. H. DAGGETT, M.D.,

Buffalo, N. Y.,

Genito-urinary Surgeon, Erie County Hospital and Sisters of Charity Hospital.

I exclaim, with St. Augustine: "If what I have written scandalizes any prudish persons, let them rather accuse the turpitude of their own thoughts than the words I have been obliged to use."

The glans penis and its adnexa are frequently the seat of morbid phenomena, which are either local in their results or are the initial, precursory signals of a systemic storm. To-day I shall discuss only two abnormal conditions involving these structures and which call for surgical interference: they are the phimosed prepuce and the stenotic meatus.

The man child is born into the world phimosed, and, if he lives to old age uncircumcised, goes out in the same condition. After a few years of growth and development, together with frequent ablutions, this condition is usually satisfactorily adjusted by nature and all goes well, until, with declining age and abatement of the genital function, the wasting phallus again withdraws within its preputial folds, and becomes redolent with urinary and smegmatic exhalations. The redundant foreskin often develops inflammatory conditions, induced by retained secretions and absorption by its receptive folds of extrinsic, morbific material, followed by thickening, induration, ulcerations, œdema, and adhesions which frequently prohibit its retraction. These conditions call for surgical interference.

There are advocates of general circumcision who claim that it promotes sanitation and health, and who refer to the Jews, noted for their longevity and immunity to disease. Richardson, in his "Diseases of Modern Life," says: "The Jews escaped the great epidemics more readily than the other races with whom they lived. Different causes have been assigned for this higher vitality of the Jewish race, and it were wise to seek for these causes, since that race which presents the strongest vitality, the greatest increase of life, and the longest resistance to death, must in course of time become, under the influence of civilization, dominant. We see this truth, indeed, actually exemplified in the Jews: for no other race has ever endured so much, or resisted so much. Persecuted, oppressed by every imaginable form of tyranny, they have held together and lived, carrying on intact their customs, their belief, their faith, for centuries, until, set free at last, they flourish as if endowed with new force. They rule more potently than when Solomon in all his glory reigned in Jerusalem. They rule, and neither fight nor waste."

Remondino, in his "History of Circumcision," says: "If circumcision is not a factor in the differences that exist between the Jewish race and other races, if it goes for nothing as an exemptor of disease and the promoter of longevity, then there must exist some other factor or cause that induces these conditions. What this factor is, the legislator, the sociologist, and the physician should make it their business to find out."

Ricord says that the prepuce is "a useless bit of flesh." Remondino says: "It has neither use nor beauty;" while Puzey, of Liverpool, claims that it makes most excellent skin grafts, unequalled by those from any other portion of the body; that their vitality is greater, their healing quicker, and with less chance of failure. This might be used as an argument for the negative side of the question. The command to

[1] Read before the Alumni Association of Niagara University, June 12, 1897.

Abraham reads as follows: "This is my covenant, which ye shall keep, between me and you and thy seed after thee; every man child among you shall be circumcised. And ye shall circumcise the flesh of your foreskin; and it shall be a token of the covenant betwixt me and you."

Paul was charged with disregarding the law, forsaking the teachings of Moses, and attempting to abolish circumcision.

It is claimed that the prepuce, like the climbing and auricular muscles and some other supposed functionless organs of the body, is a relic of man's sylvan and barbaric existence, which has not yet been eradicated in the progress of evolution. In those early days the prepuce served to protect the glans from erosion by brier and bramble, as man sped upon all fours through primæval forests or climbed the first friendly trée to escape his gastronomic enemy. During those days of early primitive unwashed civilization, and among the early Christians of the East, who mingled piety, filth, and continence, this lax structure often became the source of unnumbered woes. These people were unlike the Mohammedans, who circumcised, washed, and sinned.

The removal of the foreskin by circumcision is a procedure older than history, and is traced back into the mists of tradition and mythology. There is a legend that one of the Atlantean kings ordered his whole army circumcised, that it might escape a prevailing scourge. Bergman states that circumcision was at one time performed for the purpose of giving an indestructible mark of servitude.

Circumcision has been performed as a purely religious rite, a covenant, and an offering, without any thought of sanitary benefit, and had its origin as a general practice with the foundation of the Hebraic creed in the hills of Chaldea. It was practised by the Egyptians in the sixth century B.C., alleged by Herodotus to have been strictly a religious rite. The circumcised were looked upon with disfavor in the fifth century. Pythagoras was not granted the privilege of the Egyptian temples until he had submitted to this operation. The practice was common among the Arabs long before the days of Mohammed, who was himself circumcised and who is reputed to have said: "Circumcision is an ordinance for man, and honorable for women." It spread under the banner of Islam, and the uncircumcised were regarded as impure. In Turkey a tax was levied upon the uncircumcised, while in Rome it was placed upon the circumcised. Many savage tribes in various parts of the world practise some one of the different methods of circumcision, associated with elaborate ceremonies and curious observances. The Bassanta of Australia use the circular incision, the excised portion being placed upon the middle finger of the left hand as a ring.[1] Some of the Arab tribes circumcise just before, and some just after marriage. Sarah conceived after the circumcision of Abraham. It is evident that there was more than a sanitary or ritual purpose in the observance of this practice, since the circumcised phallus was an emblem of civil or religious orthodoxy, the symbol of national honor, an object of worship, and was grasped with the hand in the execution of the jurat of the period.

Circumcision was designated as a law of perpetual obligation to the Hebraic family, under the penalty of excommunication. There are, however, Hebrews who look upon this practice as an arbitrary rule of the remote past, and allege that it is hygienic; that it has no ritual significance; and that in modern times it has no purpose or use except such as relates to pathology and surgery.

The prepuce may be entirely absent, but usually is present, varying in redundancy, and redundancy is the rule.

"Phimosis" is a term signifying "to tie with a string," and its use is indiscriminately applied to both the redundant retractible and the redundant non-retractible prepuce. The complications arising from these conditions are balanitis, balano-posthitis, adhesions, hemorrhoids, bladder irritability, hernia, dilatation of the bladder, ureters, and renal pelves, reflex irritation, causing retention and incontinence of urine, arrested development and distortion of the glans and urethra, sexual excitement, seminal weakness, spastic palsies, pseudo hip-joint disease, muscular inco-ordination, convulsions, impotency, cancer, and herpes. The folds of the redundant prepuce serve as a purveyor, a habitat, and conveyor of venereal virus. "If it offend thee, cut it off"—it is an outlaw.

There are several different procedures used in the surgery of the prepuce. The most ancient and classic is circumcision, which consists of the removal of the entire foreskin. The glans is grasped laterally, just over the corona, with the circumcision forceps inclined at an angle of about thirty degrees to the penal axis, to escape the frenum. As the integument is drawn down, the glans slips behind the forceps; the projecting foreskin is transfixed, and cut both ways by a sawing-motion with a very sharp knife. Opening the forceps frees the skin, which slides over and behind the corona, leaving the glans covered with mucous membrane, which is slit on the dorsum and either side of the frenum. The resulting flaps are then trimmed, leaving only sufficient border for stitching to the skin. The first stitches are taken in the back and in the front. The wound is then dried and powdered. Wet dressings can be avoided by using borated vaseline or moist gauze, which will keep the parts soft. For wrapping, a small roller or the Maltese cross is used. The dressing is held in place by means of adhesive plaster. It has been recommended to apply Friar's balsam with a brush, as a protective dressing to the wound and exposed dressings. The technique of this consists in winding over all some strips of absorbent cotton, and supporting the same with a T or a suspensory bandage. Healing occurs in from four to ten days. This operation removes the entire foreskin, and the glans is constantly exposed to the buffeting of a cold and heartless world, which hardens its delicate and sensitive papillæ, destroys Tyson's glands, causes absorption and induration, and renders the procreative act less ecstatic.

There is another procedure in vogue, which consists in splitting the prepuce through the middle line of the dorsum from its margin to the coronal sulcus. This practice makes two large lateral ears, which are neither ornamental nor useful, and hence are objected to by adults on æsthetic grounds. Paring off these flaps after such slitting is done is not tidy in its results.

The offending foreskin may be slit up by the side of the frenum — an operation proposed by Celsus, revived by Cloquet, and condemned by Ricord and others. This incision is made by transfixing the prepuce through the corono-frenal pouch, and slitting down to the margin of the foreskin, thus severing all of the constricting bands. The point of the bistoury is made probe-like by a ball of hard wax, which guides the blade into the pouch, and then the ball of wax and the tissues are penetrated at the same time. The operator must exercise care, lest he pass the blade of his instrument into the urethra, and thus produce an artificial hypospadias.

Remondino, in selected cases, such as the narrow and not too long foreskin, commends the combination of the dorsal and inferior slits. He recommends a dressing made with two layers of gauze, shaped like a Maltese cross, and perforated in the centre to admit

[1] Remondino: "Circumcision."

the glans. The short flaps are folded back around the body of the organ, and held in place by means of narrow strips of adhesive plaster or of collodion. He claims that this operation is less severe, less painful, and less bloody than circumcision, and that it does not keep the patient from business. Nature will round off the protruding corners left after slitting.

Dilatation and divulsion have been recommended, and several instruments have been devised for this purpose, but the results have not been satisfactory and this plan has not been accepted by the profession.

Lallemand proposed transfixion of the prepuce on the dorsum, and from this transfixed point to cut away the flaps.

MacLeod, of Edinburgh, places the sutures in position before cutting, by passing them through the fenestra of the forceps. After excision the sutures are picked up in the centre, thus making two sutures out of one. This method of stitching makes a thick, cumbersome, preputial border, as the intervening tissue between the integument and the inner membrane is tied in with the stitches and the mucous membrane everts. The claim that it is less painful than stitching after the cutting, cuts no figure in these days of anæsthetic surgery. Another objection is that the inner membrane cannot be shortened sufficiently to prevent eversion, and the constricting bands may be reformed in the connective tissue and inner membrane, so that phimosis reappears.

Gross favored the double slit, dorsal and anterior, and claimed that the resulting deformity would disappear.

Van Buren and Keyes recommend the combined dorsal slit with the Ricord-Bumstead operation of circumcision.

Lisfranc, Coster, Vidal, and others proposed different modifications of these procedures, which are mentioned in print but never used in practice.

Ligature and the cautery knife have been used to slit the prepuce longitudinally or transversely.

It has been proposed to slit the prepuce with a straight narrow bistoury on the inner surface, and thus divide the mucous membrane and tissues through to the integument. These slits are to be made along the longitudinal lines.

The writer suggests for your consideration a new

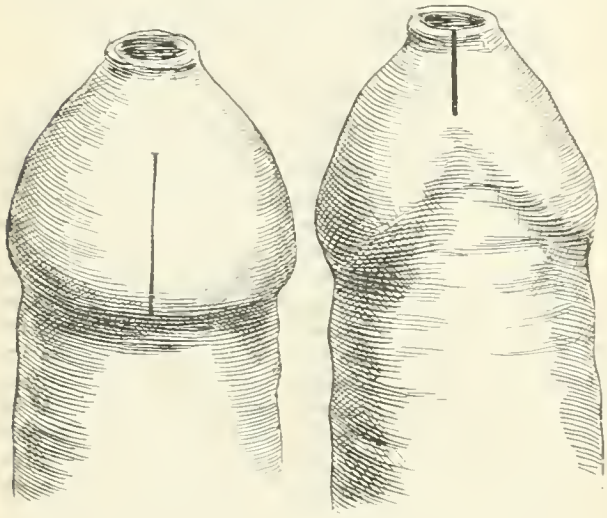


Fig. 1.—Dorsal Slit or Incision. Fig. 2.—Inferior Slit.

procedure for this operation, which consists of a modified combination of the dorsal and inferior incisions. The dorsal cut is in the central line, extending from the anfractus to within about one-third of an inch of the preputial border. The line of the proposed incision having been marked, a puncture is made at the distal end with a sharp point of the bistoury, and a loop of ligature is passed through this cut, for the purpose of drawing the prepuce tense and holding these mobile and lax structures in proper place for incision. The probe point of thin long-bladed scissors is now introduced into the puncture, and the entire cut through all the tissues is made with one movement, so that the incision shall be straight, uniform, and inclusive (Fig. 1). The inferior incision is made from the preputial

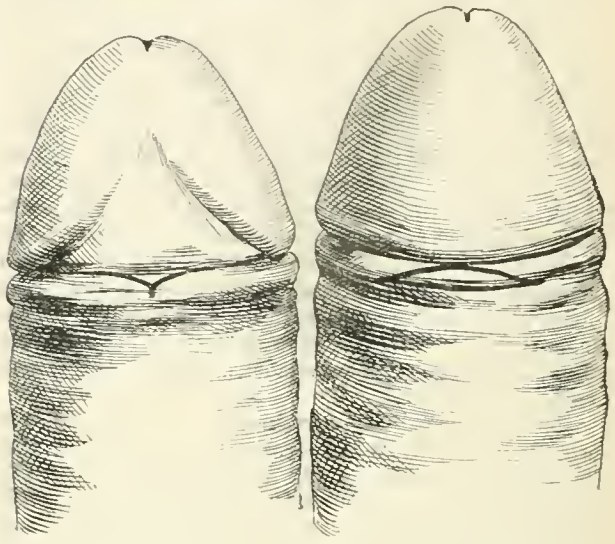

Fig. 3.—The inferior slit enlarges the prepucial orifice. Fig. 4.—The dorsal slit becomes transverse by retraction of the prepuce.

margin directly backward for a little more than one-third of an inch, or sufficient to overlap the dorsal incision (Fig. 2). These cuts will sever all the constricting tissues of the foreskin. The lower incision is stitched with a fine needle and ligature, so as to unite only the inner membrane and the integument, thus making a thin finished border for the enlarged preputial opening. The foreskin is then drawn back behind the corona of the glans, and these incisions will be transverse instead of longitudinal (Figs. 3 and 4). The dorsal opening is united by fine sutures in this transverse position, and the edges of integument only are to be stitched together. The prepuce is to be held in this position by the dressings described above, which are not to be removed for four days, unless there are surgical indications for interference. Brush over the exposed portion of the dressings with Friar's balsam to prevent absorption, and leave the apex of the glans free: pack with absorbent cotton, and apply the T-bandage. If the parts become dry and painful, apply properly medicated vaseline or moist gauze, without disturbing the first dressing. After about four days, the healing will be complete or well advanced, when the entire dressing may be removed, freeing the foreskin so that it may be drawn down upon the glans. This operation shortens and widens the prepuce: it sacrifices no tissue; it neither mutilates nor deforms; it reconstructs and creates a cosmetic, æsthetic covering and protection for the sensitive glans. "The Tysonian brood" is also preserved in both structure and function.

There is no single operative procedure applicable to all of the varying pathological conditions of the prepuce. The surgeon must choose his method with his patient before him. The surgery of the prepuce will test the mechanical skill and judgment of the operator —it is not a trivial matter.

The ostium cutaneum of the urethra may be only a pinhead hole, or it may be a vertical slit varying in length. The urethral meatus may be stenosed sufficiently to obstruct urination and necessary instrumentation. This condition calls for surgical interference, and an operative procedure called meatotomy is done. The membrane forming the ostium cutaneum, the im-

mediate urethral opening, is a flexible and dilatable structure, unlike the immobile, inflexible tissues of the glans proper surrounding the balanic urethra. The glans contains but little muscular or fibrous structure; hence forcible dilatation is contraindicated in this region. Irritation and inflammatory products thicken and sclerose the walls of the balanic urethra, and in this way narrow and constrict its lumen. Incision is the indicated operation for relieving this condition. At the proximal and lower border of the balanic urethra there is a transverse fold of membrane called the valve of Guerin, and located on either side of the vertical walls of this canal is a fold of membrane, varying in volume and extending from the ostium backward and slightly downward into the navicular fossa, which, when the lips of the urethra are opened, sometimes gives the appearance of two urethral canals, or a result of a previous balanic urethrotomy (see Figs., *A*, *B*, and *C*). One or more folds may be found upon the walls of all meatus. The function of these folds is to make a more complete nozzle of the inelastic meatus. These folds of membrane occasionally unite, forming a complete septum, and in this event the upper opening leads into a closed pouch. The membrane binding the immediate urethral orifice is slightly hooded over the upper point of the vertical canal, and also stretches across the lower apex, forming a fourchette or threshold. These structures are undoubtedly created for some useful purpose. The ostial membrane forms a gate or door at the meatal orifice, and serves to protect the nervous and muscular papillæ located in this portion of the urethral mucosa. The urethral canal is the most sensitive and vulnerable of all the mucous-lined orifices of the body. The membranous margin of this canal serves to protect the urethra from infection by sexual contact, and is a guard against mechanical, chemical, and other irritants. It also forms a nozzle for shaping and guiding the ejections impelled therefrom; also a retrenchment for the normal secretions of the parts. Cutting down through the fourchette, and even into the frenum, as is often done when meatotomy is performed, destroys the nozzle and breaks down the threshold, so that the urinary stream is broadened and thinned, causing dripping during urination, and the mucous secretion is constantly drained away.

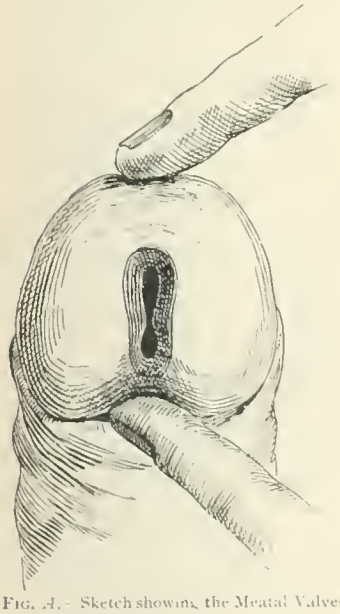

Fig. *A*.—Sketch showing the Meatal Valves.

Such an operation as this is unnecessary and unsurgical. It produces an artificial hypospadias. The operation of choice for meatal or balanic urethral stenosis is internal balanic urethrotomy. It is not necessary to incise the ostium cutaneum, since it readily dilates, and it is not usually necessary even to nick it. The balanic portion of the urethral canal is inelastic, immobile, and non-extensible; while the other portions of this canal are more or less elastic, mobile, and extensible. The vertical, bulbous form of the balanic urethra, and its lateral and longitudinal mucous folds or valves, serve the purpose of the constricting elastic and muscular tissue found in other portions of this wonderfully constructed organism; more than this, they guard from without as well as from within.

The operation for enlarging this portion of the urethral canal consists in making two or more longitudinal incisions, the Otis urethrotome, sufficiently dilated

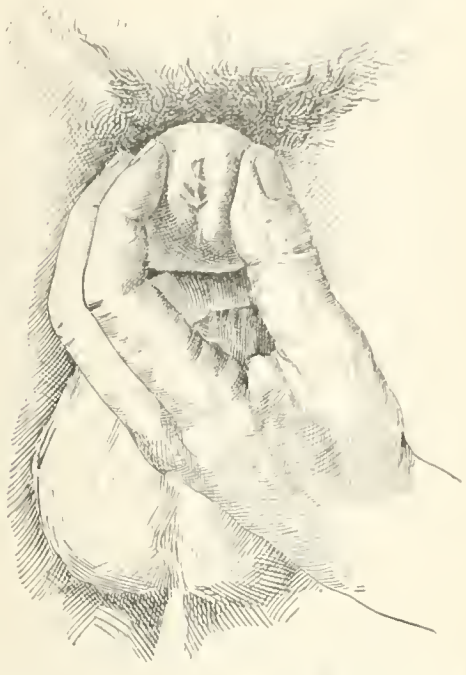

Fig. *B*.—See "valves of Daggett" on the walls (lateral) of the urethra. These folds or valves are frequently distinctly marked. In this case they form a crescent-shaped septum with a blind pouch above. The function of these folds is to give shape or form and force to the ejections.

to fix it in place, being used. The bottom or floor is first incised. Reverse incision is then made at the top of the canal, the blade being drawn forward until the orificial membrane bulges. This should extend up to but not through this membrane, with the deeper cut of the two at the top. If these cuts do not sufficiently enlarge the lumen, the vertical canal should be cut in a similar manner, on either side, and I am not sure but the lateral incision should be the cut of choice. These incisions may be made with a probe-pointed bistoury having a convex edge, the urethral canal being held open by a wire-spring speculum. These operations are very satisfactory in their results, and do not impair the usefulness or present ability of the organ. The narrowing is relieved, without leaving any external evidence of an operation. Thorough cleanliness and antisepsis must be observed, and the patency of the enlarged lumen is to be maintained by the passage of sounds. The meatus opening presents two small lateral lips, with numerous delicate papillæ, and is lined with pavement epithelium extending back into the fossa. This formation serves as another of nature's guards against absorption, lodgement, and penetration of infection.

Fig. *C*.

The appearance of the meatus is often an index of disease. When carefully observed, it gives us hints as to the condition within the urethral canal, just as the tongue tells us of the disturbance of the digestive tract:

1. A bright red, bulging, and œdematous meatus indicates acute urethritis.

2. A dull red, patulous meatus indicates passive congestion of the prostate.

3. A dark red, puffy, herpetic meatus, with a flabby elongated prepuce, indicates senile hypertrophy of the prostate.

4. A blanched, anæmic, and pinched meatus indicates atrophy or tuberculous wasting.

I have endeavored to describe only two surgical conditions relating to the "distal inch," time on such an occasion as this being too limited to consider other affections of even this small portion of the genito-urinary system—that wonderful system of twin functions, so fertile for human weal or human woe. Through the lumen of these structures passes the effete material of the great eliminating organs of the body as well as those germs of life which fit man for consummating the sacred injunction to "multiply, increase, and replenish the earth," and in this way to bear humanity onward toward eternity and immortality.

847 Ellicott Square.

THE QUESTION OF INSTRUCTION IN DISEASES OF CHILDREN.

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

Pædiatrics has been happily called the specialty of the general practitioner by the editor of the *Archives of Pediatrics*. It is certainly true that a large portion of the work of the average physician consists in attention to the ills of infants and children. This is as it should be, as pædiatrics properly forms one of the branches of general medicine. It deals with the general diseases of the body at a time of rapid growth and development, when the great physiological activity is apt, upon slight provocation, to become pathological. Although special study is required to recognize and properly treat the peculiar forms disease may take at this time of life, it is with the whole organism, and not with any single organ, that pædiatrics is concerned. Hence its kinship is with general medicine rather than with any specialty. The lamented O'Dwyer, whose name will be longest remembered among the present workers in pædiatrics for what he accomplished, was always a general practitioner. While pædiatrics should not be looked upon as a specialty, it certainly requires special study, as hinted above, to attain proper expertness in diagnosis and treatment. Some diseases are practically confined to early life, while others assume a peculiar type at this time. The physical and rational signs of disease also differ widely from adult life. While these facts are mere truisms to those who have given thought to the subject, the schedules of our medical colleges do not show an appreciation of their importance. It is certainly true that a good proportion of the men who are yearly graduated are in more or less ignorance of the branch of medicine that will form the most important and vital share of their future practice.

It is equally true that more mistakes are made in dealing with infants and young children than in any other branch of medicine. When the college course could be compassed in two years, there might have been some excuse for neglect of this vital branch: now that three and four years are properly employed in study, it is inexcusable. That the colleges do not appreciate the importance of a thorough teaching of pædiatrics is recognized most strikingly in examining candidates for hospital appointment, where the best men are apt to appear. Recently the writer examined thirty-five men upon diseases of children—candidates for positions in one of our large hospitals. These thirty-five candidates came from ten colleges situated in various parts of the country. The majority, however, were recent graduates from the large colleges of Boston, New York, and Philadelphia. They were bright looking, apparently well posted in general medicine, and were probably above the average output of their colleges. Upon pædiatrics, however, they all stumbled badly. Not one could give, in a proper manner, the physical signs of empyema in a young child; they all gave the signs that might be looked for in an adult. From the examination it is fair to suppose that all would have overlooked a common, insidious, and fatal disease of early life. And so with all the other questions. They apparently were fairly posted upon the physical and rational signs of disease in adults, but had no conception of the frequent changes of these signs in early life. They answered properly what they had been taught, and then were dumb. Another recent experience exemplified the young graduates' poor training in pædiatrics. The writer, as one of the examining board, listened to the replies of candidates for the position of interne in a hospital for infectious diseases. There were four simple but comprehensive questions, as follows: symptoms of measles; complications and sequelæ of scarlatina; causes of death in diphtheria; tests for albumin in urine. None of the eight candidates gave any evidence of thorough training and instruction upon the first three subjects. One of the most promising-looking men replied that high temperature and œdema of the glottis were the causes of death in diphtheria, and no amount of gentle prodding could make his knowledge expand upon this important topic. This abundant ignorance on the part of graduates will continue until the colleges give proper attention to pædiatrics. The fault is not with the teachers, but with the schedule. One clinical lecture a week in the last year, with possibly a little dispensary work, is not sufficient. A regular didactic course of instruction, fortified by thorough quizzing, should be the foundation. Later on, the clinical lecture and section demonstration will serve to clinch and apply the knowledge already gained. Aside from the special information thus procured, the training in and for general medicine will be of great value. Until the colleges get rid of the idea that pædiatrics is to be classed upon their schedules with diseases of the eye and ear or the nose and throat, the defect will continue. These valuable branches are taken up last, as a sort of accomplishment, but diseases of children form a necessary and fundamental equipment for the average practitioner and should be so treated. As it is, most young men on graduation go out to cope with what will probably prove the largest part of practice with the same amount of instruction that has been bestowed upon the extreme specialties. Unfortunately, this lack of early training is often never made good, as those who are teaching in our post-graduate institutions can testify.

Postanæsthetic Paralysis.—Dr. Schwartz (*Revue de Thérapeutique*, January 1, 1898) cites a case of paralysis of the crural triceps and of several flexor tendons of the fingers coming on after an operation for the radical cure of inguinal hernia. After a comparison of facts he concludes that chloroform during the period of excitation favors the production of small central hemorrhagic foci in arterio-sclerotic subjects.

Progress of Medical Science.

Nephrectomy and Pregnancy.—Dr. G. E. Twynam (*British Medical Journal*, February 12th) says that his own view as to wherein the safety of women under these conditions lies is that the answer is to be found in an increased action of all the emunctories of the body and not in hypertrophy of the remaining kidney or of the heart only. Analyzing all cases upon which he was able to obtain notes it was found that: 1. All the women who went to term made good recoveries, although Schramm notes a long recovery. 2. Slight albuminuria was noticed in Schramm's case and in one of his own. 3. A tendency to ventral hernia in one case. 4. Liquor amnii was not excessive in any case. 5. Marked œdema was not noticed in any case. 6. Schramm noted an irregularity of the pulse shortly after the confinement, although hypertrophy of the left ventricle was present. 7. Morning vomiting was severe but not dangerous in one case. 8. The forceps were used in one case only, and then merely to prevent ventral hernia. 9. Eclampsia or uræmia did not occur in any case that went to full term, but did in one of his cases shortly after miscarriage. 10. All the children were healthy, and in Tridondani's and in one of his cases it was specially remarked that they were the healthiest the women bore. 11. In all cases the mothers nursed their children. He thought that it could fairly be concluded that women can, after a nephrectomy, bear children without very great danger to themselves, provided their organs and the remaining kidney are healthy.

Gastro-Enterostomy for Pyloric Cancer.—Dr. Arthur E. Barker (*British Medical Journal*, February 12th) gives a brief account of the last four cases of gastro-enterostomy that he has had. In reviewing these four cases he calls attention to the fact that the patients were all operated upon too late. Two died from the operation, one from the shock, the other from inanition, perhaps aggravated by shock. The two others recovered from the operation, the parts uniting perfectly and leaving nothing to be desired as regarded the functions of the new openings. But in one of these cases the stomach, injured by prolonged dilatation and putrescence of food with bacterial fermentation, was the seat of ulcers, one of which ruptured an artery, causing fatal hemorrhage. In the other case, although the relief of symptoms after operation was most marked, the cancerous ulcer was too far gone in destructive change, and opened into the peritoneum just when he hoped the patient would be able to leave the hospital. In one case he used Senn plates; in another, a Murphy button; in the remainder of the cases he used his own method. So far as his own experience goes, taken with other cases of intestinal surgery, he feels justified in forming the conclusion that he would certainly prefer simple suture with fine silk to any other contrivance. The absence of free hydrochloric acid in two of his cases, in most of the washings of the stomach, strengthens the view generally held on this point. His experience on the whole is not very cheering as regards gastro-enterostomy for advanced cancerous disease of the stomach, but as far as it goes appears to deserve to be recorded, and it strengthens the belief that if done early the operation can give relief.

The Treatment of Fractures by Massage and Mobilization.—Dr. Lucas Championnière (*Le Scalpel*, January 2, 1898) presented a patient at the Academy of Medicine of Paris who had had a fracture of the inferior extremity of the left humerus. The cure was perfect and had been effected by massage and mobilization from the first. Apropos of this case Dr. Championnière said that immobility is not an indispensable element nor even a useful one in the treatment of fractures. A mobilized bone with peripheral massage repairs itself more quickly and more easily than an immobilized one. A great number of fractures of the humerus are amenable to this same treatment, all those from the finger to the elbow and those which are superior to the insertion of the deltoid. Adult and aged subjects are those most benefited by this treatment. These principles apply not only to fractures but also to all tissues which have undergone traumatism. Immobility does not favor the repair of tissues or of organs; movement is as necessary to their repair as to their life. Immobility in surgery is harmful and should become a thing of the past. Dr. Péan acknowledged that the results obtained were all that could be desired, but could not agree to a general application of this method. It is advantageous in transverse fractures when the displacement is slight, but when there is a fracture of the olecranon or an intercondyloid fracture he felt convinced that immobility for some days gives most excellent effects. The method of Dr. Championnière may be all right in his hands, but complications are likely to arise when less experienced surgeons attempt to employ it. Dr. Championnière said that he had been slightly misunderstood. He wished to say that movement never produces pseudarthrosis. Immobility is only useful to avoid deformity. There are fractures in which mobilization cannot be employed, as fractures of the humeral or femoral diaphyses, fractures of the inferior extremity of the tibia, etc.

Olive Oil in the Treatment of Hepatic Colic.—Dr. Barth (*Semaine Médicale*, No. 56, page 441, 1897) states that the work of Chauffard and Dupré in France, and of Rosenberg in Germany, have established beyond a doubt the therapeutical value of large doses of olive oil in hepatic colic, and have partly elucidated the method of its action. When a considerable volume of olive oil, say one hundred or two hundred cubic centimetres, is introduced into the stomach of a patient suffering from hepatic colic, the stomach throws it off and the spasmodic contractions cause the liquid to spread over the whole surface of the stomach and a part is driven into the duodenum; thus the lubricating action of the oil makes itself felt over the entire irritated surface. Willemin and others have noted cases when this remedy acted like a charm, and almost as quickly as an injection of morphine. When the oil is once in the duodenum it comes in direct contact with the orifice of the ampulla of Vater. If the passages are permeable it may penetrate into the bile duct, but if a calculus blocks up the way capillarity comes into play, and the mucous membrane absorbs the oil and conducts it to the foreign body. According to Chauffard and Dupré, the oil cannot dissolve the calculus. Brockbank, by employing a bath of oil at the temperature of the body, has seen a calculus of 1.6 grams lose 1.21 grams in weight in four days, and in another case he has seen a loss of forty-four centigrams in the same time. While the oil remains in the canal it is submitted to the action of the digestive juices and is resolved into fatty acids and glycerin; a part is incompletely saponified and is expelled in the form of small concretions which are often mistaken for calculi, but they are only fatty matter rich in palmitin and palmitic acid. This digestive process is accompanied by an abundant secretion of bile, which commences about three-quarters of an hour after the ingestion of the oil and persists for about three hours. Rosenberg thinks that this phenomenon is reflex. Stewart and Ferrand think, on the other hand, that it is due to the passage through the liver of the glycerin and the fatty acids formed and absorbed in the intestine. However

this may be, the abundant secretion of bile and its passage through the biliary duct favor the progress of the calculus toward the intestine. This hypersecretion also cleanses the intrahepatic passages and expels the mucus, epithelial masses, and dark bile. The usual dose is one hundred and fifty or two hundred grams, taken before breakfast in the morning; a few drops of essence of anise make the oil pleasanter to take.

The Suprarenal Capsules in Experimental Infectious Diseases.—Of all the organs of the body none have been so difficult to study as the suprarenal capsules. In a recent communication in the *Annales de la Société Royale des Sciences Médicales et Naturelles de Bruxelles*, vol. vi., 1897, p. 115, Dr. Rene Wybauw gives the results of an extended research on the suprarenals of the rabbit. He records the normal histology of these glands in this animal and the pathological changes due to diphtheria and other infectious diseases. He also gives the results of a physiological study of the extract of the glands. He believes it fairly well established that the suprarenal capsules, perhaps more than any other organ, are susceptible to the action of toxins and specially to the toxin of Loeffler's bacillus. This susceptibility argues that these organs probably have a very delicate and complicated function from the chemical point of view, and also that they have a very unstable composition. It is of interest to note in this connection that the tissues most markedly affected are those in which the medullary and reticular zones are adjacent; in other words; those in which the blood supply of the organ is richest, and hence by which the greatest quantity of poison could be introduced into the organ. These changes affect the cells and the nuclei, and are brought about rapidly, producing as a result the suppression of the physiological activity of the gland, thus causing a loss of the chief power of the gland—its antitoxic properties; for one of the chief functions of this gland, according to the author's experimental experiences and also those of others, is to destroy the organism's own toxic substances. It is to the suppression of the activities of this gland in the infectious fevers, when there is a great and sudden increase of waste toxic products, in great part at least, that death is due. The author shows that three factors are here concerned: these are: 1. Intoxication by the bacterial products. 2. Diminution of the activities of the emunctories, as the kidneys and other organs undergo degenerations. 3. The diminution of the internal chemical destruction of the poisonous products elaborated by the organism itself, precisely at a time when the body is making such products in enormously greater quantities.

Brain Surgery.—Ernst von Bergmann ("Die chirurgische Behandlung der Hirngeschwülste," Volkmann's "Klinische Vorträge," No. 200, December, 1897) recommends greater moderation in brain surgery. He considers the dangers to be apprehended from shock, infection, œdema, and possible prolapse of the brain substance, and the risk of the formation of scar tissue, inducing epileptic attacks, sufficiently great to contraindicate craniotomy in all cases when a positive diagnosis cannot be made. Tumors of the central convolutions are those easiest to diagnose and most likely to admit of successful removal. New growths in the temporal, parietal, or occipital lobes can be definitely located only when they encroach on the central convolutions sufficiently to give rise to motor disturbances. In addition to the customary motor symptoms, ophthalmoplegic examination is capable of giving much assistance in diagnosis. Choked disc is almost invariably present and its character often permits an opinion as to the probable size of the tumor. General systemic treatment of tuberculous nodules and gummata gives a better prognosis than operation, but when a tumor of another variety is suspected, although the presence of either of the above is possible, craniotomy is indicated.

Cholesterin and Biliary Salts as Chemical Vaccines against the Venom of Serpents.—Dr. Phisalix (*Le Progrès Médical*, January 1, 1898) says that the mechanism by which the toxins of microbes and venoms traverse the digestive canal without producing untoward results has been made the object of numerous investigations. For several years the author has studied this subject and has observed that minimum doses of bile, whether of the serpent or of mammiferæ, are able to neutralize a fatal dose of venom. In addition he has been led to recognize the fact that biliary salts and cholesterin exercise an immunizing action against venom. The following is the train of ideas and facts that has conducted him to this conclusion. Dr. Bertrand, together with the author, has shown that immunizing principles exist in different degrees in the blood of the serpent, the adder, the hedgehog, the guinea-pig, and the horse. The author has observed the same fact in the frog, the toad, and the dog. These principles come, for the most part, from the digestive glands, the superior labial glands, the liver, and the pancreas in the serpent and adder. But they cannot be attributed especially to the digestive glands of reptiles. In the dog the pancreas and liver produce these same principles. It takes, for example, from twenty to thirty milligrams of alcoholic precipitate of pancreatic juice to immunize a guinea-pig against a fatal dose of the venom of a serpent. These different antivenomous substances that are thrown into the blood by internal secretion raise the question as to whether they are also eliminated by external secretion, and whether they aid in neutralizing the action of venom in the intestinal canal. This is what takes place, at least with bile, the effects of which on venom the author has studied. Without going into the details of the experiment, he says that twenty to thirty milligrams of the dried bile of the viper will neutralize a fatal dose of venom in a guinea-pig, or will vaccinate it against this venom. The antivenomous properties of the bile were easily determined. The author found that neither decoloration by animal charcoal, nor filtration through porcelain, nor heating to the boiling-point for twenty minutes would cause the bile to lose these properties. To obtain this result it is necessary to keep it at a temperature of 120° C. for twenty minutes. These experiments did not give sufficient information as to the nature of the antivenomous principles, and the author studied separately the substances that entered into the composition of bile, and especially the biliary salts and cholesterin. The following points were observed: Biliary salts exercise a very marked neutralizing action against the venom of a viper. Cholesterin possesses the same property, but in addition has an antitoxic effect. The biliary salts exercise the same chemical neutralization as does the entire bile. In both cases this property is destroyed by heating to 120° C. for twenty minutes. They act as a vaccine but not as an antitoxin. As to cholesterin, the quantity contained in twenty milligrams of bile is insufficient as an immunizing dose. It is not surprising that heating to 120° C. leaves the cholesterin intact but destroys the property of the bile. It is also possible that other antivenomous substances, as yet undetermined, exist in the bile. However that may be, the interesting fact remains that pure cholesterin, in spite of its slight solubility and weak chemical affinity, immunizes against the venom of the viper. This is a difficult fact to explain for the time being, but deserves to be noted as the first known example of a definite chemical compound which acts as a vaccine.

Sphincteral Hysterotomy. — Dr. Defontaine (*Le Progrès Médical*, January 1, 1898) suppresses the functions of the utérine sphincter by a section through the entire thickness of the anterior median line of the uterus, reaching as far as the cavity of the body, and allows the lips of the wound to heal separately. He has, as a result, an easy and lasting evacuation of the pathological contents retained in the uterine cavity by contraction, so frequent and harmful, of the sphincter. As a result, all infection ascending to the tubes is arrested (as after cystotomy infection of the ureters and of the kidneys is checked), and the distended and thickened uterine walls undergo an involution toward the normal state. This new operation is indicated in chronic metritis, when the contraction of the sphincter is marked and the cavity of the uterus enlarged; in uterine flexions rendered painful by concomitant metritis; in different strictures of the neck; in dysmenorrhœas of uterine origin. In blennorrhagic metritis it constitutes a rational means of preventing the infection from ascending to the tubes. Although an absolutely benign operation, it should be limited to only grave cases, as it places an obstacle in the way of conception, for a pregnancy is almost impossible if the uterine sphincter is broken. When the cure of the primitive disease is assured, a subsequent operation may re-establish the functions of the uterine sphincter.

Enterostomy for Ulcer of the Stomach.—Dr. Hartmann (*Le Bulletin Médical*, January 2, 1898) says that, apropos of three cases of gastro-enterostomy reported by Dr. Tuffier for ulcer of the stomach when it was fully developed, he did not think that intervention was advantageous for the patient, as statistics showed eight deaths out of twelve cases, due to uncontrollable hæmatemesis; immediate death by hæmatemesis, in ordinary cases, was exceptional. The writer thinks that the curative influence of gastro-enterostomy on ulcers in the process of evolution may be very advantageous, and he agrees with Defontaine that the operation is indicated in all cases of grave dyspepsias which rebel against medical treatment. In support of this opinion, Dr. Hartmann cites a case of a woman of forty years, who had suffered with her stomach for seven years, and who, for the last three years, had epigastric and vertebral pain, accompanied by vomiting four or five hours after the ingestion of nourishment. During the last few months this woman could scarcely retain even a few drops of milk. Examination showed that there was neither hyperchlorhydria nor dilatation; the stomach simply emptied itself by the vomiting. This patient was cured by gastro-enterostomy, and gained eleven kilos in four months.

Functional Nervous Diseases in Childhood.—In an interesting article read before the Aerztlicher Verein in Hamburg, on February 1, 1898, Dr. Saenger upheld—despite the common impression—the frequency of functional nervous diseases in children. Without any sharp lines of distinction between them, the author has grouped his cases into four classes: 1, neurasthenia; 2, hysteria; 3, hystero-neurasthenia; 4, hereditary neuropathy. 1. The symptoms of neurasthenia consist generally in anæmia; liability to disturbance of the psychical balance; patients tire rapidly; palpitation; feeling of fear; dizziness; increased vasomotor irritability; lack of animation; constipation; sleeplessness (difficulty in falling asleep, "pavor nocturnus"); often trembling of the eyelids when lightly closing the eyes; sometimes real phobiæ. 2. Hysteria. The patients are more intelligent than in the above group: there are a deeply observing, watchful, sly expression of the face; monosymptomatic symptoms, as in the hysteria of adults—aphonia, contractures, paralysis of extremity, cough, tremor, anomalies of contracture positions (hysterical scoliosis, torticollis); blepharospasmus; ptosis; hemichorea; in rare cases amaurosis. 3. Hystero-neurasthenia. This is the most frequent and interesting of the groups. There are but little intelligence; indifference; pain in head and eyes; nervous asthenopia; fear of light; sinking in of the features; loss of conjunctival and of pharyngeal reflex; anuresis nocturna; hallucination; nightmares. 4. In this group there are the presence of hereditary taint; in the first years, frequent convulsions; later, "tic"-like conditions in the form of grimaces and choreic movements; great sensitiveness and sensibility; obstinacy; hasty anger; fear of being alone; wickedness; strong egotistic disposition; tormenting of people and animals. Often the body is more developed upon one side than upon the other, because of retardation of physical development. Boys and girls are equally affected, the favorite age for the disease being between the tenth and fourteenth years. The prognosis of the first three classes of cases is favorable; that of the last is unfavorable. Therapeutically the writer uses, according to the case, general neuro-tonic treatment; douches; cold frictions; baths; electricity; absence from school; improvement of the nutrition; energetic suggestion therapy when the patient is awake, never hypnotic suggestion; protective eyeglasses, often with colored lenses. The causes of these neuropathic conditions Saenger explains by the faulty ways of living, by forced mental study too early in life, by competition for study honors, by sending the children to school when too young, and by the children—that is, among the poorer—being obliged to work without having sufficient sleep and time for recuperation.

A New Anaerobic Bacillus and its Relation to Botulismus (Sausage Poisoning).—E. van Ermengem describes his discovery in the *Zeitschrift fur Hygiene und Infectionskrankheiten*, B. xxvi., H. 1. In cases of poisoning from pickled unboiled ham, which when eaten produced three deaths and made eleven persons dangerously sick, there were symptoms of typical botulismus: more or less outspoken ophthalmoplegia (blepharoptosis, mydriasis, paralysis of accommodation, diplopia, internal strabismus), dysphagia to aphagia from paralysis of the glosso-pharyngeal muscular supply, obstinate obstipation, retention of urine, increased or diminished secretion of saliva and mucus. The cases of Van Ermengem showed very much increased secretion of saliva and mucus, so much so that the patients had attacks of suffocation therefrom, lessened secretion being the rule in botulismus. There were no fever and no disturbance of cerebral function or of sensibility. In other severe cases there were also disturbances of breathing and heart action, which may lead to death under symptoms of bulbar paralysis. From a piece of ham rubbed up in water the author got a very poisonous solution. This solution, when fed to rats, cats, and mice, was borne fairly well; when fed to guinea-pigs, and particularly to apes, it produced death even in small doses. Very much severer, however, was the action of the poison when injected subcutaneously. Cats died in a few days, presenting symptoms similar to those described above in man: the animals became quiet, the mobility of the iris decreased: the tongue hung half paralyzed from the mouth; later the iris mobility ceased entirely, the animals were unable to swallow, and secreted a tenacious mucus amid symptoms of suffocation: the voice became aphonic. In four or five days the animals were very sick: the cerebral function was unimpaired; they died without convulsions, with symptoms of paralysis of the heart and respiration. The poison is just as effective when the emulsion of meat and water is filtered free of germs; thus the disease is an intoxi-

cation, not an infection. By other experiments it was found that the quantity of poison does not increase in the body. The poison, when kept from light and air, remains active many months; it is, however, very rapidly decomposed by warmth. Microscopic examination showed the presence of many spores scattered irregularly through the meat; these spores were those of a bacillus very easily isolated in anaerobic cultures. The "bacillus botulismus" is rod shaped, with spore formation at the end, much resembling the tetanus bacillus, yet differentiated from it by growth peculiarities in culture media. As a rule, this bacterium does not increase in the human body, and has not been found in any quantity in experiments on animals. On the other hand, it was found in the spleen of one of the patients who had died from the poisonous ham. Its non-increase in the human body partly depends upon this fact, that the bacillus does not grow well in a temperature above 35° C. To conclude his chain of evidence, Van Ermengem produced the same results by experiments with the pure culture of bacillus botulismus as with the ham-and-water emulsion. The author is of the opinion that a part of the cases of flesh and preserves poisoning is due to this same bacillus.

Further Contributions to the Study of Rectal Gonorrhœa in Women.—The examinations of Dr. Theodor Baer seem to prove the comparative frequency of this disease in women. The disease very often causes no symptoms, and hence may not be observed (*Deutsche medicinische Wochenschrift*, Nos. 51 and 52). He states statistically the presence of rectal gonorrhœa in 38.2 per cent. of women (four hundred and twenty-nine cases) who had gonorrhœa. The most important causes for this rectal disease are the practice of coitus per anum and the running over of infectious vaginal secretions in the uncleanly. In uncomplicated cases the mechanical treatment of the rectum with a two to five per cent. solution of nitrate of silver produced very favorable results. However, if ulcerative processes or fissures of the mucous membrane are present, milder measures are necessary—iodoform, a one-per-cent. nitrate-of-silver ointment, etc. It may be necessary to excise the ulcer under narcosis.

A New Method of Using Glycerin for Inducing Premature Labor.—This method, as described by H. Saft (*Deutsche medicinische Wochenschrift*, 1898, No. 3), consists in the introduction into the uterus of a catheter armed at its end with a dilatable balloon (a condom), which latter is to be filled with glycerin, forty to one hundred grams. This procedure, when practised upon animals for the induction of premature labor, proved more efficacious and less dangerous than all other methods. The effect depends not only on the presence of the glycerin-balloon acting upon the uterus as a foreign body, but also upon the specific pain-producing action of the glycerin itself. The latter fact is true, even though in this procedure the glycerin can act in but very minute quantities. The author regards this action as due to the fact that the glycerin, by its power of withdrawing water, exerts an irritation upon the uterine nerves and ganglia. He thinks that, instead of glycerin, there may possibly be substituted a non-poisonous, equally endosmotically equivalent substance, *e.g.*, sulphate of sodium.

On the Permeability of the Epidermis.—Dr. W. Filehne has made some very interesting examinations on this subject. He does not here include absorption by the sweat and sebaceous glands, or by the hair bulbs. The skin is to be looked upon as a diffusion membrane, covered with fat and skin sebum and saturated with cholesterin fats. Only such substances can be diffused as either dissolve or can mix with the covering of this diffusion membrane, or in the material (*i.e.*, the cholesterin fats) with which it is saturated (*Berliner klinische Wochenschrift*, 1898, No. 3). The experimenter examined those medicaments, therefore, which can either mix or dissolve in the cholesterin fats, or in what he used as a substitute—lanolin and olive oil. The following substances did not meet these requirements when put in anhydrous lanolin, and hence cannot be absorbed by the epidermis: salt, chloride of potassium, iodide of potassium, carbonate of iron, arsenic, tartar emetic, mercury precipitates. These medicines therefore force their way into the circulation by way of the hair follicles, sweat and sebaceous glands. The following dissolve in lanolin, and hence may be absorbed by the epidermis even in toxic quantities: sulphur, sublimate, oxide and acetate of lead, sulphur and chloride of iron; among organic substances, alcohol, chloroform, ether, oil of turpentine, oil of savin, oil of mustard, croton oil, iodoform, carbolic acid, chrysarobin, camphor, nicotine, cocaine, strychnine.

Urethrectomies.—Dr. Audry, in an article in *Le Progrès Médical*, January 1, 1898, says that it is right to recognize Bourguet as having introduced resection of the urethra into surgical therapeutics. Urethrectomies have been revived by Daniel Mollière and popularized by Guyon, while König and other surgeons, Dittel in particular, have popularized this operation in Germany. The reader is referred to the excellent articles of Vignard, July, 1892, and March, 1894, published in the *Archives Provinciales de Chirurgie*. It is necessary to determine the exact sense of the term urethrectomy. The operation is demanded by the existence of cicatricial and infected masses, more or less voluminous, occupying ordinarily the perineum, and consequently adherent to the superior part of the urethra. This type is furnished by old perineal fistulas, whose existence seems to be more rare than formerly. In such a case the surgeon is led to make an excision of these masses; resection of the urethra is never total; only the adherent part is removed. On the contrary, certain stenoses, such as cicatricial strictures of traumatic origin, require total excision of the cicatrix, which is annular, and of the corresponding section of the urethra. As to partial urethrectomy, it is absolutely impossible to give a precise description of this operation, because the circumstances in which the operator finds himself are so varied. However, three stages of the operation may be noted: (1) examination and opening of the urethra; (2) resection; (3) suture. The examination and opening are carried out in the same manner as in an ordinary external urethrotomy. A catheter has been introduced if possible. The cystotomy position is taken and a large median incision is made. If a guide has been introduced one proceeds with the opening; if this has not been feasible, the catheter should be pushed as far as possible. The posterior segment of the urethra having been reached, the callous masses are extirpated like tumors. In general they have been opened in order to arrive at a knowledge of the urethra. Almost always they are inferior and lateral, and the superior vault of the canal is healthy or nearly so. In resecting, if the callosities are infected, they should be thoroughly removed; it is not sufficient to remove only the very hard and diseased portions. The moderately infiltrated tissues may recover; but it is evident that all cicatricial tissue should be removed. One should be guided especially by the finger as to the state of the tissues, and the scissors are perhaps more useful than is the bistoury. The author thinks that it is better to remove the mass piecemeal than to take out the callosity *en masse*. Generally one is obliged to operate from before backward, because the lesion is often extensive and one cannot always reach

the termination. If the callus is limited and short, it is best to remove it by dissecting and enucleating it with the finger and the scissors before opening the canal. It is necessary to isolate the urethra both in front of and behind the lesion, without opening it. Puncture immediately behind the callosities and be assured of the posterior limit. This technique is applicable principally when one finds himself in the presence of short cicatricial strictures which justify total urethrectomy. In every case resection of the urethra is an accessory of the intervention; it involves callosities especially; in general the loss of substance is on the inferior and lateral portions of the urethra; continuity of this latter is respected above; in a word, the conditions are not very different from those found in the majority of external urethrotomies. If the resection, although partial, of the urethra is as much as twenty-five or thirty millimetres in extent, we should not hope to make a complete suture of the walls edge to edge. We must be content to make a new urethral calibre over a sound to be left *in situ*. Guyon recommends this method, and several of his pupils have shown that a canal, clothed in epithelium capable of retaining a convenient calibre, is formed. One can easily understand, in such a case, how the preservation of the superior urethral vault is important as an aid to the formation of epithelium. The only difference between the suture used for partial resection and that used in external urethrotomy is that here we make the suture in one layer, which brings together the neighboring layers of the urethra and the bulbo-cavernous muscles. It is necessary that the most anterior and most posterior threads should be in immediate contact with the extremities of the urethra. The sutures ought to be very near together. If the loss of urethral substance is less than twenty-five millimetres, and if the walls of the canal are pliable and healthy and can be brought together, the cut extremities of the canal should be sutured edge to edge. It is well in such cases to allow a small sound, No. 15 or No. 16, to remain *in situ*. The catgut sutures should not be too numerous, three or four being sufficient. When possible, the threads should not traverse the mucous membrane; it is very necessary that the edges be in exact contact. The perineum is restored in the usual manner. Total urethrectomy consists of excision of the entire urethra. As to the examination and opening up of the urethra, this ought to be done freely but prudently, for it is in this exploration that we can judge of the possibility and of the indication of intervention. It is necessary to isolate, as far as possible, the cicatrix from the neighboring tissues, and to note its extent and its relation to the surrounding tissue and the necessity of making a resection of the entire canal, *i.e.*, comprising its superior wall. As to the resection, after having obtained the necessary information, when the excision does not exceed twenty-five millimetres and the surfaces of the section of the urethral wall are healthy enough to be mobilized and to be sutured we proceed to resection. In such a case it is preferable not to slit the stricture, as in external urethrotomy and partial urethrectomy. We cut the urethra immediately back of the stricture and assure ourselves of the posterior limit by threads or pincers, these latter having the inconvenience of wounding the tissue. Then the urethra itself is cut immediately back of the cicatricial tissue, and with the fingers we proceed to enucleate and dissect out the fragment and remove it. This done, hemorrhage being controlled, a sound of small calibre, which is to be left in place, is passed. A suture is made as in the previous operation, only here the placing of the superior thread gives some trouble, and sometimes it can scarcely be made to pass in the urethral lumen. It is preferable to cut off the threads as they were placed. The threads take in as much tissue as possible and are left immediately beneath the mucous membrane. In the post-operative treatment it is preferable to leave a sound *in situ* four or five days. About the tenth day, pass a catheter in order to investigate the condition of the canal. In all cases it is well to commence with the guiding bougie, to which is attached a Phillipp sound. In regard to post-operative accidents, there is no more to fear from hemorrhage than from infection, especially if one leaves in a small drain. It may happen that the reunion is only partial, but the fistula which remains repairs itself spontaneously in a short time. Total urethrectomy is capable of giving results more brilliant than when the canal repairs itself. The indications for this operation are exceptional. It is necessary only in the presence of cicatricial strictures of traumatic origin, short enough not to require an opening of more than twenty-five millimetres and extensive and compact enough not to be amenable to longitudinal urethroplasty. On the other hand, partial urethrectomy is an excellent operation, expressly demanded by the existence of callosities and of old infectious foci in the perineum. Cicatrices of traumatic origin that are very extensive create unyielding strictures, demanding always more or less extensive operation. The chances for performing this interesting operation are very rare.

Laryngitis Acuta Rheumatica Circumscripta (Nodosa).—Besides the previously described forms of rheumatic angina and laryngitis, Uchermann (*Deutsche medicinische Wochenschrift*, No. 47) calls attention to a less frequent form, which he designates by the above name. This appears as circumscribed, very sensitive, reddish or blue-red, fairly hard infiltrations. They may be unilateral or bilateral. If they have their seat in the region of the crico-arytenoid articulation, then a pseudo-ankylosis with immobility of the affected vocal cord will occur.

The Diazo Reaction in the Urine of Nurslings.—Dr. Umikow (*Deutsche Medizinal-Zeitung*), as a result of an extensive experience, arrives at the following conclusions: 1. The diazo reaction never appears in the urine of healthy children. 2. High fever has no influence upon the occurrence of the reaction. 3. The acute and chronic catarrhal pneumonia run their course without the presence of the diazo reaction in the urine. The reaction is also wanting in diphtheria, varicella, otitis media, coryza, facial eczema, lymphangitis, hereditary syphilis, laryngitis, bronchitis, pleuritis, enteritis, and erythema after the injection of diphtheria antitoxin. 4. Erysipelas and measles practically always give the diazo reaction in the urine, and more distinctly the greater the severity of the disease. 5. One or two days before death the diazo reaction appears regularly in most cases, irrespective of what form of disease the child suffered from. 6. In measles the reaction is occasionally seen in the prodromal stage.

Dulness on Percussion over Lung Apex without Pathological Changes being Present.—During a period of seventeen years, in the vast material of a St. Petersburg hospital, Dr. V. Kernig (*Russisches Archiv für Pathologie, klinische Medicin, und Bakteriologie*, Bd. iii., Heft 1) collected from thirty to thirty-five cases showing bilateral dulness over the lung apex, in which at subsequent autopsy no pathological changes were demonstrable. The dulness occurred in patients who from various causes (frequently diarrhœa) were emaciated and had been confined to bed for a long period. The dulness was always bilateral and symmetrical, involving both sides equally. Auscultation elicited diminished, seldom normal vesicular breathing, never mucous râles or bronchial breathing. The rare occurrence of the latter symptoms is noteworthy. In ex-

plaining this condition the author lays some stress on the emaciated condition and long confinement to bed of these patients, who as a consequence require and consume less oxygen, and make feebler respiratory movements; as a result the lungs are not distended with air to the ordinary capacity. Since the intensity of a percussion note is relative to the volume of air contained in a given space, it is possible that by a certain amount of shrinking or collapse of the lung apex the volume of air is diminished to such a degree that percussion elicits a dull note instead of the normal resonance. The dulness spreads over the supraclavicular and infraclavicular grooves and the supraspinal fossa. The differentiation between this condition and dulness due to tuberculosis may become very difficult; in such cases we must recall (1) the emaciated condition of the patient and the long period of confinement to bed; (2) the bilateral nature of the dulness; (3) the absence of abnormal auscultatory signs (with the exception of diminished breathing); and (4) the rarity of this condition.

Lenticular Necrosis of the Lung and the Formation of Lung Stones.—According to Dr. Arnold (*Munchner medicinische Wochenschrift*, No. 47, 1897), the formation of concretions in the lumen of the bronchi (inspissated and calcified mucus or blood; calcified, broken down bronchial glands; incrusted foreign bodies) is not very infrequent. Also in a similar manner, stone formation may occur inside the air vesicles; less often such processes take place on the walls of pulmonary cavities, in which a portion of the wall becomes incrusted or impregnated with dust of various kinds, and is afterward thrown off by necrosis. The author had an opportunity to examine both clinically and anatomico-pathologically a case of the latter variety. It was a case of lenticular necrosis in a stone-cutter's lung, which progressed to the formation of small pneumoliths in a cavity and the expectoration of the same. The autopsy showed in the right lung apex a cavity with many branches and recesses, in which small, hard, black, angular stones in large number (seventy) were found. One sharp-pointed, jagged, stone of larger size was wedged in between the wall of the cavity and a branch of the pulmonary artery. The stones varied in size up to seven millimetres; some were round, others flattened, others prickle pointed—most often spotted, always very hard. They consisted of concentric layers of a hyaline and highly pigmented substance. The fibrous nodules embedded in the lung tissue showed the same structure: the stones were formed from small particles of the calcified lung tisssue thrown off by necrosis, thus differing in their formation from other bronchial and lung stones. Dr. Arnold has previously demonstrated the formation of similar fibrous nodules in the lung tissue; they originate either from shrunken, inspissated masses of dust and cell elements contained in an alveolus, with subsequent thickening of the alveolar wall and perialveolar tissue; or from a fibrous peribronchitis; or from a fibrous perivasculitis; or from a fibrous perilymphangitis.

Tuberculous Meningitis Produced Artificially.—At the meeting of the Society of Biology, held in Paris on March 5th, Dr. Louis Martin gave a demonstration of how tuberculous meningitis could be produced in guinea-pigs and rabbits by injecting tubercle bacilli into the cerebro-spinal fluid. He took a slightly curved needle and put it into the cavity of the cranium, passing through the ligaments joining the occiput to the atlas, keeping the needle against the occiput, and using this bone as a guide so as not to injure either the medulla or the cerebellum. This operation in the guinea-pig is one of extreme delicacy. When the injection is made it must be made very slowly, so as not suddenly to increase the tension of the cerebro-spinal fluid. Guinea-pigs injected with tuberculous cultures in the cerebro-spinal fluid die on from the ninth to the fifteenth day. After the injection the animal suffers from fever, but it does not waste and there is no paralysis. Three or four days before death the coat stares; the guinea-pig rolls itself into a ball and loses weight very rapidly; paralysis appears during the last day or two and especially affects the hind limbs; the animal is very ill and dies with its temperature much raised. Dr. Martin has generally noticed flattening of the abdomen. In the rabbit the operation is very easy and these animals are much less sensitive to tubercle than are guinea-pigs. The progress of the malady is less rapid; wasting and paralysis do not appear before the third week or even later. The rabbits die after five weeks or even two months, and on post-mortem examination tubercle is found surrounding the vessels, and there is general gelatinous œdema spread over the peduncles of the brain exactly in a similar manner as in children. By the courtesy of Marfan Dr. Martin was enabled to use some cerebro-spinal fluid from a child who had died from tuberculous meningitis. Half a cubic centimetre was injected into a guinea-pig in the manner above described, with the result that it died in eight days, and under a microscope the meninges were found to be swarming with tubercle bacilli. Dr. Martin cultivated the meninges and obtained a culture of the tubercle bacillus. A control guinea-pig inoculated under the skin with the same dose died in four weeks. Dr. Martin also obtained some cerebro-spinal fluid from a tuberculous patient during life by means of a lumbar puncture and inoculated this fluid into the cerebro-spinal space of a guinea-pig. The animal died in eighteen days. A control guinea-pig inoculated hypodermically showed only a small ulcerated patch at the point of injection. In two months after the injection the animal was still alive. With the view of finding out if this investigation would be a help in the diagnosis of tuberculous meningitis, Dr. Martin drew off some cerebro-spinal fluid from rabbits infected with tuberculous meningitis, and, having injected it into guinea-pigs, observed that they died after an interval of time in direct relation to the date at which the rabbit died. From a rabbit already showing signs of paralysis Dr. Martin drew off two cubic centimetres of cerebro-spinal fluid, and on the next day the rabbit, which had been lying motionless on its side, was able to stand upon its feet; the improvement, however, was of short duration for the rabbit died six days after the operation.—*Lancet.*

On the Nursing of Patients with Hypertrophied Prostate.—Dr. P. F. Richter lays great stress upon the importance of adhering to the strictest antiseptic rules in catheterization (*Zeitschrift für Krankenflege*, 1897, No. 6). Hygienic and dietetic rules are necessary to prevent congestion of the pelvis and consequent retention of urine. The patients should subsist on bland articles of diet, but very mildly spiced; thirst is best alleviated by drinking milk or lemonade; alcoholics (red wine) are to be allowed only in very small quantities; tea and coffee should not be allowed. Every call for urination should be immediately answered; this is of great importance. Tendency to constipation should be avoided by appropriate remedies, but no saline cathartics should be given; cascara, either alone or with aloes and rhubarb, is best for this condition. Patients should wear woollen underclothing the whole year. To lessen the work of the kidneys friction of the skin and massage are of value, also lukewarm full and sitz baths; cold douching and spraying are to be avoided. Walking and other exercises are helpful.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 7, 1898.

TREATMENT OF TYPHOID.

IT is probably true that no single medical disease has been talked about in the societies and written about in the journals to a greater extent during the past eighteen months than has the subject of typhoid fever. Not to enter upon the question of why this is so, it may perhaps be profitable to look over the field that has been so laboriously worked and see what conclusions have been reached, and to note such claims as have been put forward for new remedies or new methods, so that they may be compared with the older. The progressive practitioner of the day usually has for his motto, "Be not the first by whom the new is tried, nor yet the last the old to lay aside," and, acting upon this guiding principle, he is always ready to accept the new way, when it has been shown to be the best one.

Unfortunately, perhaps, in typhoid as in almost every other morbid process, there can be no single royal road to cure applicable in every case. While, however, each individual affected must be treated more or less according to the conditions presenting themselves, there are certain general principles of management which apply to all.

In a recent discussion by the Lenox Society almost all the members agreed that a generous dose of calomel at the onset of decided symptoms of typhoid was in order, and not a few believed that subsequent smaller doses might do much in the way of establishing antisepsis of the intestinal canal by their effect in calling forth normal secretions which are antagonistic to germ life rather than by any direct action of the remedy itself upon the germs. The abortive plans, and especially that of Woodbridge, have been much discussed. If the data, as given in recent reports, are to be accepted on their face, one need scarcely look further, since the mortality is less than two per cent. in a series of cases running into the thousands.

The figures presented have not, however, been universally regarded as above honest doubt, and many authorities still maintain that antiseptic plans *per se* are not to be relied upon. Modified forms of the Woodbridge method are, however, springing up here and there, with reports to demonstrate their value. This would seem to indicate that there is more worth in antiseptics than many are willing to admit, unless the plan of administration is of their own device.

Advocates of the bath treatment appear to be increasing in number, and, while all do not agree as to the exact method of tubbing to secure the best effects, it is generally conceded that excellent results are to be obtained by judicious cold-water treatment, and the closer the Brand method has been followed the better the reports seem to be.

Among recent devices for decreasing the disagreeable features of the bath are a tub on wheels, to be brought close to the bedside; a hammock for lifting the patient in and out, with a minimum of discomfort for the latter and of labor for the attendants; and a folding rubber tub with inflatable sides, which can be inserted like a sheet beneath the patient, filled, emptied, extracted, leaving him undisturbed in bed.

The serum treatment has as yet met with slight success, though an antitoxic would seem to be the ideal method. Some successful trials of antityphoid serum have been reported from England.

Hygienic and dietetic measures still have to be mainly depended upon, and Delafield's dictum that milk is the best food for typhoid patients is generally acquiesced in; but many practitioners have learned to watch for evidences that the too exclusive milk diet is causing injury, and they know that in a sudden rise of temperature, otherwise not to be accounted for, milk is to be wholly withdrawn and broths, soups, gruels, eggs, etc., substituted for a time. Aside from securing mental and bodily rest, keeping the temperature within bounds, supplying sufficient fluids, and giving proper foods, each subject of typhoid must be treated according to the symptoms he presents. For the majority of patients showing high fever it is probable that tub baths will be found efficacious, since there is no longer question that the mortality has been greatly reduced by this method of treatment.

SOME MODERN OUTLOOKS IN THERAPEUTICS.

EMPIRICISM still holds sway in modern therapeutics, yet it is far from the rule of thumb of our forefathers in the healing art. Little by little, rational therapy has advanced, to be met with the too prevalent attitude of therapeutic nihilism. Patient pharmacological students, aided by all the allies of the biological sciences, have begun to occupy the middle ground between empiricism and sceptical inertia, and are laying the foundations of a truer knowledge of drugs and their actions.

It has been within recent years only that investigators have come to a realizing sense that drugs are extremely complex bodies, and that even when their proximate principles are obtained, even then the pure products—alkaloids, glucosides, resins, etc.—have a complex molecular structure, which has a profound influence upon the action of the drug and to which the chemist alone is able to furnish a clew. It is thus a sign of new and better things when students are to be found turning to the investigation of the relationship of the physiological action of a drug to its chemical constitution. The great flood of synthetic

remedies is an exponent, from the chemical side, of the remarkable activity of this recent therapeutic movement. Some recent English work, entitled "A Comparison of the Physiological Actions and Chemical Constituents of Piperidine, Conine, and Nicotine," by B. Moore and R. Row, *Journal of Physiology*, vol. xxii., 1898, p. 273, is worthy of attention. The authors first discuss the chemical structure of these three liquid alkaloids, and then present the results of an extended series of experiments upon their physiological actions. Their conclusions show that: "The three alkaloids are very similar in physiological action, although the intensity of action varies, and we believe that this similarity is due to the presence of a reduced pyridine (or pyrrol) ring in each molecule; and, further, that the intensification of the action is due to the introduction of an organic radical as a side group into this ring. The points of similarity of physiological action may be summarized as follows:

"1. The subcutaneous injection of each drug (in frogs) in sufficient doses causes complete motor paralysis.

"2. This motor paralysis is mainly due to paralysis of the intramuscular part of motor nerves. This is shown by the fact that muscle remains irritable, directly, but not through its nerve, when the poison has been allowed to circulate through the muscle, and that an unpoisoned muscle may be caused to contract reflexly through a spinal cord which has been subjected to the poison. We have not been able to demonstrate that there is no central action; but this, if present, must be slight.

"3. The excised frog's heart is somewhat slowed and the duration of the systole prolonged by each of the three drugs.

"4. The heart *in situ* (in mammals) is at first slowed, but afterward unaffected.

"5. The arterial blood pressure is enormously raised, and the rise is due to constriction of arterioles and not to increased heart action. This constriction of arterioles is independent of connection with the central nervous system, and is probably due to vasomotor excitation in peripheral ganglia.

"6. At a certain stage this vasomotor mechanism would probably become paralyzed, for further administration of any of the three drugs no longer affects the arterial blood pressure."

THE TRAINING OF GIRLS IN RESPECT TO THEIR PHYSICAL DEVELOPMENT.

The manner in which girls are brought up nowadays is vastly different from that of but a short time ago. Mothers even of the past generation would have eyed askance the methods now used in the mental and physical training of daughters, and which are regarded as indispensable to the production of a nineteenth-century woman. But the question is whether the course pursued is in every respect a wise one, and whether the old system of teaching a woman to read a little and to write a fairly grammatical letter, while allowing her to reserve sufficient strength and energy to develop into a healthy mother and housewife, had not much to commend it. That a girl should have the opportunity of being thoroughly educated is freely granted—in fact, in the existing state of affairs it is necessary that she be able to earn her own living; but the tendency of education now is unduly to develop the mind at the expense of the body. It is true that physical culture plays a part in the training of the girl of to-day, but it is doubtful if the methods employed are the ones best calculated to attain the desired result. Up to the age of puberty there is comparatively little difference between the sexes. When, however, that period arrives, the entire system undergoes a change, the asexual girl becomes a woman, and it is at this time that the greatest care should be exercised in her training. The old-fashioned girls' boarding-schools, with their perfunctory education, have passed out of existence, and the movement for the higher education of women has, after much jeering and scoffing, gained a firm foothold. This is, without doubt, an advance in the right direction, but nevertheless the system has its defects, and discretion is needed in carrying it out. The great fault with those in charge of these modern establishments is that they do not or will not understand that the sexual question is of any importance, and still cling to the belief that a girl between the ages of fourteen and twenty is able to undergo an equal amount of physical and mental exertion as a boy of the same age. That this is a mistaken view is plain on the face of it. In the schools for boys perhaps the attention given to exercise is excessive; on the other hand, in too many of the girls' schools it is not sufficient. What is required in the establishments for the education of girls is that more time should be allowed for health-giving, out-of-door exercise; if this were done, the number of neurotic women would be greatly lessened, and the services of the doctor could in most cases be dispensed with. In the words of Dr. Playfair: "It is not the work which in my judgment hurts, but the perseverance in work after nature has hung out its danger-signals; work in an unhealthy body; the attempt, in fact, to fight nature. Then, indeed, the careless, prejudiced, or unwise mistress or parent may well find that 'over-pressure,' the very existence of which so many deny, is a stern reality and may shatter the whole future of the girl."

Dr. Harriet E. Garrison, in an able paper on "The Physical Development of Women," read at the meeting of the American Medical Association held at Philadelphia, and printed in the *Journal* of the association, deals with the same subject in an instructive way. After discussing the point as to whether there is much inherent difference between the physical capacity of the sexes, and concluding from the fact that in many foreign countries the women perform most of the hard manual labor, that the difference is but slight, she goes on to say: "If our girls were turned loose to amuse themselves spontaneously, to run up hill and roll down, to skip and jump without rhyme and reason, except as it is supplied by the exuberance of their own innocent natures, there would

be less headache in adult life. . . . Fresh air, fresh water, and sunshine should be the inalienable right of every child in this land of the free and home of the brave, but our women are starving for these very things. Not only are the girls from the sweat shops and factories, who are shut in for ten or twelve hours where no sunshine or fresh air can reach them, but the woman of social position must give at least ten hours daily to her duties, shut in as closely from fresh air and sunshine as her humble sisters."

These are true remarks, especially in regard to the condition of the poor. Exception may perhaps be taken to Dr. Garrison's view that there is but little inherent difference between the physical capacity of the sexes. The *British Medical Journal* says: "Some of us were of the opinion that by a little courage and habit, and in a higher state of bodily vigor, the menses might be disregarded in regular callings and exercise. We have rendered this opinion, and have convinced ourselves that girls and women are unwise in pursuing their exercises, whether of body or brain, during the first two days of the period." With the contention of Dr. Garrison that fresh air and exercise are essential to the well-being of every woman and girl, we cordially agree and hopefully look forward to that time when this fact will be fully appreciated by those who are responsible for the training of the young female population.

News of the Week.

Dr. Frank P. Maguire has been appointed by the commissioner of correction physician to the city prison.

The Determination of Sex.—If the reports to the daily press are to be credited, the long-promised and much-advertised book by Schenck, of Vienna, on the determination of sex, is a fake of the purest order. The book was published on April 28th. The entire question, in the opinion of Dr. Schenck, appears to be one of the varying proportions of albumin and of sugar in the organism of the mother, and therefore boys or girls may be turned on or off at will by simply regulating the amount of carbohydrates in the diet of the mother. It appears that an excess of sugar favors the female sex, so that science comes to the support of sentiment and we find that the sweet creatures have a physiological right to their appellation.

Volunteer Army Surgeons. — Surgeon-General Sternberg has prepared a circular letter to be sent in reply to the many offers to the government of services from physicians, which now aggregate nearly fifteen hundred. "The surgeon-general highly appreciates the patriotic motives which have induced this offer of services, in many instances by men prominent in the profession and enjoying a lucrative practice, but the labor of answering these numerous letters interferes with the necessary work of the office, which has been greatly increased by the exigencies connected with equipping the regular and volunteer armies for field service. It therefore becomes necessary to acknowledge letters offering service, and inquiries relating to the medical department, by the circular letters. No appointments are made in the regular army except after examination by an army medical examining board, and all applicants must be graduates in medicine and less than twenty-nine years of age. The surgeon-general of the army has nothing to do with the appointment of medical officers for the volunteer army. Comparatively few contract surgeons (acting assistant surgeons) are likely to be required, and it is the intention to employ for service with troops going to Cuba or at hospitals on the Gulf Coast only such as are immune to yellow fever. All applications and offers of service will be placed on file for future reference, and for selection of the most available persons for the special duty required, in case of need."

Mortality of the Plague.—Up to March 1st the total number of deaths from the plague in Bombay had been 71,000, the mortality for February (7,845) having been the highest for any one month since the appearance of the epidemic.

The American Representative at the Congress of Hygiene.—Major Girard, surgeon, U. S. A., who was an official delegate to the International Congress of Hygiene and Demography at Madrid in Easter week, has arrived again in this country, having left the Spanish capital a few days before the war began. The correspondent of *The Lancet* thus refers to Dr. Girard's participation in the opening exercises: "Dr. Girard, surgeon-major in the United States army, was now called upon to respond. To avoid causing any irritation he had refrained from putting on his uniform and was not at all anxious to speak. The occupants of the platform, on their side, applauded his approach, and Dr. Girard, so as not to incur the risk of any aggressive interruptions, spoke so low that it was impossible to hear him at a few feet from the platform. He said that he desired to express, on behalf of the official delegation from the United States, their high appreciation of the very kind reception which had been shown them since their arrival in Spain. This was particularly gratifying under the present political circumstances. He wished the congress all the success it so well deserved, and hoped that before the congress had terminated its labors the difficulties existing between Spain and the United States would be smoothed over. The occupants of the platform could not but be gratified by these judicious remarks, while the people who crowded the hall could not hear what had occurred. Thus this episode, which if less prudently managed might have given rise to some demonstration which would have still further complicated the political situation, passed quietly and terminated in a graceful exchange of bows as the American delegate withdrew from the platform."

An Important Health Decision. - - An important and far-reaching decision has recently been rendered in Albany County in the case of Cartwright against the board of health of Cohoes. The case was heard before a referee, and after dragging along two years a decision was rendered last week in favor of the defen-

dant with costs. The local board had ordered the plaintiff to fill a vault which had been declared a nuisance; she refused and the board had it filled, whereupon the plaintiff promptly dug it out again, and when the board started to refill it she secured an injunction and began a suit against the board. The testimony filled three hundred and eleven typewritten pages. The referee held that the board of health had power to abate the nuisance and that the plaintiff had violated the public health laws and the regulations of the board of health. The decision is important, inasmuch as it seems to be the first of this character rendered in the State and as the local board was acting upon the advice of the State board. If affirmed, it will be of great value to health boards in enforcing the public health laws.

The Degree of M.D. in Prussia. — The Prussian government has decided that, after this year, the degree of M.D. will be given to no one who has not passed the state examination and so become legally qualified to practise medicine in the German empire.

The Cumberland County (N. J.) Medical Society. —The annual meeting of this society was held at the Doughty House, Millville, Tuesday, April 12, 1898, Dr. H. W. Elmer presiding. The officers for the ensuing year were elected as follows: *President*, Dr. Judson, Newport, N. J.; *Vice-President*, J. B. Ware, Bridgeton, N. J.; *Secretary*, Hamilton Mailly, Bridgeton, N. J.; *Treasurer*, Joseph Tomlinson, Bridgeton, N. J.; *Reporter*, J. C. Applegate, Bridgeton, N. J.; *Delegates to American Medical Association*, H. W. Elmer, T. G. Davis, W. L. Newell; *Delegates to State Medical Society*, L. L. Hand, M. K. Elmer, J. B. Ware, Ellsmore Stites, D. H. Oliver, and Rulon Dare; *Delegates to Gloucester County Society*, Ellsmore Stites, D. H. Oliver, and J. C. Applegate.

Dr. Weir Mitchell Asserts Himself.—An English contemporary, having spoken of Dr. Weir Mitchell as "the late," received the following: "Sir: On page 321 of *The Medical Press and Circular* for March 23, 1898, is a brief but very flattering notice of 'Hugh Wynne,' by the 'late' Dr. Weir Mitchell. I beg to assure you that I was never 'late,' and am just now punctually present. As it is not enough to assert that a man is 'the late' among the unrecognized tests of the presence of life, possibly a letter from the unbelated may be reasonably taken into account as proof of the incorrectness of your certificate of the demise of yours truly, S. Weir Mitchell."

Dispensary Practice has been affected by the war. In a down-town district a falling-off in attendance at one of the dispensaries was noted for a few days, which could not be accounted for until it was found there was a "run" on a neighboring bank and the patients were busy drawing out their deposits.

The New York University.—The executive committee of the council of New York University announces that the Medical College will be enlarged and strengthened for the year 1898–99. A full statement of plans, equipment, and faculty will be presented to the students and graduates of the Medical College not later than the date of the annual commencement at the Metropolitan Opera House, May 18, 1898.

Dr. Edward S. Peck has been appointed professor of diseases of the eye at the New York Post-Graduate Medical School and Hospital.

Fourth International Congress of Physiologists. —This congress will be held at Cambridge, England, August 23 to 27, 1898, under the presidency of Prof. Michael Foster. The meetings will take place in the physiological laboratory of the university, and the members of the congress will there be afforded all possible facilities for experimental demonstration, as well as for the exhibition of preparations and of scientific apparatus. The official languages of the congress are English, French, and German. Each member of the congress is required to contribute the sum of ten shillings toward defraying the expenses of the meetings, in receipt for which a card of membership of the congress will be issued by the local secretary, Dr. L. E. Shore, Physiological Laboratory, Cambridge. In connection with the congress, an exhibition of physiological apparatus will be held. Exhibits may be contributed by members of the congress, by directors of physiological laboratories, and by makers recommended by any member or director. The exhibition of apparatus will open on Monday, August 22d, and remain open for the five following days.

Dr. William P. Northrup, of this city, delivered an address on April 12th before the Philadelphia Pediatric Society, on "The Portal Entry of Tuberculosis in Childhood." The meeting was largely attended, and after it a reception was tendered Dr. Northrup.

The Omaha Medical Society.—At the recent annual meeting of the Omaha Medical Society, the following officers were chosen for the year: *President*, Richard C. Moore; *First Vice-President*, Elenore S. Dailey; *Second Vice-President*, E. W. Lee; *Secretary*, J. M. Aikin; *Treasurer*, W. R. Lavender; *Board of Censors*, D. C. Bryant, B. B. Davis, and C. C. Allison; *Committee on Programme*, W. O. Bridges, Louis Swoboda, and H. B. Wilson. Eighty members are now enrolled. The society meets bimonthly. Efficient work, scientific and legal, is being accomplished by the society. Members of the profession, not residents of Omaha, but visiting in the city during the exposition, will be cordially received by the local members, if they will announce their presence.

The Lycoming County (Pa.) Medical Society held its annual meeting at Williamsport on April 5th. The following officers were elected for the ensuing year: *President*, Sidney Davis; *First Vice-President*, W. E. Delaney; *Second Vice-President*, C. M. Adams; *Secretary*, W. F. Kunkle; *Treasurer*, B. H. Detwiler; *Censor*, George D. Nutt; *Trustees*, J. A. Klump and C. W. Youngman.

The Cuyahoga County (Ohio) Medical Society met in fourteenth annual session in Cleveland on April 7th. The following officers were elected for the ensuing year: *President*, F. E. Bunts; *First Vice-President*, W.

W. Rogers; *Second Vice-President*, Charles Hintzelman, *Secretary*, Charles C. Stuart; *Treasurer*, L. S. Chadwick; *Censors*, A. J. Brockett, Frank Payne, D. S. Hanson; *Trustee*, W. A. Knowlton.

Wisconsin State Medical Society.—The fifty-second annual meeting of this society was held in Milwaukee, May 4, 5, and 6, 1898. Dr. William Mackie is president, and Dr Charles S. Sheldon secretary of the society.

The Tri-State Medical Society.—The following officers were elected at the annual meeting of this society in Dubuque, Iowa: *President*, C. E. Ruth, Keokuk; *First Vice-President*, Dr. Murphy, St. Louis; *Second Vice-President*, F. H. Martin, Chicago; *Secretary*, J. W. Fowler, Dubuque; *Treasurer*, D. S. Fairchild, Clinton. The next meeting will be held at Quincy, Ill.

New York County Medical Association Transportation Committee.—The New York County Medical Association has formed a committee of transportation for the purpose of commuting fares to Denver on the occasion of the coming meeting of the American Medical Association. Communications may be addressed to any of the following gentlemen constituting the committee: Drs. J. J. E. Maher, A. E. Gallant, F. H. Wiggin, Louis Fischer, and W. R. Dalton.

Beriberi at Matanzas.—The sanitary situation at Matanzas City is reported to be wretched. An epidemic of beriberi prevails there, and three hundred people are afflicted with that disease at the public jail and the hospital.

Medical Meetings at Denver.—The following is the list of medical societies the annual meetings of which will be held in Denver in June: The American Medical Association, the American Academy of Medicine, the American Medical Editors' Association, the American Publishers' Association, the Association of American Medical Colleges, the Rocky Mountain Interstate Medical Society, and the Colorado State Medical Society.

An Aseptic Newspaper.—The publisher of a daily paper in England has profited by the occurrence of a mild epidemic of small-pox to announce to his alarmed readers that each issue of the paper will be impregnated with a disinfectant. In this way the enterprising purveyor of news says that he will convert his paper into an agency for the widespread distribution of disinfecting influences and for the provision to all the readers of the means of safeguarding the home and the person. What a chance there is in this idea for the pink and yellow journals on this side of the water! It could be extended to the cure as well as prevention of disease. Special editions might be issued with impregnations for the cure of special diseases. Thus the man with a cold in his head can send out for the rhinitis edition of the *Morning Prevaricator*, or the one with appendicitis for the olive-oil edition of the *Evening Cablegram*, and slowly chew his paper as he reads, refreshing and renewing mind and body. With the first consignment of Florida cucumbers could be issued a diarrhœa extra impregnated with the *Sun* cholera mixture, and so on. The idea is grand, and the English publisher is a genius.

The American Neurological Association. — The twenty-fourth annual meeting of this association will be held at the New York Academy of Medicine, No. 17 West Forty-third Street, on Thursday, Friday, and Saturday, May 26, 27, and 28, 1898. There will be two sessions daily, one from 10 A.M. to 12:30 P.M., the other from 2 P.M. to 4:30 P.M. The annual dinner will be given on Friday evening, May 27th.

New Periodicals: A Protest.—Nine new German medical periodicals were announced in the last months of 1897, and medical literature in other countries is almost equally prolific. Von Düring writes to the *Deutsche medicinische Wochenschrift*, protesting against this multiplication of professional organs as a waste of energy, time, and money, rendering it impossible for any one to keep an intelligent oversight of medical literature. "Each new journal," he says, "contains possibly one or two important articles during the year, but these might just as well have been contributed to some established journal. The rest of the contents—news, abstracts, etc.—are found almost simultaneously in all the leading established journals." He therefore appeals to his confrères not to allow themselves to be cajoled into lending their name and prestige or contributing to these sprouting journals. If they will take *Punch's* advice to those about to marry, "Don't!" they will save the rest of the profession much time and money, while maintaining the dignity of science, which will inevitably be impaired by the "*Vielschreiberei*" necessitated by a host of new periodicals. And the new publications, refused the name and support of prominent members of the profession, would "die aborning."—*Journal of the American Medical Association.*

Taxing Medical Men. — In Italy physicians are taxed upon their incomes, the amount of which is fixed arbitrarily by the tax collector, and against the assessment no protest is of any avail. The amount so charged against the medical man is often so excessive that he cannot make the balance of his income cover his expenses. The Rome correspondent of *The Lancet* writes to that journal that Prof. Enrico Bottini, of the University of Pavia, has actually been driven out of practice by the extortions of the tax collector, and has published the fact in the following declaration, made February 8th: "Oppressed by a return for income tax which I hold exorbitant, and, having no further means of defence, I declare that I renounce entirely the private exercise of my profession. In good faith, Prof. Enrico Bottini."

"El Criterio Católico en las Ciencias Médicas" is the title of a new medical periodical published in Barcelona. It is stated to be the official organ of the Medico-Pharmaceutical Society of SS. Cosmas and Damian, and will fill the place formerly held by *El Sentido Católico en las Ciencias Médicas*, which suspended publication about six years ago.

Clinical Department.

AN UNUSUAL CASE OF UTERINE SARCOMA.

By JOSEPH WIENER, Jr., A.B., M.D.,
NEW YORK.

Mrs. P. T——, aged twenty-six, first presented herself to me in November, 1896. Her family history was good. Her father had died of endocarditis; her mother was alive, and had always been well. I could obtain no history of a malignant growth in either of her grandparents. She had lost neither brothers nor sisters; those living were well.

Her personal history was as follows: Aged twenty-six years; had never had any serious illness. Menstruation began at fourteen years—regular, four-weekly, moderate flow, not associated with much pain. A perfectly healthy girl, then of seventeen years, when she married. Soon after marriage she became pregnant, and was delivered at full term of a healthy girl, alive to-day. Her second gestation terminated in an abortion at two months. Her third gestation, five years ago, terminated with the birth of a male child, still living. Her fourth gestation, two years ago, terminated in an abortion. Owing to hemorrhage, she was curetted at that time, no anæsthetic being employed. Following this she menstruated regularly and was entirely well. According to her history, taken a year ago, she had come from California to New York nine months previously. She flowed on the train, and has been flowing off and on since then. She was treated for several weeks by a physician who promised to cure her with douches. At first she merely noticed more profuse menstruation; then she began to have metrorrhagia. Still the physician persisted with his douches. After a few months the patient noticed that her abdomen was increasing in size, and she began to have abdominal pain. Her appetite became poor and she lost some flesh and strength, especially during the past two months. Micturition was not painful; the bowels were a little constipated.

On examination I found a fairly well-nourished, somewhat pale young woman. Heart and lungs normal. Pulse about 100, of fair quality. On examination of the abdomen, a round hard tumor could readily be mapped out. It was centrally located, not freely movable, and somewhat painful to the touch. On bimanual examination the tumor was found to be quite low in the pelvis and to move with the uterus. The cervix was enlarged and hard; and there was a slight bloody discharge from the uterus. As the patient had lost considerable blood of late and was quite anæmic, it was decided to wait a few weeks to improve her general condition. An exploratory operation was then proposed to the husband, who readily assented. This was performed at St. Elizabeth's Hospital on December 19, 1896.

A median abdominal incision was made. The abdominal parietes were œdematous, and owing to many adhesions the peritoneal cavity was opened with difficulty. The omentum was found adherent to the abdominal wall as well as to the fundus uteri. The uterus was enlarged to the size of one at the fourth month of gestation. The adhesions between the omentum and the uterus were tied off with several silk ligatures, and the omentum was raised. It was then found that the posterior vaginal and anterior rectal walls were infiltrated by the new growth, which extended upward along the spinal column almost to the liver. All idea of a radical operation had to be abandoned. I removed a small piece of the growth from the fundus of the uterus, and closed the abdomen. The patient recovered from the effects of the operation without any untoward symptoms, and was able to leave the hospital and return to her home after twenty days. The abdominal wound healed, with the exception of two small fistulæ, which continued to discharge what looked like necrotic tissue.

Ten days after her return home I began a course of injections of Coley's toxins of bacillus erysipelatis and bacillus prodigiosus. I injected this through the abdominal wall directly into the tumor. For six weeks these injections were made three times a week, and were followed each time by a chill and rise of temperature—the chill lasting from a few minutes to an hour, the rise of temperature at times being as high as 105° F. After these six weeks the injections were continued for five weeks longer, but only twice weekly. During all this time the patient was able to be up and about, even go out for a walk. Her appetite improved and she gained in flesh and strength. She lost scarcely any blood from the uterus, but pain was present at times, especially on the right side, never, however, severe. Three months after the injections had been discontinued, the patient, after a ride in an elevated railroad train, had a severe uterine hemorrhage, which stopped on tamponade. This was in July last. From that time on she became steadily worse. The pain, which had been moderate, became severe, and there was a bloody discharge almost constantly. On August 23d there was a profuse hemorrhage from the uterus, and four days later the patient died.

The chief points of interest in the case are:

1st. The youth of the patient, twenty-six years.

2d. The probability that if the uterus had been curetted and the scrapings examined when the patient first came to New York she might have been cured.

3d. The temporary improvement from the use of Coley's extract.

4th. The anatomical structure of the growth, a small, round-celled sarcoma with alveolar arrangement—a rare form of uterine growth.

HYDROCEPHALUS AND SPINA BIFIDA.

By H. H. VINKE, M.D.
ST. CHARLES, MO.

The accompanying illustration is from a photograph of a case of congenital hydrocephalus complicated with spina bifida. The little girl was born at full term on the 6th of September, after a tedious and difficult labor, but no instruments were used. The head is enormous, measuring eighteen and one-half inches in the fronto-occipital circumference, eleven inches from external meatus to external meatus, and thirteen inches from root of nose to occiput. The occiput is poorly developed, and the bone proper has not yet united with the condyloid pieces. The different bones of the cranium are more or less widely separated by intracranial pressure, and different parts of individual bones are not as yet united. Most widely separated are the parietal bones from the occipital bone, and the bulging out at this point causes the distance between the root of the nose to the occiput to be so great and out of all proportion to the circumference of the head. The head is very soft and compressible, and could be moulded by the maternal structures in such a manner that it escaped from the vulva like a long bladder filled with water, and explains how a child with such a large head could be born without instrumental aid. The hydrorrhachis is at about the middle of the dorsal region, and has a broad base. The thyroid body cannot be felt, and I am certain that this gland is either rudimentary or absent. Should I be permitted to make a post-mortem, I could determine this point definitely.

There is no deformity of the roof of the mouth or the uvula. She constantly moves her hands and has complete control over the lower extremities. There is nothing abnormal about the pulse or temperature. The child refuses to take the breast, but takes the bottle readily. She cries but little, sleeps much, and is of

but little trouble to her mother. The parents are perfectly healthy; this is their first child. It is certainly surprising that such a frail and deformed being should live so long.

A CASE OF HALLUCINATION.

By T. J. HUTTON, M.D.,
MILLINGTON, ILL.

A MAN, aged fifty-eight years, sought my opinion of his own case. He said that by day he had no trouble whatever, except a fearful dread of night. And this dread of night was caused by the fact that the moment he lay down in bed at night a woman dressed in black came in through his bedroom window, lay down on his bed, and kept up a conversation with him until he fell asleep, which did not occur until far into the night.

Was this man fooling, or was he drunk, or, worse still, was he mad? I soon satisfied myself that he was not fooling, and that neither was he drunk; but it took me a little longer time to decide that he was not insane. He himself considered that he was becoming insane, and confessed that he thought of committing suicide.

He had the drink-habit history. I diagnosed alcoholic thickening of the sheaths of the optic and auditory nerves in the inner part of their course through the cranium, where they traverse a common canal; that in the dorsal decubitus this thickening caused irritation or compression of these nerves—perversion of function and the strange dual illusions. Acting on this theory, I put him on iodide of potassium, and in less than three months he was completely cured.

Prof. Adolf Baginsky of Berlin, director of the Kaiser and Kaiserin Friedrich Children's Hospital, has been made an honorary member of the Societ of Paediatrists of Moscow.

DYSTOCIA DUE TO ASCITES IN THE FŒTUS.

By I. C. EISENBERG, M.D.,
NEW YORK.

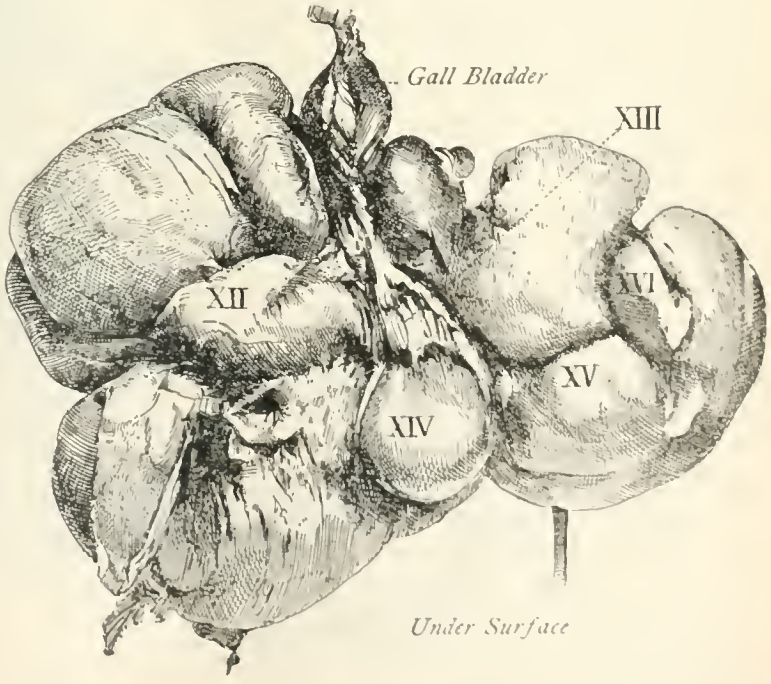
ON the 29th of August last I was called in haste to attend Mrs. B. F—— in her confinement. She was nineteen years of age, healthy, primipara; period of gestation, the eighth month; presentation, L.A.O. Being satisfied with the position and presentation of the fœtus, the condition of the mother, and the good labor pains, I expected an easy and normal labor. An hour later the head was delivered, but then labor was arrested. I recognized that dystocia was caused by the distention of the fœtal abdomen, but waited, thinking that delivery might possibly be effected naturally, in consequence of the gravitation of the fluid from one part to another. But I saw the woman becoming prostrated, and decided that the only resource was in evacuation of the fluid, and so I punctured the abdomen near the insertion of the cord. A large amount of brownish watery fluid was discharged, and labor was soon terminated. Examining the child to see if possible the cause of the ascites, I found that it was a hemiteratic and cryptorchid. In lieu of penis there was a long, solid, cylindrical, curly, muscular appendage, without urethra, corpus cavernosum, spongiosum, or meatus. The abdominal cyst was due in all probability to retention of urine. The child died ten minutes after delivery.

A LIVER WITH SIXTEEN LOBES.

By W. MOSER, M.D.,
BROOKLYN, N. Y.,
PATHOLOGIST TO ST. CATHERINE'S AND ST. MARY'S HOSPITALS.

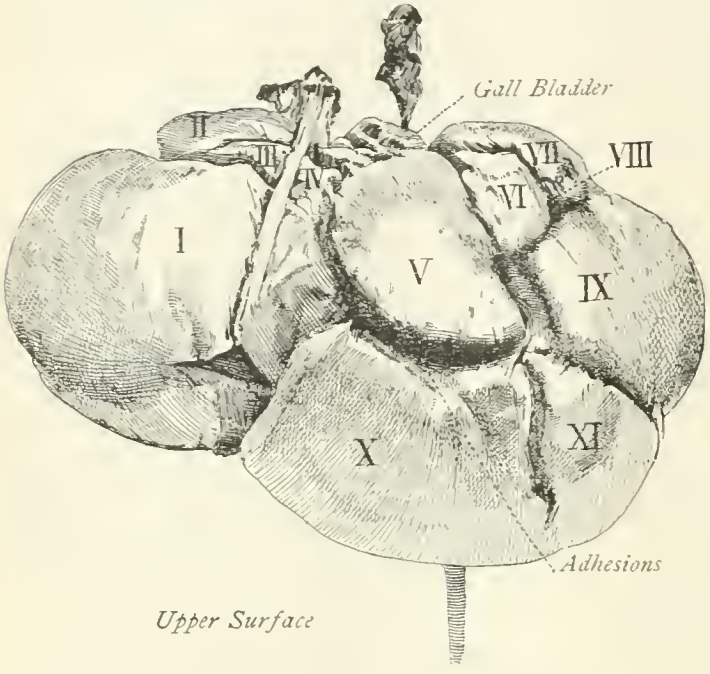
ACCESSORY or supernumerary lobes of the liver are not common; nor are supernumerary livers common, most of which appear to have been situated or attached to the suspensory ligament. They are not so frequently encountered as a supernumerary spleen or spleens.

The liver normally consists of five lobes, viz.: 1, right; 2, left; 3, lobus caudatus; 4, lobus quadratus;



5, lobus Spigelii. With these five lobes another or accessory lobe may sometimes be found. McPhedran has encountered an accessory lobe of the liver in a few laparotomies, and in fact, in a few instances there have been operations for an alleged tumor of the right hypo-

chondriac region. In place of one accessory lobe we may have as many as sixteen. Such a specimen was found recently at an autopsy at St. Catherine's Hospital. The upper surface of the organ contained twelve distinct lobes, the under surface four. These lobes were separated by deep fissures, so that, in place of the usual five lobes, eleven accessory lobes were found.



Upper Surface

Strange as it may seem, this liver was not much enlarged, for the reason that the right and left lobes were subdivided into several lobes. While such a liver is mainly of anatomical interest, I believe with McPhedran that cases of accessory lobe or lobes of the liver could be mistaken for tumors. If we bear in mind the occurrence of accessory lobes of the liver, their smooth, elevated surfaces and abrupt depressions (corresponding to the individual fissures), it might prevent error. If the liver be enlarged, then liability to error is enhanced. A liver with sixteen lobes reminded me of the lobulated kidney indicative of arrested development. In the liver, however, I am unable to explain their origin.

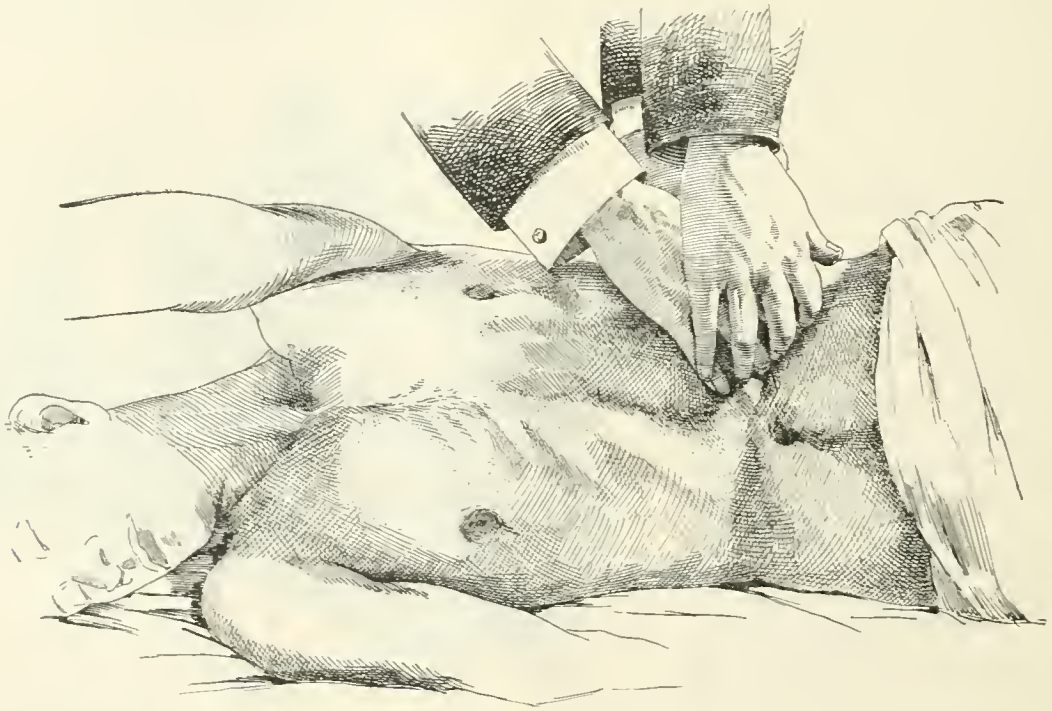
A SUGGESTION TO INSTRUCTORS IN PHYSICAL DIAGNOSIS.

By J. N. HALL, M.D.,
DENVER, COL.

The uncertainty as to whether a student hears, with the stethoscope, the sound which we intend that he shall hear, especially in cases in which the sound is an inconstant one, has been quite effectually obviated by the use of the multiple stethoscope; for by its use the instructor can at least be certain that the particular sound to be heard is present and audible at the time the student listens for it. I have often doubted, however, whether a student actually felt the edge of the liver, the spleen, or a pyloric tumor, in spite of a halting affirmation that he was pretty sure he did feel it. The interlocking of the fingers of the student with those of the instructor, as in the illustration, gives the latter opportunity at least to make certain that the object to be felt is actually under the fingers of the student, so that, at the least, he should feel it. In movable tumors, particularly, I have found the procedure of considerable value. After the student once knows what he is to feel for, half of his difficulties vanish, and the smile which lights up his face after he first distinctly feels by this method the edge of an enlarged spleen, for example, is better evidence to me than his oral statement as to what he has found.

(I am indebted to a senior student, Mr. F. W. Rumsey, for the excellent photograph from which this illustration is made.)

A Biography of Ernest Hart.—It is announced that Mrs. Hart is preparing for publication a life of her husband, the late editor of the *British Medical Journal*, and she requests all those who have records of public work done in conjunction with Mr. Ernest Hart, who have letters of interest from him, or who can give personal reminiscences of him, to communicate with her, as she is anxious to collect the material for the proposed biography at an early date.



Society Reports.

SIXTEENTH GERMAN CONGRESS FOR INTERNAL MEDICINE.

Held at Wiesbaden, April 13, 14, 15, and 16, 1898.

(Special Report for the MEDICAL RECORD.)

Wednesday, April 13th—First Day.

President's Address.—PROF. MORITZ SCHMIDT, of Frankfort, in welcoming the members of the congress took occasion to say that much was to be hoped for in medicine from such meetings. Medicine was no longer in the position where advances were made only by geniuses and where we must wait for genius to light the way before we could go on. Much more was to be gained by the gradual accretions to medical knowledge of a number of seemingly unimportant contributions from very ordinary mortals, but which, taken all together, showed that natural process in the evolution of knowledge which so closely imitated nature, and whose results were as lasting as nature's own because they had come in her own good way. Much of the future of medicine, he said, must depend on animal experimentation. This did not mean the infliction of unnecessary cruelty on animals, nor did it mean that we must be heartless toward animals. So great a vivisector as the distinguished Leipsic physiologist, Ludwig, had been the president of the Society for the Protection of Animals. The movement among hypersensitive females to do away with vivisection could not but do harm if it became popular. The triumph of animal experimentation was the serum therapy of diphtheria. With the glorious prospect this opened up of relief to millions of human beings suffering from manifold ills, no false and foolish sentimentality could deter the medical man from vivisection. In the beginning animals were given to man, who was to rule over them, and in this was involved the right of life and death.

The Clinical Teaching of Medicine. — Professor von Ziemssen, of Munich, and Professor von Jaksch, of Prague, had been invited to open the discussion of the question of the clinical teaching of medicine, the first as it regarded the German, the latter, the Austrian universities.

VON ZIEMSSEN thought that the present teaching method was defective in the matter of the practical technical training of physicians. To remedy these defects he considered it necessary to have: 1. A longer medical course, at least ten half-years (semesters) instead of nine as now. 2. Practical laboratory experience in chemistry, anatomy, physiology, pathological anatomy, and pharmacology. 3. A course of lectures covering the whole ground of general and special pathology and therapeutics. 4. Practical courses with demonstrations in all diagnostic and therapeutic methods. On the teaching of these therapeutic methods he laid great weight, as he considered that the greatest fault of modern clinical medical instruction was its neglect of practical exercises, especially in therapeutic methods. These practical matters he thought could be best learned in connection with a dispensary, where the students, under proper control of a teacher, would themselves have to assume responsibilities in the treatment of the patients and visit them at their homes. All this practical work would have to be shown to have been done before the student would be admitted to examination, and the clinical professor would himself have to take care that the dispensary practice did not degenerate into mere routine. Besides all this, however, the graduate before he entered on practice should have a year of practical work in a hospital. This ought to come after graduation, because before that everything was learned with an eye solely to what would be needed for the examination.

PROFESSOR VON JAKSCH demanded instead of ten semesters at medicine, as they now had in Austria, twelve semesters. He thought, however, that two of these semesters might be taken from the preparatory years at the gymnasium and devoted at the university to zoölogy, botany, and mineralogy, to which should be added a certain training in photography and in the management of electrical apparatus. There was a tendency to too great decentralization in medicine, and the invasion of specialism would tend to make mere mechanics of physicians. Even Billroth shortly before his death seemed to think, as he wrote in a private letter to Professor Wölfler, that the future medical school would have to consist of a number, a large number of almost independent special departments. This, of course, would be fatal to scientific medicine. The way to avoid it was to reclaim for internal medicine her position as the mistress in the medical household, in which her status had been somewhat impugned by impudent handmaidens. A regular course of didactic lectures would be most desirable, but the students would not attend them. It was true that a student could not go home and read up a subject to grasp it in the way he could after its presentation to him in a lecture, but even the great Billroth had found his didactic lectures unattended. Into the clinical presentation of a case must be put the ideas that the students would get in didactic lectures; and a variety of cases to carry the series of clinics c er the field of special pathology and therapy must be selected. He believed that during the regular medical course the specialties should be taken up only so far as they referred to the general diseases. For those who wished to devote themselves to a specialty, a year in a special clinic or under a specialist's care should be required. Specialism must not be allowed to undermine the solid foundation of general medicine or the effect would be fatal. With regard to mental diseases, the speaker said that they had become so important of late years that their study and a special examination in them should be obligatory.

The discussion was continued by JÜRGENSEN, HOFFMANN, SCHULZE, QUINCKE, and others. The general agreement seemed to be that clinical teaching of practical medicine must work out its own salvation in the course of time, and no definite plan, in view of the diverse opinions held, could be agreed upon just now.

Chlorosis.—The remaining hours of the first day were devoted to papers on pathological blood conditions and their treatment. The discussion of the treatment of chlorosis showed that the profession in Germany was still waiting for some method of treatment that would prove successful in severe and relapsing cases of chlorosis. Von Noorden's definition of chlorosis and anæmia and their differentiation passed without question. Chlorosis was a disease of the blood-making organs; anæmia, a symptom of defective blood composition, that might be due to a variety of causes. Good words were said of diaphoretic treatment for chlorosis, and even the suggestion to venesect chlorotic patients for the sake of the stimulant effect on the blood-making organs was not thought inadvisable.

ROSIN, of Berlin, advised hot baths up to 110 –115° F., or as hot as the patient could stand them. Hot baths were excellent when one was very tired and they had a correspondingly refreshing effect upon the perennially tired feeling of chlorotics. This tired feeling was the result of muscular malnutrition in both cases —in the fatigued from the exhaustion of the nutritive material stored in the muscle: in the chlorotic from the bringing of insufficient nutriment and the gases for its proper consumption by the disordered blood.

Determans, of St. Blasien, thought the blood plates portions of the protoplasm of the red blood corpuscles which had been constricted off. This occurred more frequently when the red blood cells were not in normal health. The number of blood plaques then could be taken as an expression of the coefficient of the vital resistance of the red blood cells to disturbing influences. They were not characteristic for any disease, but they were an expression of the degree to which the red blood corpuscles had fallen victims to the underlying disease. As such they formed an important clinical symptom.

Dr. Engel, of Berlin, demonstrated in the blood of human and animal embryos a special form of large nucleated red blood corpuscle, which was differentiated from the ordinary normoblasts and megaloblasts of embryonic blood by its reaction to Ehrlich's triacid stain, and especially to orange G. This new corpuscle he called a metrocyte (a mother cell). It was found in the blood also of those suffering from pernicious anæmia, and constituted the only absolutely sure means of diagnosticating genuine progressive pernicious anæmia from any severe anæmia, a differentiation which had become one of the most important points in modern blood pathology. The finding of these metrocytes in the blood of a pernicious-anæmia case made the prognosis absolutely bad.

Thursday, April 14th—Second Day.

Diabetics.—Professor Leo, of Bonn, read a paper on the treatment of diabetes. He did not believe in the absolute diet without vegetables that Cantani had suggested, as in bad cases it led surely to more rapid accumulation of acids in the blood, and diabetic coma was an acid intoxication. He believed with Naunyn that vegetables contained certain salts absolutely necessary to the organism. Even in the lightest cases, however, he believed that for two or three weeks three or four times a year absolutely no carbohydrates should be taken, as thus the metabolic faculty for sugar which had been injured was given that strictly physiological rest so conducive to its recuperation. He had shown by a series of experiments on animals that glycosuria could be produced by the administration of a ten-per-cent. sugar solution, in which fermentation had been allowed to begin by the addition of yeast. He did not think that this meant that beer might directly produce diabetes, since the disease occurred more frequently in women than in men; but he had no doubt that beer in people disposed by heredity or otherwise would increase the tendency to the development of the disease.

Von Jaksch spoke of his attempt to replace grape sugar, which the organism had unlearned how to use, by some chemical equivalent of sugar, of which the system might be able to avail itself. His experience with methyl peritose, the arabinose of commerce, had been encouraging. He did not believe that the physician's attention should be given so much to making the urine absolutely free from sugar. It was another such a mistake as the treatment of fever by antipyretics, the sad mistake of some years ago. No one now thought of making typhoid run an afebrile course by giving large doses of antipyretics, and in a few years no one would think of making the urine free from sugar, but of furnishing such a diet that, despite this, bodily metabolism might be kept up.

Minkowski reported a series of good results from the administration of pancreas extract in dogs, in which diabetes had been produced by the removal of the pancreas.

Von Jaksch believed that not all cases of diabetes were due to defective function of the pancreas. He had seen a number of cases, notably of phosphorus poisoning, in which the lesion had been in the liver.

Then began a lively tilt between Minkowski and von Jaksch as to pancreatic and hepatic diabetes. Minkowski suggested that in phosphorus poisoning the pancreas was affected as well as the liver. Von Jaksch had after autopsy in his cases been able to find no lesions of the pancreas. Minkowski thought that pancreatic lesions always existed, though present technical and microscopical methods were not refined enough to detect them.

The mention of the subcutaneous injection of sugar as a nutritive agent brought out the fact that with care in the avoidance of infiltrations at the point of injection sugar might be with safety introduced into the organism, though the procedure had not been sufficiently tried as yet to indicate that it would be of any material assistance in the treatment of diabetes.

Leube, of Wurzburg, and Jacob, of Berlin, had used olive oil often by subcutaneous injection in gastro-intestinal diseases, and had had no trouble with it and some excellent results.

As to saccharin, all were agreed that it was not merely the indifferent sweetening agent that it was considered.

Boas thought it hindered fermentation in the intestinal tract.

Von Jaksch thought it caused gastro-intestinal trouble, and thought that Boas' explanation would account for its interference with digestion by inhibiting the normal digestive ferments.

Bornstein had seen dyspeptic symptoms after its use, so that the substance should not be readily prescribed for patients, and, above all, they should not be given *carte blanche* to use as much of it as they liked.

Urotic Acid.—Minkowski, of Strasburg, described a new nitrogenous substance which he had found in the urine of dogs fed on calf's thymus. He called it urotic acid, and believed that, like uric acid, it was an oxidation product of the nuclein bases, especially of adenin. He thought that in its chemical constitution it was an amido-pseudo-uric acid. Up to the present time it had been absolutely overlooked, though it occurred in the urine of thymus-fed dogs in more than twenty times the amount of uric acid. He believed it to be an intermediate compound that had escaped from the organism before all the usual processes of oxidation were completed, and that it consequently played a rôle in the human organism as a step preliminary to the formation of uric acid, and that it might thus be of clinical and pathological importance.

Pseudo-Tabetic Spinal-Cord Degenerations.—Professor Edinger, of Frankfort, demonstrated artificially produced tabes-like degenerations in the spinal cord of rats. The animals had been first subjected to a *régime* which made them anæmic, and then compelled to work hard for a certain number of hours. This overexertion while they were in a run-down condition had produced lesions very different from those usually found in anæmia alone. In anæmia the edges of the cord all round, though more particularly in the posterior and lateral columns, showed spots of degeneration. In these cases of Edinger the degeneration, as shown by the Marchi method, was limited to the posterior columns. Edinger thought that the real etiology of tabes was the degeneration of nerve fibres called on to do much work when they were in an abnormally susceptible condition, as a result of heredity—for instance, in Friedreich's ataxia; or of syphilis, as was usually the case in locomotor ataxia; though the disease might be from other toxic influences as well. Tabes was a progressive disease under these circumstances, because, once a number of nerve fibres had degenerated, then others were easily subjected to overwork and so followed in the degenerative process, especially as they, too, had been affected by the toxin that

lowered the vital resistance of the first fibres. Edinger called special attention to the fact that with these degenerations and this etiology as their basis, a great lesson in prophylaxis was taught. Anæmic, rundown people must be warned of overexertion, and the same was true of syphilitics. Once the process had begun, then the extremest care as to anything like overexertion must be taken. It was no unusual thing to find that in a case in which the tabes had been at a standstill for years, it suffered a new exacerbation after injudicious and unusual exertion. The modern movement therapy for locomotor ataxia, now so fashionable, was liable to lead to serious consequences in this respect, unless most judiciously employed.

Dr. Friedel Pick, of Prague, called attention to the fact that the preparations shown contained certain points of degeneration at the periphery of the cord, such as Ehrlich had shown to occur in cases in which the aorta was compressed for a time. These represented the association fibres binding together different segments of the cord, but not fibres from the posterior roots.

Streptothrix Hominis.—Petruschky, of Dantzic, demonstrated cultures and preparations of streptothrix hominis, a sort of mould which was pathogenic for man—at least he had found it in the sputum in two cases of lung affections. He thought that it was the etiological factor in a disease that occurred in Dantzic and had been called malaria, but in which no hæmatozoa could be found in the blood.

Von Ziemssen, of Munich, had found the same form of parasite in certain atypical lung affections with a slow course, and he, too, regarded it as of pathogenic significance.

Roentgen Demonstration of the Results of the Schott Treatment of Heart Disease.—Dr. Schott, of Nauheim, exhibited some skiagrams showing that reduction in the size of the heart had become less after a course of his exercises against graduated resistance than it had been before (see page 436).

Friday, April 15th—Third Day.

Intestinal Sepsis and Antisepsis.—Müller, of Marburg, and Brieger, of Berlin, read papers on "Intestinal Auto-Intoxication" and "Intestinal Antisepsis." Professor Müller reviewed the subject as far as the ingesta were concerned, whether these were poisons or poisonous food products or bacteria. He absolutely refused to accept the conclusions of Bouchard and Charrin, of France, that it was through the intestinal walls under slightly abnormal conditions that bacteria entered the blood, to set up such diseases as meningitis, pneumonia, influenza, etc. Except in the presence of gross anatomical lesions, bacteria did not penetrate mucous membranes. The symptoms of auto-intoxication as we knew them were not bacterial, certainly not due to the ordinary saprophytic bacteria of the intestine, but the results of the absorption of chemical poisons, and these were always formed in the gastro-intestinal tract whenever there was stagnation of its contents, whether in the stomach or in the intestines. As to the urotoxic coefficient, especially as it was determined by the injections of quantities of urine into animals, though so much had been heard of it of late years from French and Italian sources, Müller pronounced it utterly untrustworthy.

Brieger and Ewald took the same position, which seemed to be the generally accepted one here in Germany. As to intestinal antisepsis, very little could be hoped for from it. The best treatment was a purgative, or an emetic if there was stagnation of the stomach contents. As to the treatment of auto-intoxication, as in the treatment of poisoning cases generally, after elimination as far as possible had been effected, then the treatment was purely symptomatic.

Boas reported cases in which with symptoms of acute auto-intoxication he had found the quantity of urine passed in twenty-four hours very much reduced—as low as three or four hundred cubic centimetres. He considered a diuretic always indicated, and thought it fortunate that the best-known intestinal antiseptic, calomel, was also an efficient diuretic.

A Pathogenic Protozoon.—Dr. Jacoby, of Berlin, described a protozoon, hitherto not known to be pathogenic for men, which accompanied dysenteric symptoms in several patients.

Reaction of the Intestinal Contents.—Professor Mathes, of Jena, had been testing the intestinal contents of dogs immediately after the death of the animals, and had not found that they were simply alkaline in reaction, as the physiologists had been teaching up to this time. He found that they were amphoteric. While they reacted constantly alkaline to litmus and certain other test substances, they reacted usually distinctly acid to rosolin and another series of reagents. The salts contained in the food had a good deal to do with the reaction, and the consumption of vegetables rich in certain salts, especially the various phosphates, had a distinct effect on the reaction of the intestinal contents.

Dural Infusion.—Dr. Jacob, of Berlin, said that Quincke's lumbar puncture had not fulfilled its promise as a therapeutic or diagnostic measure, although its almost universal use showed that it was not a serious procedure. This had occasioned the idea that after the evacuation of a certain amount of cerebro-spinal fluid, a medicated liquid might be introduced in its place. Jacob had tried, first, ordinary salt solution, and afterward carbolic solution and solution of iodide of potassium. Only in cases in which excessive amounts (over one hundred cubic centimetres) were introduced did any unpleasant symptoms develop. Some animals bore one hundred and fifty cubic centimetres of medicated fluid without the slightest inconvenience. Solutions of iodide of potassium were injected then in severe syphilitic cases in men and borne very well, the iodine appearing in the urine in fifteen hours. Dr. Jacob believed that this new therapeutic measure would be of the greatest service, after improvement in its technique, in leading to the rapid absorption of gummatous processes in the cortex and cord before they had had time to degenerate and produce sclerotic changes.

Disorders of Cutaneous Sensibility in Visceral Disease.—Dr. Seeffer, of Halle, showed the regions of cutaneous nerve endings that in affections of various internal organs were rendered either hyperæsthetic or hypæsthetic. The determination of these sensible disturbances was made with a very sensitive æsthesiometer, the invention of Head. The studies had two practical applications: 1st, the local hypæsthesia or hyperæsthesiæ of hysteria or neurasthenia might thus be traced to the organ which perhaps by it sfunctional derangement was disturbing nervous equilibrium; 2d, the question of counter-irritation took on a more exact meaning, and the region in which alone counter-irritation would be of effect was definitely indicated.

Saturday, April 16th—Fourth Day.

Micro-Organisms in Syphilis.—Van Niessen, of Wiesbaden, but now working in the laboratory of the Imperial Institute of Experimental Science in St. Petersburg, demonstrated the micro-organisms he had found in the primary sore in syphilis, in the epiphyses of hereditary syphilis, and in the blood, especially that obtained by cutaneous incision, since the bacteria

seemed to be distributed on the surface, of tertiary syphilitics. He believed that no single form of micro-organism was responsible for the manifold lesions of syphilis, and his demonstration included such varied forms as staphylococci, diplococci, and streptococci, as they were found in various characteristic lesions of syphilis. These took the ordinary stains, the carbol-fuchsin and Gram's being the two methods used in the specimens exhibited. The micro-organisms had undoubtedly been seen by other observers, but the facts that Virchow admitted to his *Archiv* some time ago one of Van Niessen's articles, and that after this the Russian government called Van Niessen to St. Petersburg to continue the distinguished Sperk's researches into syphilis, gave these discoveries an extraneous interest. Van Niessen claimed to have produced syphilis-like lesions in hogs by the injection of specific infectious material.

The Urine in Pneumonia.—Dr. Friedel Pick, of Prague, reported a special characteristic of the urine in pneumonia just after the crisis. While during the disease it was uniformly acid, twenty-four to forty-eight hours after the crisis it became neutral or even alkaline, or in rarer cases its acidity was much decreased. This lasted for from twenty-four to thirty-six hours, when it became normally acid once more. Pick thought this alkalization of the urine was due to the absorption of the exudation in the lung, especially of the sodium salts.

Pathogenic Action of the Proteus.—Dr. Kühnau, of Breslau, claimed that the proteus had a special pathogeneity. It was dangerous in surgical infections, but especially dangerous when it attacked mucous membranes. That it caused severe enteritis and cystitis, he thought was clear. In two recent cases he had found it as the probable cause of a deeply destructive ulcerative process in the soft palate, pharynx, and tonsils, in cases which ran a fatal course. He had found it in a fatal tuberculous empyema that became deeply destructive. He regarded it as the most probable cause of the ulcerative complications of scarlet fever and diphtheria. As more than twenty forms of it were supposed to exist, and its morphology was most inconstant, a simple change of culture medium serving to change entirely its appearance, a most difficult problem in microbiology would seem to be opening up.

The next congress for internal medicine is to be held in Carlsbad, in April, 1899.

CONGRESS OF THE GERMAN SOCIETY OF SURGERY.

Held at Berlin, April 13, 14, 15, and 16, 1898.

(Special Report for the Medical Record.)

Wednesday, April 13th—First Day.

Professor Trendelenburg, of Leipsic, the president, opened the congress with a short address, in which he welcomed the new and the old members, and recalled the painful loss the society had suffered during the year in the death of several of its members. The most important donation to the society during the year was by the Langenbeck family, of 50,000 marks ($12,500). The interest on this capital was to be used for the purpose of giving German health officers and civil physicians, in case of war outside the empire, the opportunity to obtain military surgical experience; or to serve as an aid in furthering scientific war surgery.

The Latest Methods to Improve the Aseptic Treatment of Wounds.—Professor Mikulicz, of Breslau, first gave his method for sterilizing silk. Boil one-half hour in four-per-cent. carbolic-acid solution, place in five-per-cent. iodoform in ether for twenty-four hours, and preserve till needed in a four-per-cent. carbolic-acid solution in alcohol (about seventy-five per cent.). He described an addition to a surgeon's armamentarium, in the shape of a gauze mask, to be worn over the nose and mouth while operating. The mask was made to rest on the bridge of the nose, below the spectacles, and extended to just beneath the chin, fitting closely around it. Its sides rested on the cheeks. It was held in place by wires similar to those on spectacles, curving over the ears. This invention was the outcome of a series of experiments carried out by himself and his assistants. They talked, coughed, and sneezed at reasonable distances from agar plates, and then counted the colonies. In most cases they were innumerable. They repeated the experiments while wearing the mask, and the number of colonies was decreased to one or two and in some cases there were none at all. The speaker concluded by showing the gloves he uses in doing all operations, and recounting their advantages over bare hands. His gloves, he said, were made of linen. They lessened the danger of infection from the operator's hands; being antiseptic, the suture material was preserved from contamination, and they protected the operator himself from infection.

Professor Landerer, of Stuttgart, said he was convinced that the skin played a large rôle in the septic infection of wounds, since it was so difficult to make sterile. He also attributed, like Mikulicz, much to the air, though he added that he did not believe it necessary to work in an atmosphere absolutely free from germs. He had always had success in his operations after careful washing of his hands and previous preparation of the region to be operated on, by means of formalin. He did not believe that we could always argue from the results of bacteriological experiments to the conditions which were found in the living patient.

Dr. Perthes, of Leipsic, believed gloves were necessary, and advocated a glove made of silk and rubber. Linen gloves, he held, were not practical, because as soon as they became wet they would allow micro-organisms to pass through them. Those made entirely of rubber, as advocated by Wölfler, he did not like, as they were too thick and so the sense of touch was disturbed. Especially in emergencies and in military surgery did he find gloves useful, because in the first case one had not the time thoroughly to disinfect the hands, and, in the second, there was in addition often a lack of water. He showed a very pretty pair of silk-rubber gloves fitting the fingers tightly and reaching to the elbow. Each was covered first by a white linen mitten or stocking, and was pulled on the hand while inside this. When both were on the mittens were removed, leaving the gloves without the hands having touched them. He was, however, scarcely through his description before a hundred voices had cried out, "The price—but what is the price!" He answered: "Well, gentlemen, I must acknowledge they are dear, but we expect to have them made cheaper later. They cost 10 marks [$2.50] a pair." The crowd seemed to think this a little too expensive.

Professor Döderlein, of Tübingen, thought there were too many kinds of gloves in use—linen, tricot, tricot treated with xylol and paraffin, rubber, and now silk-rubber. Examination showed that cloth gloves were worse than useless, since when wet they allowed perspiration and whatever bacteria might be in it to pass. All such gloves examined after operations were found full of bacteria. In certain cases, as, for instance, sudden hemorrhage with no time for sterilization of the hands, rubber gloves might be useful, but he strongly recommended a return to the old methods with the naked hands.

Dr. Bunge and Dr. Prutz, both of Königsberg, did not believe in the usefulness of the gloves, and found alcohol an excellent and sufficient disinfectant for the hands.

Dr. Zoge, of Manteuffel, had for a long time used the ordinary rubber gloves of the chemist, and found that the number of his septic cases was diminished. He also advised the use of instruments as often as possible, saying that the fingers should never be used when forceps could take their place.

Professor Wölfler recommended leather gloves which had lain several days in xylol solution. He had introduced cultures of prodigiosus into these, then worn them for varying periods, wetting them, etc., but no bacteria were found on their exterior.

Professor Mikulicz closed the discussion by saying that he no longer recommended plain linen gloves, but only such as had been rendered impermeable.

Aseptic Treatment of Fresh Wounds. — Professor Friedrich, of Leipsic, showed by experiments on animals that the infection of fresh wounds remained superficial for from six to eight hours. He cut into the triceps muscle of animals and introduced dust and earth. Then after two, four, six, and eight hours respectively he cut out the wound and the surrounding flesh and examined them. Up to the sixth hour bacteria were never found below the surface, and then not in any marked degree, nor were they found in all cases till the eighth hour. He concluded, therefore, that the proper treatment of open wounds not yet six hours old was to freshen the cut surfaces and stitch the edges accurately together. When the wound was more than eight hours old it should be packed and treated without stitching.

Dr. Noetzel, of Königsberg, confirmed Schimmelbusch's conclusions, that from fresh wounds bacteria were resorbed with wonderful rapidity. Ten minutes after infecting a wound with anthrax bacilli he had discovered them in the body. But he believed, nevertheless, that those which were so rapidly taken into the circulation always died, and that probably this quick resorption was a measure of self-protection on the part of the body.

Dr. Schloffer, of Prague, in examining wounds which had healed by first intention had always found bacteria. But he thought too that he was able to prove that the secretion of all such wounds had bacteria-destroying properties.

Local Anæsthesia.—Dr. Hackenbruch, of Wiesbaden, described his method of local anæsthesia, consisting in the injection of one-fourth-per-cent. cocaine-eucaine solution, warm, around the field of operation, which was as much as possible deprived of its blood supply by means of an elastic ligature above. He had done with it a large number of operations, some serious ones, with the best success. Schleich's infiltration anæsthesia had not been successful in his hands.

Dr. Braun, of Leipsic, had made many experiments with Schleich's infiltration anæsthesia and proved especially its anæsthetic effect. He used salt solutions of different strengths, increasing and decreasing the proportions of the different ingredients, but he had been able to improve it in only one way, and that was by the omission of the morphine. He believed that if the morphine was omitted the result would be the same, and there would be done away with much of the œdema which so frequently followed the use of the solution. He claimed it was the specific action of the morphine on the blood-vessels that caused the œdema. In the removal of malignant tumors or large purulent collections he did not consider this method practical.

Dr. Rubinstein, of Berlin, thought cocaine the most practical anæsthetic for small operations. He had seen teeth pulled successfully after infiltration of the surrounding gum, he had done operations for hemorrhoids with the thermo-cautery under cocaine anæsthesia, and he had found it useful in many operations in the joints and for the removal of superficial bone disease. In case of tuberculosis of the bone it was necessary to infiltrate only the periosteum with the Schleich solution, the bone itself being insensible.

Dr. Mankiewicz, of Berlin, thought the employment of morphine as recommended by Schleich particularly useful to allay the pain subsequent to the operation. He did not agree with Braun that it had anything to do with the œdema.

Dr. Gottstein, of Breslau, said that in Mikulicz's clinic they had most favorable results even in large operations, such as cœliotomies, with Schleich's method.

Dr. Wohlgemuth, of Berlin, said that the mixture of eucaine with cocaine was not to be recommended; first because the injection of eucaine was very painful, and, second, because it caused an inflammation of the tissues.

Thursday, April 14th—Second Day.

Resection and Extirpation of the Stomach. — Professor Krönlein, of Zurich, gave some of the details of the extirpation of the stomach performed by Schlatter, as reported in the Medical Record. The patient is still living and well, and since the operation has gained thirteen pounds. Besides bearing witness to the remarkable success of the operation, the patient is now the subject of a scientific study in relation to certain physiological processes of digestion. The speaker had performed twenty-one resections of the stomach for cancer. Five patients died as a result of the operation. Sixteen of these operations were done within the last ten years; of these sixteen, only two patients died as a result of the operation. Of the sixteen patients who recovered from the operation two died of intercurrent disease within ten months, eight died of a recurrence of the cancer, and six were still living and well, two of these having survived the operation more than four years.

Regeneration of an Exsected Stomach. — Dr. Schuchardt, of Stettin, said: stomach carcinoma appeared in three different forms: the first spread quickly, attaching itself early to the surrounding tissues, making a radical operation very difficult; while the other two, the infiltrating and tumor forms, could often be easily removed after having existed a long time. He mentioned a case of almost total extirpation presented at the congress two years ago. In this case there seemd to be no impairment of digestion, and the patient remained healthy and well nourished till she died of pleurisy a short time ago. The autopsy revealed complete regeneration of the stomach from the slight portion left. The specimen was passed around, and macroscopically it appeared like a normal stomach.

Gastro-Enterostomy. — Dr. Stendel, of Heidelberg, gave the results of stomach operations in Czerny's clinic. In cases of stricture of the pylorus they never attempted to dilate but did perform gastro-enterostomy. This operation was also done if a malignant tumor of the pylorus was found inoperable. Even in those cases in which a malignant tumor was left behind untouched there was marked improvement, the patient often living for a long time after the gastro-enterostomy; in one case for three years. He believed that not only was life prolonged in those cases by the growth of the tumor coming to a standstill for an indefinite period, but that there was even a retrograde change in the tumor itself. Gastro-enterostomies had been performed with the aid of the Murphy button, the results as regarded mortality having been twelve per cent. better with the button than without it. The button was passed by the natural way in all the

cases, though sometimes not for some days; in one case only after three months.

Professor Mikulicz, of Breslau, after exhibiting numerous pictures and specimens showing different kinds and intensity of infiltration of carcinoma of the stomach, said it was only by the knowledge of these different conditions and by attention to them during the operation, that surgeons would be able to improve the results of resection. He said that in doing such an operation it was necessary to understand and know its technique perfectly. In doing this, as well as any other cancer operation, it was absolutely necessary to remove, as far as possible, the lymph glands that were diseased. He exhibited pictures showing how the lymph glands increased in number on the smaller curvature as one approached the cardia, there being oftentimes none at all at the pyloric end; but on the greater curvature the contrary was true, the glands increasing in number toward the pylorus and only an occasional one being seen at the cardiac end. He mentioned a case in which in dissecting out the posterior wall he had once accidentally tied the splenic artery, but no bad results came from it. He did not favor Billroth's operation of resection, but said that the end of the duodenum should be sewed up, a new opening made in it, and then by means of a button joined to the stomach.

Dr. Doyen, of Paris, presented a new method of resection with gastro-enterostomy. The principal thing was his use of a large broad-ligament clamp and the crushing of the wall of the intestine. Having located the tumor, he clamped the duodenum at a sufficient distance from it, and slowly but carefully crushed the entire wall of the gut, without going through it completely. The serous coat remained intact. In the groove made by the clamp he put a strong silk ligature which went entirely around the gut. An ordinary clamp having been placed on the intestine on the side of the tumor, he cut through the intestine between this and the silk ligature. The stump was touched with a Paquelin cautery, and a purse-string suture superadded to the ligature. *Mutatis mutandis*, the same was done on the side of the stomach, except that a temporary elastic ligature or guarded clamp was put on about twenty-five millimetres from the tumor and the crushing done between this and the tumor. In doing a gastro-enterostomy he first put in the stitches in both intestine and stomach, then he crushed the wall of one after the other, and cut into them in this groove, the rest of the operation being done as the operator preferred.

Dr. Loebker, of Bochum, said he had seen cases in which surgeons thought they had removed almost the entire stomach, but the autopsy showed the most of it still remaining. In cases of hour-glass constriction he thought one might easily be deceived. When he found attachments to the pancreas, he cut away part of the pancreas too.

Professor Hahn, of Berlin, gave his statistics of one hundred and forty-one cases of gastro-enterostomy and twenty-eight of resection. Of these twenty-eight, eighteen were cured. As to ages, of six patients between thirty and forty years, three died; of twelve between forty and fifty years, two died; of four over sixty, all died. When patients were very weak he recommended the operation of resection in two stages—first the gastro-enterostomy, and after some days the resection.

Professor Wölfler said that all resections with gastro-enterostomy previously performed, whether done according to Mikulicz's or Doyen's method, should be called Billroth's, as at most they were only modifications of the latter's procedure.

Professor Jordan, of Heidelberg, reported a case in which, on opening the stomach, no tumor or pathological condition was found, but the patient was much improved for months.

The Murphy Button, Frank Coupler, and Wolfler Button.—Dr. Storp, of Königsberg, presented a paper on the Murphy button, of which he was a strong advocate. But the general discussion that immediately followed brought up the other two.

Dr. König, Jr., of Berlin, described the Frank coupler and his experiments on dogs. He concluded that it was more suitable for side-to-side anastomosis than for end-to-end.

Professor Wölfler said he had tried to improve the Frank coupler. His button was absorbable and consisted of a tube with two rings on it that came slightly apart and sprang fast together.

Dr. Storp found the Frank coupler of more practical use and not so quickly absorbed if kept from twenty-four to forty-eight hours in formalin.

Shot Wounds of the Intestine.—Professor Poppert, of Giessen, reported a case in which he made five resections of the small intestine for shot wounds (twelve wounds in all), with complete recovery.

Meckel's Diverticulum.—Dr. Sprengel described a case of acute inflammation of a persistent Meckel's diverticulum which resembled very closely a perityphlitis.

Dr. Walzberg, of Minden, and Dr. Stubenrauch, of Munich, described cases of intestinal trouble due to persistent diverticula.

Forcible Reduction of the Deformity in Pott's Disease.—Professor Hoffa, of Würzburg, described and advocated Calot's method of applying pressure to the prominence while extension was being made. When the hump had disappeared the patient was fixed in the position of correction by a carefully applied plaster jacket, retained, or replaced by a similar one, until the tuberculous process had ceased. The contraindications were, if the deformity was of very long standing, if several (more than two or three) vertebræ entered into the formation of the kyphosis, or if purulent collections surrounded the diseased vertebræ. Paralysis of the legs was not a contraindication; on the contrary, some paralyses had been cured by the procedure. The most suitable cases were those in which the prominence was just appearing. To determine whether or not in a long-standing case the procedure ought to be tried, he advised that extension be made without anæsthesia; if the kyphosis partly disappeared, the further operation might be performed; if not, further procedure would probably be useless.

Professor Lorenz, of Vienna, said the disadvantages of the procedure were that a pressure sore could easily be caused at the point of the kyphosis, and that, on account of the bandage, there was no way of treating it.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 25, 1898.

Arthur M. Jacobus, M.D., President.

An Important Practice-Law Decision.—The salient features of a hard-fought legal battle over a question of the right to practise medicine were presented to the society in the following report. The case was that of the People *vs.* Benjamin W. Hawker, and the suit was brought by the society on the ground that the law forbade any person who had been convicted of a felony to practise medicine. In 1878 the defendant had been convicted of having produced a criminal abortion, and had been sentenced to ten years' imprisonment. Having served his sentence and resumed practice, he was indicted in 1896 for illegally practising medicine. His counsel argued that such a construction of the law

added a new punishment for his crime, and was therefore unconstitutional. On the other hand, the people contended that the law was constitutional, and that the State had, in its police power, the right to exact good moral character as one of the qualifications for the practice of medicine. The first trial before Judge Fitzgerald resulted in a verdict of guilty and an imposition of a fine of $250. The case was then taken to the appellate division of the supreme court, and was tried before five judges, who, on January 5, 1897, after two months' consideration, set aside the conviction, Justice Ingraham delivering a vigorous dissenting opinion. The case was then carried to the court of appeals in Albany. This court, in handing down its decision on March 16, 1897, reversed the judgment of the appellate division and restored the conviction. Eight judges held that the State had the right to exact good moral character of an individual who desires to practise medicine, but they stated that from the record they were not sure that the defendant was a duly licensed physician at the time of his conviction. The defendant then took the case to the supreme court of the United States in Washington, D. C., because of the question of the constitutionality of the law being at stake. The case was argued on December 10, 1897, before eight judges, and was reargued on March 10, 1898, before the full bench of nine judges. On April 18th they delivered their decision, which confirmed the conviction and sustained the constitutionality of the law. Many cases and decisions were cited to show that the State of New York had the right to exact a good moral character, and that in the exercise of that right could exclude those of bad character. The exclusion of the defendant from the practice of medicine was, therefore, not an additional punishment for past offences. The general effect of the decision is thought to be of profound value in securing a proper enforcement of the laws relating to medical practice.

Mother's Milk as an Infant Food.—Dr. S. Henry Dessau read a paper with this title. He emphasized the overwhelming superiority of mother's milk as a food for infants, yet admitted that some mothers did not secrete milk suited to the digestive powers of their infants, or did not secrete the milk in sufficient quantity. A very common fault was an undue proportion of solids and a high specific gravity of the breast milk, leading to indigestion. It seemed to him rational that more attention should be given to the mother's condition rather than to modifying cow's milk or maintaining that satisfactory substitutes could be found. The condition of the mother's stomach could be determined by giving a "test meal," the condition of the blood by ascertaining the percentage of hæmoglobin and examining the blood with the microscope. Both before and after labor it would be found that the hypophosphites were very useful. Retracted nipples could be improved by instructing the mother to seize the nipple between the thumb and finger, and pull it out, repeating this process many times a day.

Galactagogues.—Faradization with a gentle current, the positive pole being applied to the nipple, would be found a useful measure in increasing the secretion of milk. In arranging the diet, it should be remembered that beans, lentils, parsnips, and most foods containing phosphorus were beneficial in increasing the quantity of milk. One of the best foods for a nursing mother was cow's milk, which should be taken in quantities of three or four glasses daily. The internal administration of the fluid extract of the leaves of the castor-oil plant had achieved a considerable reputation as a galactagogue. They had also been used externally in the form of a fomentation of the green leaves applied to the breast. Above all, in these times when the social temptations to shirk nursing were so great, the physician should give all the encouragement and moral support possible to those mothers who were minded to do their whole duty by their offspring.

Raw Cow's Milk for Infant Feeding.—Dr. Edward F. Brush read this paper. He said that clean raw milk, devoid of pathogenic germs, constituted the best substitute for the mother's milk in feeding the infant. Boiled milk was practically dead and sterile; raw milk, on the other hand, retained a certain degree of vitality inherent to such animal substances. Other things being equal, the germs which predominated would be likely to produce the first specific change in a substance like milk. Naturally the first change which took place in ordinarily clean milk was lactic-acid fermentation. After this came butyric-acid fermentation, and then putrefaction and the development of ptomains. He believed that lactic-acid fermentation played an important rôle in infant feeding. In many cases the lactic-acid fermentation would aid the feeble digestion of infants, provided this process had not extended far enough to allow the development of a thick, hard curd. In milk that had been pasteurized or sterilized, this lactic-acid fermentation could not take place. Nature did not attempt such a nice adjustment of the elements of milk as the advocates of modified milk imagined they had achieved. Dr. Brush said that it had been his practice for many years, when milk was becoming sour, but not coagulated, to hasten the coagulation by heat and break up the coagulum. This form of milk he had never known to cause digestive disturbances in infants. It was, of course, foolish to advocate feeding infants in a large city from the general milk supply, because there were too many chances for contamination and infection. Boiling the milk caused a considerable proportion of the albuminoid material to become insoluble. This passed into the intestine unchanged, and led frequently to putrefactive changes. The poisons in milk resulting from nervous disturbances in the animal, or excreted in milk from the food, were not affected by heat. Many years ago, when he was in charge of the New York Infant Asylum at Mount Vernon, where there were two hundred and forty children, ranging in age from two weeks to two years, there were no deaths from intestinal disease, notwithstanding the fact that the infants were fed on raw cow's milk.

Home Modification of Milk.—Dr. William L. Baner discussed this phase of the subject. He said that the most rational substitute for the mother's milk was cow's milk properly modified. It was not generally appreciated that any desired formula could be readily obtained by appropriate and simple combinations of whole milk and cream. The use of separated milk must be regarded only as one of those economies which were necessary when the process was carried on on a large scale. With whole milk, part of the fat was furnished by it, thus allowing the use of lighter cream. The method of calculation for home modification must be extremely simple. The scheme which he had suggested in a recent article was based upon the fact that good cow's milk practically contained four per cent. of fat and four per cent. of proteids. The fundamental facts were: (1) the proteids and fat were practically equal in whole milk, each being about four per cent.; (2) the cream must be always thought of as whole milk plus a certain percentage of fat, *e.g.*, twenty per cent. cream represented whole milk plus sixteen per cent. of additional fat. From this it followed that the extra fat available in any cream was four per cent. less than its total fat content. The desired proteid percentage could be established by properly regulating the quantity of whole milk introduced into it. The total whole milk must always be kept at the desired proteid percentage, *i.e.*, four. A mixture of one part of whole milk and three parts of water would contain about four per cent. of proteids:

hence by multiplying one-fourth the entire amount of the mixture by the desired percentage, any other desired proteid percentage could be obtained. As the vast majority of percentage mixtures called for more fat than proteids, cream must usually be added. Any mixture of whole milk, cream, and water might be considered as having a sugar percentage equal to its proteid percentage. If, therefore, it was desired to modify milk so that an eight-ounce feeding would contain four per cent. of fat and 1.5 per cent. of sugar and proteids, the calculation would be made as follows, using twelve-per-cent. cream: Divide the total quantity (8) by the extra fat (8), and multiply by the difference between the fats and the proteids (2.5). The result was 2.5, the number of ounces of twelve-per-cent. cream which must be added. The quantity of whole milk to be used was determined by multiplying the total quantity (8) by the proteids (1.5), dividing this by 4, and then subtracting the quantity of cream (2.5). This would give half an ounce as the quantity of whole milk required. The rest of the mixture—three ounces—was water.

Wheat Products of Infant Feeding.—Dr. L. Duncan Bulkley read this paper. At the outset he said he wished to proclaim his unqualified adherence to the idea that, when it could be taken, milk furnished the best and the only proper nutriment for infants. He also spoke disapprovingly of the many proprietary preparations which had been foisted upon the profession and the public, mainly for commercial purposes. Nature and all human experience, he said, testified that milk was the proper food for infants. For infants whose nutrition was at fault, especially when this was indicated by persistent and recurring eczema, he had found the greatest possible benefit from the addition of the wheat product about to be described.

Directions for Cooking.—It was essential that the directions be very accurately followed. A teacupful of the ordinary wheaten grits or crushed wheat was put in a pint of cold water, in a china receptacle in a double rice or milk boiler. This was placed on the fire at the time of preparing the evening meal, and was allowed to cook slowly for two hours. It was then set aside, properly covered, and allowed to stand all night. In the morning it would be found to be more or less jellied. Some water was now added so as to make it quite thin, and it was placed on the fire to cook for two hours more. It was next turned out upon a fine sieve and rubbed with the bowl of a spoon, more water being added, if necessary, until the finer portion passed through, leaving the hard wheat behind on the sieve. The gelatinous mass so obtained passed easily through the feeding-bottle, and contained all the nutritive portion of the wheat. It should be prepared fresh every day. The quantity to be given would vary considerably with the individual case. For very young infants, one or teaspoonfuls should be added to each feeding; older children would take as much as a tablespoonful. The indications for its use were found in the conditions of the digestive system. It was a little laxative in its action, but he had not known it to disagree when prepared and used in the right manner. By the prolonged and slow heating all the soluble elements of the whole wheat were extracted, including not only the starch and gluten, but also the phosphates, and all were made to combine, while the hard and undigestible portions were left behind on the sieve. The slow process of preparation possessed an additional advantage, *i.e.*, the setting up of a certain fermentative change, which led to a partial digestion of the mass. This fermentation was checked by the second cooking in the morning.

Advantages of this Food.—The advantages of this prepared wheat were: (1) the whole wheat kernel represented the nearest approach, next to milk, to a complete food; (2) it was a perfectly soluble, partially digested, and thoroughly cooked material, ready for immediate assimilation; (3) if prepared rightly, it was a uniform product; (4) it was a very cheap food, easily procured even by the poor. The labor of preparation was relatively slight, and easily accomplished when once it had become a routine. The plan described differed essentially from others for using wheat—*e.g.*, prolonged boiling of wheat flour in a bag. The essential point was the employment of the whole wheat, whereby, in addition to the starchy portion, all the other elements of nutrition were retained, including the phosphates. A weak solution of this wheat jelly would be found an excellent substitute for barley water when it seemed to the physician desirable to make such an addition to other infant foods. The speaker said he had employed this method with the greatest satisfaction for the last ten years.

A Theory Concerning the Absorption of Milk.—Regarding the absorption of milk, in both infants and adults, Dr. Bulkley said that he believed that milk, if taken into the healthy stomach at certain periods, did not undergo the various fermentations already alluded to, but was absorbed as a whole through the lacteals, and passed from there into the vena cava, and did not pass at all through the liver. This theory supposed that the milk was placed in the stomach in the absence of all other food that might excite the action of the gastric juice. He had had a discussion with the late Dr. Dalton on this subject, and the latter had accepted the theory as probably correct. On mentioning it to Dr. Andrew H. Smith, that gentleman had remarked that it explained something that he had noticed many years ago and had been unable to account for. While experimenting upon kittens, having wounded the jugular vein, he was surprised to find that the blood was whiter than that obtained elsewhere in the body. He had repeated the experiment on a number of kittens that had been suckled by the mother, and with the same result.

Dr. Bulkley said that his personal experience had shown him that there was a great difference in the individual toleration of milk, dependent upon whether it was taken with other food—even cracker—or whether it was taken entirely by itself on an empty stomach.

Dr. David P. Austin said that it was difficult to suppose that an infant that had been fed exclusively on milk from birth up to the end of the first year had never used its liver in digesting the milk. During this year the bile must have been obtained from the milk. Regarding the interval between nursings for infants, the speaker said that it took at least two hours for a meal to be digested by an infant, so that, allowing twenty minutes for a nursing, there would be only an interval of one hour and forty minutes left for the digestion of each nursing. A long experience had taught him that the shortest safe limit should be three hours—better longer. The child should never be nursed until the stomach was absolutely empty. He thought much infantile indigestion would be avoided by having the baby nursed at 8 and 11 A.M., 2, 5, and 8 P.M., and at midnight, and not again until eight o'clock the next morning. Fresh clean milk from every healthy cow would not suit every infant.

Dr. Dessau said that the rule to have the infant nursed only once in three hours was good in theory, but he did not believe mothers could often be persuaded to put it in practice. He did not see how Dr. Bulkley could account for fæces in an infant's bowel if the milk was absorbed by the lacteals as such.

Dr. Brush said that cow's milk and goat's milk, being the secretion of cud-chewing animals, was intended to be curdled for digestion. Dr. Bulkley's theory was based on his own personal experience with the digestion of cow's milk; *i.e.*, he had found that if

he swallowed milk very rapidly without allowing it to be mixed with the saliva, it would agree with him; but unfortunately there were other individuals who could digest milk only when it was allowed to trickle slowly into the mouth.

Dr. Bulkley said that his theory that milk was absorbed by the lacteals did not imply that the liver did not act at all. His remarks on the absorption of milk were not by any means based upon his own personal experience; but he was willing to waive the question of the correctness of the theory, provided he could persuade physicians to give the method a fair trial. A very large portion of the fæcal mass was made up of the secretion of the intestinal glands, and not of the food, hence the presence of fæces in the intestine was not incompatible with his theory.

The Fate of the Dispensary and Health-Board Bills.—The committee on legislation presented a preliminary report relative to the dispensary bill. It was stated that, although it had been ascertained unofficially that the Homœopathic State Medical Society approved in a general way of the bill, it was learned afterward that if it had been presented to it for formal consideration opposition would probably have been avoided. The bill was received favorably by the assembly, and would have undoubtedly passed had it not been held in committee by one man for purely personal reasons. It had been found that much of the opposition to the bill had arisen from unauthorized and misleading statements made by certain recalcitrant members of this society.

Dr. T. E. Satterthwaite reported that the health-board bill had been smothered in a committee of the assembly, through the influence of the chairman, who had boasted that no amendments to the charter would be allowed to go through.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL COUNCIL AND THE MIDWIVES—MENSTRUATION AND OVULATION—ACTION OF TISSUE EXTRACTS ON COBRA POISONS—STEWART CLARK—SMALL-POX.

London, April 15, 1898.

The General Medical Council has given a new face to the midwives question. To the surprise of many, a discussion which threatened to be of great length has been closed by a determination to reply to the Privy Council in a few resolutions on the general principles that should regulate legislation on the subject, instead of giving a detailed answer to the many points raised in the bill before Parliament. The chief recommendation offered is that, instead of midwives being registered as proposed, they should be licensed, the license to be issued for a small fee and renewed annually. It is hoped that this will have the effect of keeping the midwives under supervision and will prevent them from becoming an order of inferior practitioners. Considering that the question has been discussed by the council at intervals since 1872, it seems rather too hopeful to conclude that we have at length done with it, more especially as there seems little chance that Parliament will pass the bill this session. It is indeed down for second reading on May 11th, but the Irish local-government bill is likely to stop the way.

It is curious to notice how little is really known about menstruation and ovulation. The relation of these processes was considered at the late meeting of the Obstetrical Society, when Mr. Walter Heape read a paper on the subject, in which he related his observations on a large number of monkeys. In these animals he found that ovulation and menstruation are not necessarily coincident, and frequently menstruation takes place without any sign of ovulation. He does not, indeed, hold that the two processes are as distinct as some observers maintain, but either may occur without the other, though we know also that they do often occur together. For the origin of the stimulus which sets up these processes, he thinks we must look to a capacity for storing up excess of nutriment existing in all female animals under satisfactory conditions.

Dr. Horrocks mentioned the clinical evidence that ovulation occurred without menstruation, pregnancy occurring during periods of amenorrhœa or lactation, and in India even before menstruation has begun.

Dr. Griffith accepted the evidence as conclusive, and added that there was quite as much proof that menstruation takes place without ovulation, though Dr. Horrocks demurred to this.

Dr. Herman thought the discussion showed the fallacy of the idea that the date of menstruation could be determined from the rupture of a Graafian vesicle. He is disposed to believe that menstruation depends on and does not occur without ovulation; for there is no menstruation when the ovaries are absent, and when it occurs after their supposed removal probably the removal has not been complete.

The president protested against the way in which loose statements on this subject, on which so little is known, are servilely copied by one text-book from another.

Mr. Walter Myers has brought before the Pathological Society a research he has made as to the action of tissue extracts on cobra poison. Experimenting on guinea-pigs, he finds that the suprarenal body neutralizes the poisons. No other organ seems to possess this power. In seven experiments the result was negative in three, but in one of these there were only trivial symptoms after seven hours, though the control animal died in two and one-half hours. In the other cases there were no symptoms in six and three hours respectively, by which times the controls were dead. Experiments were made with a number of other tissues, but the results were uniformly negative, the animals dying in about the same time as the controls. Positive results were obtained also with the suprarenal of the sheep in three cases.

The current number of the *Westminster Review* has an article on Stewart Clark, an Indian medical officer, whose services during the mutiny were of the utmost value, but who nevertheless had to fight for the rights of the doctors who were transferred from the company to the crown. Stewart Clark served in many civil appointments in which science, tact, and zeal were required. He was postmaster-general at the time of the mutiny and director of the government workshops where the mail carts were made. When the factories were destroyed and all the wood burned by the rebels, Clark devised a plan of drying green wood in a few hours, reorganized the works, and forwarded troops at a time of the utmost difficulty. The provincial secretary, the governor, the Indian secretary, and other of the highest officials acknowledged his services, and Lord Canning was heard to say that he would see that he was rewarded. But Lord Canning died, and Stewart Clark was a doctor and had to fight for his rights—so he remained untitled. He received the thanks of the Queen as well as the whole array of officials, but, having fought the war office, nothing further. He retired in 1872, and died about a year ago. A memoir from the pen of his widow has just appeared, under the title of "Stewart Clark, One of Nature's Noblemen." It is curious that our London medical papers gave no obituary account of him when he died. Per-

haps that may have been due to the fact that on retirement he dropped the "Dr.," and his death was announced simply as that of Stewart Clark.

Middlesborough is not yet quit of small-pox, although the epidemic seems declining. From three to ten cases a day were notified during the week. The disease has also appeared on the Tyne.

The Jenner Society has issued a pamphlet by Dr. Bond, comparing the present epidemic at Middlesborough with that at Gloucester last year. Taking the same period, the mortality of the former has been fourteen per cent., while the latter reached twenty-five. He shows pretty clearly that the excess of deaths at Gloucester was due to the greater number of unvaccinated persons who were attacked. An analysis of the age incidence is equally instructive, and once more enforces the necessity of revaccination.

OUR BERLIN LETTER.

(From our Special Correspondent.)

BALNEOLOGICAL CONGRESS — PHYSICIANS' CLUB — A CHAMPION FOR THE RIGHTS OF THE GOVERNMENT MEDICAL APPOINTEES AND OFFICERS — PROTOZOICAL DISEASES.

BERLIN, March 31, 1898.

THE congress of the German balneologists, which usually is a welcome change in the March programme of us Berlin physicians, was held this year for the first time in Vienna. Professor Liebreich presided, and the attendance of German and Austrian physicians was a very large and appreciative one. It is of universal interest to note what one of the cabinet council says regarding the increase in the use of mineral baths. Within fifteen years the number of those needing such treatment and taking it has increased from 100,000 to 200,000: and the number of bottles exported has increased from ten million to nineeen million yearly. Not the least factor contributing to all this has been an improvement in travelling facilities, more comfortably arranged cars, and cheaper rates. At the opening of the proceedings, more by way of a jest than seriously, the question was debated whether or not Priessnitz was the discoverer of hydrotherapeutics. Liebreich stated that from history we know the Roman physician Antonius Musa had used the water treatment with success with the Emperor Augustus, who suffered from a disorder of the liver. So successful was the treatment that he as well as all other physicians who employed these same measures were exempted from military duty. Dr. Kish, of Marienbad, spoke of the scientific elaboration of the balneological question. He asked that there be erected or established at each of the larger baths a laboratory in which physiological and chemical investigations, as well as those relating to the metabolic changes and processes of the body, might be conducted by experts. Römpler, of Görbersdorf, spoke of the contagiousness of tuberculosis as compared to its heredity. His vast experience had led him to attribute to the factor of heredity a much greater influence. It was decided to erect a monument in Görbersdorf, the place of his activity, to the deceased Herr Brehmer, who had accomplished so much in the therapy of phthisis. Finally, at the close of the congress, many of the members made a trip to Kaltenleutgeben, the place where Winternitz has his sanatorium.

A physicians' club, which aims to be a cheerful home for Berlin and all other physicians, has recently been established in Berlin. Three hundred physicians have already joined, notwithstanding the annual dues are 50 marks (about $12). Because of these high dues the club has been dubbed the "Association of the Carriage-Riding Physicians."

The proceedings in the Abgeordnetenhaus, at the beginning of this month, relative to the withdrawal of the medical department from the jurisdiction of the minister of ecclesiastical affairs and of instruction, were of general interest to us all. Some of the representatives wanted to have a separate ministry for medical affairs established, but the government declared itself opposed to this scheme. Virchow championed the medical cause, and put in a strong word for the improvement of present conditions. He wished that the appointees might be so well salaried as to admit of their public duties being their main employment. The conditions relating to the extraordinary professors and the assistants in the universities should be improved. If an assistant derives an extra income from giving courses, he is a Rothschild in the eyes of the ministry. Nowadays only sons of rich parents can afford the luxury of becoming assistants; the poorer ones must decline, and herein lies a great social injustice. Virchow requests therefore at all events an increase in the salary. The minister opposed him, and replied that many extraordinary professors in Berlin have a larger income than a minister has. The chances for a reform are at present by no means bright.

At the Berliner medicinische Gesellschaft, Jürgens, a pupil of Virchow, demonstrated a case of multiple sclerosis of the brain. In a six-months-old child, which *intra vitam* suffered from convulsions and paralysis of the right arm, there were found signs of an acute brain sclerosis. In addition, there were peculiar egg-shaped patches in the heart muscles. Within these areas as well as the sclerosed ones of the brain, Jürgens found protozoa which proved fatal to animals. A fine emulsion of the brain was prepared. In one drop of the upper layer of this emulsion there were hundreds of thousands of protozoa. Six rabbits, inoculated each with such a drop, died in six days. The heart muscle showed cloudiness and contained protozoa. It was thus proven that the lesions of the heart and of the brain of the child were etiologically related to each other. The heart lesion appears to have been primary; that of the brain secondary. It was impossible, though, in this case to learn anything more definite of these protozoa. In the discussion Katz related a case of a man who had acquired a malignant tumor of the testis eighteen years after a blow upon it. The main portion of the swelling showed carcinomatous growth, and contained a remarkably soft, yellow tumor, in which living organisms were found. They had a long torpedo-like shape. On the second day they showed no motion, and on the third they were no longer to be found, though they were plainly visible in the hardened specimens. Certainly these two cases add to our knowledge of the etiology of malignant tumors, but the proof that malignant tumors are caused by the emigration of protozoa is still very remote.

Dr. Playfair, in a lecture on the progress of obstetries and gynæcology, reported in *The Lancet* of March 19th, makes the following pertinent remarks: "A man's skill as an operator depends on his brains and on his fingers, not on the letters he writes after his name. I know fellows of the College of Surgeons whom I would not trust to vaccinate a baby, and I know fellows of the College of Physicians to whom I would unhesitatingly confide any operation they chose to undertake; and, *per contra*, if I were asked to select as obstetric physician to a hospital between a man who was an M.D. and F.R.C.P. Lond. whom I knew to be an inferior man, and a man who was a simple M.R.C.S. whom I knew to be a superior man, I would certainly select the better man of the two, irrespective of his qualifications."

Medical Items.

From Butcher Boy to Royal Surgeon.—An English journal is responsible for the following sketch of Dr. Zakharin, the late Tsar's favorite physician. "Dr. Zakharin started life as a humble butcher-boy. The turning-point of his career was reached when a local surgeon took him in hand as his page boy. Turning his attention to medicine, he soon attracted the notice of his sovereign, and, becoming the best-known doctor in Russia, before middle age had acquired a handsome competency. He was somewhat of a character, and his feats of eccentricity added to his fame. When the state of the late emperor became alarming, the governor of Moscow received a message from St. Petersburg, ordering him to send Professor Zakharin without delay. The governor dispatched his aide-de-camp to the doctor. "In two hours," said the officer, "the express train will start." "The express! What do you mean?" exclaimed the professor. "The emperor is ill, and you talk to me about leaving in two hours! Go to the railway manager and command him to get a special train ready for me in twenty minutes." At the end of that time the train was speeding out of the depot with the doctor aboard.

Leprosy in Hawaii.—While the reports show that the number of lepers at the settlement, December 31, 1895, was ten hundred and eighty-seven, and on December 31, 1897, there were eleven hundred, still the fact remains that leprosy is diminishing in the islands. The government physicians and agents of the board testify to this fact. The chief reasons why the numbers at the settlement have not decreased are the more thorough enforcement of the law of segregation, and the fact of the more complete removal of all persons afflicted with the disease in its earlier stages. During the years when the law was less strictly enforced, a much larger proportion of those taken to the settlement were in the advanced stages of the disease and death followed sooner. The mortality rate is becoming smaller.

The Ehrlich Diazo Reaction.—Solution 1: Acidi sulphanilici, 5; acidi hydrochlorici pur., 50; aquæ destillatæ, 1,000. Solution 2: Potassii nitrosi, 0.5; aquæ destillatæ, 100. Take fifty cubic centimetres of solution No. 1 and one cubic centimetre of solution No. 2; add equal parts of urine, and one-eighth volume of ammonia; shake thoroughly. The rose-colored froth proves the test.—KLEMPERER.

A Nose Competition at Milan.—The nose has at all periods of their history possessed a peculiar significance for Italians. As a symbol of intelligence it figures in familiar speech, ancient and modern, a *homo nasutissimus* being Seneca's equivalent for a very clever man, and *naso* a name held in honor by the Otacilian, Octavian, Ovidian, and Voconian *gentes*, while *nasica* was a cognomen of the Scipios, one of whom, Publius Scipio Nasica, was, as the most virtuous man in the state, chosen to accompany the image of the Mater Idæa to Rome. In the Italy of to-day, *aver naso* and *esser di buon naso* (to have nose, to be of good nose) are the first of a series of phrases turning on that feature in its symbolic sense, and giving rise to proverbs infinite in the variety of their application. The great Napoleon was true to his Italian origin in his preference for a "big nose," and the late Lord Beaconsfield, descended from Venetian Jews, never concealed his scorn for the "flat-nosed Frank." He held, in fact, that to be *simus* was the first step toward being a *simia*, or ape—a "retrocession in evolution," admitted by some among the "facts for Darwin." Such a horror have Italians of any lesion costing the face its nose or robbing the latter of its due proportions, that rhinoplasty among them has long been one of the "surgical fine arts," and the great Bolognese anatomist, Tagliacozzi (1546-99), has for all time given his name to an ingenious method of replacing the feature when lost. Quite in keeping, therefore, with all precedent as well as with the fitness of things, it is in Italy that we find the "cult of the nose" as vital as ever, insomuch that within the last seven years she has had two *concorsi di nasi* (or nose competitions), in which the owners of the feature received prizes according as they could present it in greatest perfection as regards type, size, beauty, and olfactory power. The former of these *concorsi* was held in 1891 at Padua, on the initiative of the students of that medical school, and the citizens were invited *con ischeda segreta*, by universal suffrage and secret voting, to name the possessor of *i nasi piu soiluppati e rispettabili* (noses the most pronounced and respectable) of the ancient Venetian town. The prizes, consisting of pocket handkerchiefs and snuff boxes, were in due course awarded by plurality of votes. At Milan and quite recently a much better ordered and conclusive competition of the same kind has just come off, the whole proceedings being controlled by a committee and the "examinations" conducted in a *nasoteca* furnished with drawings and watercolors of heads well provided with noses such as would have gladdened the artistic sense of William Hogarth. The competitors numbered thirty-six, but not more than twenty-three appeared before the "examiners." The first prize (gold medal) was won by a Venetian, Fortunato Michieluth by name, a vender of lucifers, whose nose was found to be of *proporzioni inquietanti, lungo, deciso, ardito, tagliente come una lama di cottello* (formidable proportions, long, well pronounced, aggressive, trenchant like a knife blade). The second prize fell to one Antonio Pozzi, possessed of a nose *prepotente, presumtuoso, con nari larghe e cavernose* (domineering, assuming, with nostrils wide and cavernous). The award for this was a medal in enamel; while the third prize (a silver medal of the first order) was adjudged to Carlo Ascani for the refined, symmetrical proportions of his nasal feature. The last two prizes (the fourth and fifth, silver medals of the second and third order respectively) were given for a nose "without pretension, ingenuous, but solid and well planted," and for one "considerable, regular, and worthy of respect." The candidates who were unsuccessful—perhaps ploughed would be a more suggestive word—shared the festivities with which the committee concluded its labors, and so the *concorsi di nasi* became a thing of the past, till the *buon temponi*, merry makers of a future year or another city, think fit to revive the harmless, not inartistic, though dubiously "scientific" competition.—*The Lancet.*

Poisoning in the Old Times.—The ancient Egyptians were acquainted with prussic acid prepared from peach kernels, as appears from the words, "Pronounce not the name A. I. O., under the penalty of the peach," deciphered by M. Duteil on a papyrus in the Louvre. Here is evidently a threat, to such as reveal priestly secrets, of water distilled from the peach kernel, which we know to contain prussic acid. From Egypt the knowledge of the fatal potion seems to have passed to Italy. A Roman knight in the reign of Tiberius, accused of high treason, swallowed a draught of poison and fell dead at the feet of the senators. Unless we fall back upon the theory of some sudden syncope from natural causes, nothing but prussic acid, and that fairly strong, can account for this sudden death. A further example of the use of prussic acid in Rome is the murder of Britannicus by his brother Nero. Hot water was a favorite drink in fashionable Roman cir-

cles at the time. One day after dinner a slave brings to Britannicus his beverage. It is too hot. Cold water is added, presumably containing the poison. Immediately on drinking, the victim lost power of speech. The breathing ceased. His mother and sister were horror stricken. Nero, the murderer, looked coldly on, remarking that such fits often happened to him in infancy without evil result. In a minute or two the banquet proceeded. If this again were not sudden death or brain disease, the cause of death must have been the prussic acid. Owing to the loss of ancient knowledge of anatomy and physiology possessed by the Egyptian embalmers, no post-mortem was possible. In the absence of such knowledge much importance was attached to outward signs. Doubtless many persons must have died from poison, and the reason of their death remained unknown: while others who died naturally, but whose bodies putrefied rapidly, were supposed erroneously to have died from poison.—*Scientific American.*

Byways of the Brain.—In *Harper's Monthly* for April is an able article, entitled "Some Byways of the Brain," by Dr. Andrew Wilson, drawing attention to the evidence which may be deduced regarding the effects of deficiency in one hemisphere of the brain. He says: "The cases from which one may quote may be divided into two sets or series—those in which disease or want of development is responsible for such deficiency, and those which represent the results of actual injury to the brain. Thus, in the notable case of Bichat, one of the foremost anatomists of his day, one lobe of his brain was found markedly smaller than the other. He was, in fact, deficient in one-half of his brain, and yet his mental and physical life was in its way notably of a high order. In another case, reported by Cruveilhier, a man died in hospital at the age of forty-two, from heart disease. He exhibited no lack of intelligence, yet after death it was discovered that his left brain was practically destroyed and replaced by a watery substance. Another case, reported by Andral, was of a man who died at the age of twenty-eight. He had suffered from a fall when three years old, and as a result was paralyzed on his left side. The right half of his brain had practically disappeared, so that the parts below this half constituted the floor of an empty space. Andral says of this man that he had received a good education and had profited by it; he had a good memory, his speech was free and easy, his intelligence was such as we should expect to find in an ordinary man."

The "Revue des Revues" contains an illustrated account of the laboratory of physiological psychology at the Sorbonne, under the auspices of the École des Hautes-Études, directed by M. Binet. It appears from the article that, in addition to the laboratories at Paris, there are laboratories at Rennes, Louvain, Liege, and Geneva.

A lady doctor has been appointed by the London county council as inspector under the new "infantile-life protection act." The advantage of the trained eye in discerning the real state of the babies in the farms is plain, but it is only the larger towns that will be able to afford a salary sufficient to engage a registered medical practitioner.

Quacks in Germany.—The "Fatherland" is not a happy hunting-ground for quacks, as probably many of the fraternity have found to their cost. The latest quack nostrums are those of which the late Count Mattei made himself the commander. His successors and the German public have just been informed that the Mattei treatment has nothing to do with Hahnemann or his disciples, and is to be considered utterly worthless.—*Medical Press.*

The Roentgen Rays.—Two investigators have recently used the Roentgen rays to very good purpose. The first of these, Prof. H. C. Bumpus, was by their aid enabled to note accurately the number of vertebræ and record the position of the pelvis in one hundred specimens of Necturus. The other, W. C. Cannon, used the rays to obtain figures showing the changing shape of the stomach during digestion, using for the purpose a cat. The animal's food was mixed with subnitrate of bismuth, and the wave-like movements of the pyloric portion of the stomach were made clearly visible. The total number of waves passing over the antrum during the seven hours a cat was digesting a meal was about twenty-six hundred.—*Science.*

TO MY ANTI.

What cures my head when full of aches,
All joy my racking brain forsakes,
And all life's pleasures seem but "fakes"?
My Anti.

What cools me when I feel as hot
As Dives when below he'd got
And envied Lazarus' happy lot?
My Anti.

What helps me when I have the fits,
And every one who round me sits
Immediately gets up and "gits"?
My Anti.

What fills the German chemist's purse,
And incidentally perhaps the hearse?
What always terminates my verse?
My Anti.

The Alert Prescriber.—A man in the car was telling how good his doctor was. "Clever?" said he; "well I should say he was. The other day I called him in when I had swallowed five cents. He said if the coin was not counterfeit it would pass, and made me cough up two dollars."

Vaccination Shield.—Dr. John Winslow, of Ithaca, N. Y., improvises a convenient vaccination shield of rather fine wire gauze, cut to fit the number of insertions, pressed into a dome-shape by the fingers, and bound around the edge with rubber adhesive plaster. This plaster is better than isinglass to hold the shield in place.

Health Reports.—The following statistics concerning small-pox, cholera, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended April 30, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile	April 16th to 22d	2	
Arkansas, Pulaski County	April 20th	42	
Dist. of Columbia, Washington	April 22d	4	
Ohio, Columbus	April 16th to 22d	1	
South Carolina, Charleston	April 22d	1	
Texas, Columbus	April 2d to 22d	18	

SMALL-POX—FOREIGN.

Bohemia, Prague	April 2d to 9th	5	
China, Hong Kong	March 6th to 12th	1	6
England, Leeds	March 19th to April 9th	4	1
Leith	April 2d to 9th	1	
Newcastle-on-Tyne	April 2d to 9th	3	
India, Bombay	March 22d to 29th	..	4
Calcutta	March 12th to 19th	..	3
Madras	March 12th to 25th	..	14
Italy, Messina	April 9th to 16th	..	1
Norway, Christiania	April 2d to 9th	..	1
Russia, Odessa	March 2d to 9th	1	2
St. Petersburg	March 26th to April 2d	19	8
Spain, Madrid	April 1st to 6th	..	1
Uruguay, Montevideo	March 6th to 12th	2	

CHOLERA.

India, Bombay	March 22d to 29th	..	3

DRY LABOR—ITS DANGERS AND TREATMENT.[1]

BY GEORGE LIVINGSTON BRODHEAD, M.D.,

ASSISTANT ATTENDING PHYSICIAN TO THE SOCIETY OF THE LYING-IN AND NEW YORK MATERNITY HOSPITALS

THIS subject, dismissed in a few words in many of our text-books and treated far too lightly in obstetrical works generally, seems to me to be one of sufficiently great importance to merit special consideration. The dangers of a premature rupture of the membranes are, as we shall see, manifold, and so grave are the effects at times that cases in which the accident occurs should receive the most careful attention. Strictly speaking, a dry labor is one in which the membranes have ruptured at some time prior to or with the first labor pain. But for practical purposes it will be better to broaden our definition, so as to include all cases in which the membranes rupture during the first stages of cervical dilatation, when as yet the "water wedge" has much to accomplish

It is surprising to note the frequency with which such early rupture occurs. From observation of a large number of cases during my service as resident physician of the Sloane Maternity Hospital, I found that in fully fifteen per cent. of all cases the membranes ruptured either before or with the first labor pain. In other words, about fifteen women in every hundred have labors which are strictly dry, and if we add to these fifteen cases all of those in which the rupture of the fœtal sac takes place early in the first stage, we have a comparatively large number in which certain dangers may arise and which should be given special attention Fortunately the accident, for such it must be called, occurs nearly twice as often in multiparæ as in primiparæ. It is true that in the former class of cases this early rupture seems often to be followed by no untoward results, but in other cases, and especially in primiparæ, the course of the labor may be modified in various ways, varying from the degree of mere discomfort and tedious protraction to that of great danger to the child and possibly to the mother. Even though the point of danger is not actually reached, a dry labor, particularly in a primipara, is usually more painful, and indeed, as one can readily appreciate, almost necessarily so, from the fact that now dilatation must be accomplished by some fœtal part, usually the head, in place of the fluid dilator, the bag of membranes. In normal labor, during the intervals between pains comparatively little if any pressure is made upon the cervix, but in dry labor the presenting part is often "wedged" down into the cervix, in such a way that pressure upon it is almost if not quite continuous, with a consequent increase in the amount of pain suffered. Such continuous pressure, too, is liable to and often does cause œdema of the cervix and other soft parts. Again, some of the worst cases of protraction with which we have to deal, in both multiparæ and primiparæ, are those in which the labor has been dry or practically so. That infant mortality is much higher in such cases there can be no question, yet many lives are lost through the failure to recognize the danger, and therefore to make use of the correct treatment at the proper time.

Before entering, however, upon the detailed discussion of the serious aspect of these cases, the full knowledge of which is so important for successful treatment, let us consider for a moment the several ways in which rupture of the membranes may occur. In the majority of the cases, in my experience, no cause can be found, the woman perhaps being perfectly quiet or even asleep at the time liquor amnii begins to come away. There are cases undoubtedly in which disease of the cervix "thins out" the membrane lying near it, thus making rupture easy; or some exertion or trauma may be the apparent cause, the fœtal sac being perfectly normal. Occasionally the accoucheur, while making a digital examination in the attempt to make a diagnosis of position, or perhaps while introducing a bougie for the purpose of inducing labor, accidentally punctures the fœtal sac At times the rupture takes place high up, at some distance from the most dependent portion of the sac, and as the presenting part descends the opening becomes obstructed and further escape of fluid is prevented. This, indeed, is a fortunate occurrence, for usually when the flow has once begun it will be more or less continuous during the entire labor, and thus large quantities of fluid be lost.

Now, what are the dangers of a dry labor, or one made practically dry by the early escape of amniotic fluid? How are the dangers to be recognized? And, finally, how are such cases to be treated?

Let us consider, first, the dangers to the child. These are two in number—asphyxia and meningeal hemorrhage, the two being frequently associated. The higher infant mortality in cases of dry labor is to be attributed to one or both of these conditions, the child being stillborn or dying within a few hours or days after birth. It is surprising to note the frequency of asphyxia of different grades, and I am positive that the mortality is much higher than it is generally believed to be. I am of the opinion, however, that with close observation and careful treatment from the very first the prognosis for the child will be very much improved. The reasons for the presence of asphyxia are several, and it is not difficult to understand the frequency when one considers for a moment the conditions present in such cases. When the liquor amnii has drained away or is escaping constantly from the uterus, the latter contracts much more tightly about the child, with the possible result of compression of the placenta or cord between the body of the child and the uterine wall. Again, the cord is much more likely to be compressed at any point than if surrounded by amniotic fluid, and the compression is more apt to be continuous because of the closer proximity of the uterine wall to the child, thus preventing at least perfect freedom of motion and in some cases practically all. Such compression means necessarily interference with the fœtal circulation, and hence asphyxia to a greater or less extent, depending on the amount of pressure and

[1] Read before the section on obstetrics and gynæcology, New York Academy of Medicine, April 25, 1898.

its continuation. Then, again, as we well know, the uterus in a dry labor tends to become exhausted much sooner than it normally would, the tonic contraction interfering greatly with the circulation in the uterine sinuses, this in turn affecting the child seriously.

In regard, secondly, to meningeal hemorrhage. In the absence of the "water wedge," so called, dilatation must be accomplished, as a rule, by the fœtal head. This means usually, especially in primiparæ, the formation of a large caput succedaneum and oftentimes very extensive moulding. In this process, the vertex is naturally exposed to great pressure, and a pressure, too, which from the nature of the labor (in the absence of fluid) is apt to be more or less continuous. As a result we have hemorrhage into the meninges, with symptoms of pressure, in varying degrees, with perhaps the death of the child several hours or days later. In many ways, then, the life of the child may be in grave danger, and the study of the danger signals becomes one of great importance.

Before taking up the discussion of these points, let us consider for a moment the dangers of dry labor to the mother. As I have already said, the great dangers are those of any protracted labor—laceration of soft parts, to which the œdema predisposes, pressure necrosis, hemorrhage, liability to sepsis, and slower convalescence, not to mention rupture of the uterus, either spontaneously or during difficult efforts to extract the child.

Turning now from the dangers, let us take up the signals or signs pointing to them. Firstly, with reference to the child, we see a number of labors in which all seems to be going well, until meconium is found escaping from the vulvar orifice, or when the examining finger is withdrawn covered with meconium, or liquor amnii tinged with it. This occurs at times in the first stage, but more usually in a protracted second stage. In any case (with the possible exception of a breech, in which the presence of meconium could be easily accounted for) the sign of danger must not be overlooked, for as a rule, unless methods are at once resorted to for the delivery of the woman, the probability of asphyxia is great, with, in some cases, the death of the fœtus *in utero*. We cannot promise, however, to save the life of the child under such circumstances, even by prompt interference, for asphxyia may be already too deep. I am sure that many of you will recall, as I do, cases in which the labor, although dry, had been apparently not unduly prolonged, and yet, in spite of prompt interference, the child was either stillborn or very deeply asphyxiated. Another sign which may indicate embarrassment of the fœtal circulation is that of unusually vigorous movements on the part of the fœtus. This unusual activity in many cases leads us to believe that the child is beginning to suffer from the lack of pure blood, and when examination is directed to the fœtal heart we are able to distinguish changes there. This brings us to the consideration of the fœtal heart sounds. By careful observation the normal rate of the heart action can be known for each case. Any marked deviation from what is normal for the case under consideration must be looked upon with great care. There is no fixed rule for the danger line, but by a series of examinations one can detect readily whether there is a decided tendency for increased or decreased rapidity. In general, one may say that fœtal heart action above 160 or below 120, in a case whose normal is between those limits, should be the object of careful attention, for oftentimes it will be seen that the rate is becoming steadily higher or lower. Of course it is not difficult to suspect trouble when the heart rate gets to be 170 or 180, or when it becomes as slow as 80 or 90, but it should be our purpose to detect the very commencement of trouble, for by so doing the chances for a successful termination will be much brighter. Then, again, an irregular or intermittent action in a case previously normal should invite close attention; but it must be remembered that some fœtal hearts do beat intermittently or irregularly at various times when no cause can be discovered, labor not having commenced in some. When asphyxia begins the heart beats are sometimes "muffled," so to speak, or indistinct, although the rate may remain the same. In other cases an umbilical souffle develops, showing probable compression of the funis. One case of that kind comes vividly to mind, in which the souffle developed immediately after the replacement of a prolapsed cord by means of a bougie, showing obstructed circulation at some point. Important as observations upon the fœtal heart are in cases of normal labor, in dry labor they become of even greater value, because of the greater likelihood of complicating asphyxia.

Protracted labor, in its effects upon the mother, need not detain us long. The rise of pulse, temperature, and respiration, the restlessness, anxiety, and despondency, the diminished vaginal secretion, the weak inefficient pains, are all so plain as to be recognized with comparative ease. In some cases of dry labor, when protracted, we find an odor also, putrefactive changes having already started in. Mild sapræmia is not uncommon after dry labor, but it generally yields to treatment readily. Many cases of sapræmia do well with no other treatment than that of simple cleanliness, the elimination of putrefactive material proceeding rapidly, drainage being free. In my opinion, warm antiseptic vaginal douches will answer the purpose in almost every case, but should be given with every possible care as to cleanliness, and given very gently, in order not to open new channels of infection by removing the protective covering of abrasions in the vagina and vulvar orifice. In some few cases a uterine douche seems indicated, and if given with all possible care will be productive of good. The vulva and vagina should first be thoroughly cleansed, and the douche nozzle when carried into the uterus be simply held in its cavity, for what is loose and ready to come away will be washed out, and the active use of a douche nozzle as a sort of curette has been followed by serious results, owing to the laying bare of denuded areas and increased absorption of infective material. At times severe symptoms will follow even the gentle irrigation of the uterus. In one instance in my experience, within thirty minutes after a uterine douche had been given in the hands of a careful assistant, the patient had a sharp chill, followed by a temperature of 106.4 F. As a rule, however, one or a few uterine douches will be sufficient, and with care little if any harm will be done.

Passing now from the dangers and their symptoms, we come to the treatment. To my mind, many cases do badly for the reason that they are treated as cases of normal labor. I maintain that the early rupture of the membranes puts a new phase, so to speak, on the labor, and certain plans of treatment, which in normal cases are unnecessary and unadvisable, seem to produce good results in cases of dry labor. Let us take up for consideration, first, those cases in which the membranes rupture before labor sets in. In every case, whether before labor or during labor, even though an examination has been made a short time before, a careful examination should be made as soon as possible after the rupture of the membranes or their reported rupture. Some women are mistaken in their diagnosis of the condition, but it is far better to assure one's self of the exact condition of affairs. By doing so we verify or disprove the woman's statement, detect any accident, such as that of a prolapsed cord or small part, and, moreover, are able to make the diagnosis of presentation and position an accurate one.

Again, it is perhaps needless to state that, if the case be one of malpresentation, operative interference immediately after the rupture of the membranes will be possible, and with excellent chances of success; whereas the failure to learn of the exact condition at once may result in the death of the child, the correction of the abnormal presentation being later impossible. After one careful examination has been made, however, further efforts should be infrequent, and then not be prolonged, for in some cases, as I have already said, the presenting part in its descent blocks up, so to speak, the point of exit of fluid, and further escape is thus prevented. This is, of course, most favorable to the child, and we may in further examinations undo, as it were, the assistance which nature has kindly given us. After the rupture of the bag of membranes, the sooner labor commences the better, as a rule, will be the prognosis. My plan in these cases is to administer at once a large dose of castor oil and glycerin, followed shortly after by ten grains of quinine sulphate, to be repeated every three hours, with one-thirtieth grain of strychnine sulphate every two hours, careful watch being kept for unpleasant effects of either. These drugs, I believe, aid in the induction of labor, and, given during labor, seem to increase the number and strength of the contractions, in some cases at least. Under close observation they can do no harm, and serve to stimulate the patient to a certain extent as well. At this time women are able, it has seemed to me, to take much larger quantities of these two drugs than at any other time, without unpleasant effects. Before the digital examination is made, the genitals should be scrubbed with soap and water (the officinal sapo viridis being preferable); then with a solution of bichloride, 1 to 2,000, or a solution of lysol, one per cent. After the examination a sterile pad of gauze, covered over with a towel or small vulvar pad, should then be placed over the vulvar outlet, and changed as often as saturation with amniotic fluid makes necessary. In this way the vagina can be kept free to a certain extent from the entrance of "outside" infection. Another procedure, which in my experience has been followed by excellent results, is the use of vaginal douches of lysol in one-per-cent. solution, as hot as can be borne, one being given every six hours, to the amount of about three quarts. These douches will keep the vagina sweet and clean, will leave the mucous membrane smooth and soft (acting in just the opposite way from bichloride solution), will stimulate uterine contraction, and in some cases seem to soften the cervix somewhat. Here again the importance of absolute cleanliness must be emphasized, for unless these douches can be given with the greatest of care they may easily be the cause of the introduction of septic material. When, now, the membranes rupture during the first part of labor, the treatment as outlined above is carried out, with the exception of the cathartic perhaps. This can be given or not, according to the necessity. The use of chloral and opium in dry labor must be a guarded one, the danger of asphyxia and protraction being always kept in mind, and it being remembered that these cases often need stimulation rather than a period of rest, during which time more and more fluid is escaping. The fœtal heart should be carefully noted before such drugs are administered. I can recall one case in which chloral was administered in the latter part of the first stage, the fœtal heart being then somewhat more rapid than it had been during the earlier part of labor. Very soon afterward the fœtal heart became so much more rapid that the forceps was used, the cervix offering practically no resistance. Meconium was found when the blades were introduced, and in spite of a quick delivery, made more difficult by the sluggish action of the uterus induced by chloral, the child was born deeply asphyxiated and was with only the greatest difficulty resuscitated. Several months ago, at the Sloane Hospital, in the attempt to induce labor on a patient with deformed pelvis, the membranes were accidentally ruptured and a considerable amount of amniotic fluid escaped. When informed of the condition of affairs, Dr. Tucker, who was then in charge of the hospital, advised that the vagina be tightly tamponed with sterile gauze, in order to hold back as far as possible the escaping fluid, both for the sake of the child and to aid in softening and dilating the cervix. This procedure, of such great value in abortion and placenta prævia with rigid cervix, proved in this case to be of apparently great assistance, the cervix dilating perfectly within a very few hours. Having seen the good effect of the tampon in one case, the question has arisen in my mind, "Would it not be a good plan to apply such a tampon as a routine procedure in all cases of dry labor?" At present I am unable to state any results from following such a plan, but theoretically at least it should be successful. When the progress of labor is very slow, I believe it is best to stretch the cervix a little every few hours, a preliminary vaginal douche of lysol having been given. Care must be taken also that the strength of the patient be kept up in every possible way, by the use of plenty of nourishment and stimulants if necessary.

Now, is operative interference ever advisable during the first stage of a dry labor, except when complicating conditions—such as eclampsia, hemorrhage from placenta prævia, etc.—arise, or when from any cause the condition of mother or child strictly indicates operation? In my opinion, there is one condition of affairs in which much good can be accomplished, namely, in breech presentation. When a breech labor is protracted in the first stage, even though as yet no symptoms of danger are present, I think we are justified in giving the patient a little chloroform, the vagina having been first thoroughly cleaned, and in introducing the hand for the purpose of bringing down one foot, preferably the anterior, with which to make traction from time to time. If this be done early, it can usually be accomplished with no great difficulty, whereas later on it may be a very difficult matter. If both legs are extended, the operation will accomplish even a better result, in that it will have broken up the existing "wedge," at a time when the operation is comparatively easy. After the escape of a large amount of liquor amnii, it is sometimes a difficult task to grasp a foot lying high up in the uterus, and the difficulties increase the longer the operation is delayed. If danger symptoms are present, or if for any intercurrent condition it becomes necessary to deliver at once, the usual methods of cervical dilatation, forceps or version, are to be used.

When we now come to the consideration of the second stage of dry labor, the statement just made with reference to the first stage holds true here as well. But in the absence of danger symptoms the question arises: How long shall we wait, in the second stage, for its natural termination? It is very difficult and, in fact, impossible to fix any definite period of time; but in my opinion, if in one-half hour after the commencement of the second stage there has been little or no advance, the forceps (or extraction if the breech presents) is advisable, chiefly in the interest of the child, but with the welfare of the mother also in view. I have never had occasion to regret early operation in the second stage of dry labor, but there have been many, many children lost owing to delay at that time and the failure to interfere promptly.

Reference has already been made to lysol for vaginal douching, and its use preliminary to all operative measures is a most excellent one. It not only cleanses the parts very thoroughly, but leaves the mucous mem-

brane smooth and soft, thus making any operative procedure much easier and the liability to laceration far less. Early interference in these cases is obviously in the interest of the soft parts of the mother, for time can be allowed to preserve their integrity, whereas if operation be undertaken when meconium is being passed or the fœtal heart is already bad, the welfare of the child demands speedy delivery, with consequent laceration oftentimes of vaginal and perineal tissues.

In closing, allow me merely to emphasize in a few words the great importance of dry labor, the possible dangers, chief among which is fœtal asphyxia, and the belief that with close observation and prompt energetic treatment our statistics both for mother and child will be greatly improved.

60 West Fifty-Eighth Street.

PERSONAL OBSERVATIONS IN PULMONARY PHTHISIS.[1]

By THOMAS NEIL McLEAN, M.D.,

ELIZABETH, N. J.,

VISITING PHYSICIAN TO THE ELIZABETH GENERAL HOSPITAL AND DISPENSARY, MEMBER OF THE CLINICAL SOCIETY OF THE GENERAL HOSPITAL AND DISPENSARY, THE AMERICAN MEDICAL ASSOCIATION, AND THE DISTRICT MEDICAL SOCIETY OF THE COUNTY OF UNION, NEW JERSEY.

After an experience of twenty-five years I desire to present some conclusions which I have arrived at as the result of my own personal observations in pulmonary phthisis. I use the term advisedly on account of its comprehesiveness, including as it does all that has been known and taught from Laennec to Koch. I am convinced that the preparatory or premonitory conditions which almost invariably exist in all cases of phthisis do not receive the attention which they deserve. It is the little leak, at first no bigger than a straw, which could be easily checked, that causes the dike to give way and carry death and destruction in its resistless flood.

Let us apply this principle of early recognition of these little departures from functional and organic integrity to the disease in question. They deserve to live who, by careful attention to the various functions of the body, strive to keep them in harmonious rhythm. Ignorance does not pardon in the eye of the law, and the penalty must be paid even though it may cost the life.

Max Nordau says, "The degenerate must die." An inheritance of conditions which must inevitably end in an early death is the result of ignorance, crime, and fatuitous circumstances, many, if not all, of which might have been avoided.

To educate the people out of this phenomenal darkness, and, where they cannot be educated, to legislate them out of it, is the duty of the medical profession. Out of the complex phenomena of a disease which presents such a diversity of symptoms and conditions, it has been my aim to determine what is the first appreciable departure from health, the most constant symptom discernible by patient and physician alike, which would lead us to suspect that the individual in question is in danger of ultimately becoming tuberculous. Many of the disagreements between physicians as to the natural history of diseases have arisen from the fact that they have observed from different standpoints and from different starting-points, the latter being of much greater importance than the former, for the standpoint may be changed from day to day, but the starting-point can be changed only as a confession that the *fons et origo* have not as yet been discovered.

A few years ago I arrived at a conclusion from which I have seen no reason in later years to depart. I have been more and more convinced that the first symptom (aside from general malnutrition) is a slight cough or hack, repeated two or three times on an average on reclining at night. This cough antedates the morning cough by a considerable period, varying in length in different subjects. It is a little thing, but its etiology is important beyond measure. The nearer we get to the spring the narrower is the stream. It is the diagnostic symptom, which, having been found and understood by the physician, gives him an enormous advantage in the prevention and cure of phthisis.

The patient believes himself to be in fair health. He has no pain, no cough at any other time, no disturbance of any other function, is only a little below par, and will sometimes deny that he has any cough until told by the members of his family that they have repeatedly heard him cough when he has lain down at night. This same evidence has been repeated to me so many times that I do not doubt its significance, and I consider it the test question, "Does he cough on reclining?" If there is a symptom prior to this, I have been unable to find it. The etiology of it I believe to be that the mere change of position from the erect to the recumbent has produced an immediate change in the circulation of the blood and air in the pulmonary structure, disturbing the equilibrium which always exists in healthy chests, controlled by the natural tension through the vasomotors. A temporary passive congestion or hyperæmia is produced thereby, due to an insufficient expansion of the finer tubes and vesicles. The blood pressure being out of proportion to the air pressure and the coats of the vessels being overdistended or varicosed from lack of support, the blood currents come under the influence of an extraneous force, gravity; this never occurs in vessels whose coats are normal, except by complete inversion of the body or in the hypostatic congestions of long illnesses. The change to the recumbent posture immediately causes an increase in the distending force within the blood-vessels and a decrease in the amount of air in the tubes and cells. As a result of this, a backwatering of blood into the bronchial vessels and a sensation of fulness or tickling are perceived in the region of the head of the sternum.

The cough that occurs is nature's own effort to remove this fulness, which it accomplishes at first with only a few long breaths and coughs. If this pathological condition is not relieved early, it goes on until it requires stronger and more prolonged effort in the act of coughing to remove it. The objective symptoms of this condition are found in a slightly diminished resonance of a higher pitch, slight depression under the clavicles follows this, and still later the mucous click or catarrh of the apex. Mensuration shows a deficient expansion above, normal often below, except in women from the effects of corsets and other tight clothing, which they invariably insist is not tight, being convinced only by ocular demonstration with the tape line. (The tape line should never be out of the physician's pocket except when he is using it.)

Auscultation reveals a still more important point, viz., a diminished or absent true respiratory or vesicular murmur. This symptom I consider of greater importance than all the other objective symptoms, and it is invariably found somewhat before and always associated with the gravitation cough.

In the wondrous mechanism of the lungs we find the ramifications of the pulmonary artery intertwining among the air cells, forming a close and delicate network of capillaries in the interspaces, supported by the highly elastic structure of the air cells. Elasticity is one of the most distinguishing characteristics of these cells. They are in health never empty and in death can be emptied only by force. With every in-

[1] Read before the Clinical Society, December 7, 1897.

spiration both air and blood are aspirated into the lungs. When air is in excess we have emphysema, when blood is in excess we have congestion, which, being continued indefinitely, brings on in time an endless chain of pathogenic conditions, which must end in death if not relieved by proper systematic treatment. Of emphysema I need not speak further than to say that the emphysema which results from spasmodic bronchial asthma is antagonistic to phthisis.

Now I believe that all the influences which diminish nervous and muscular force—and their number is great, such as sedentary pursuits, the dark side of life, residence in low and malarial regions, clothing that prevents a perfect action of the diaphragm and chest walls, dissipation, indoor occupations, worry, and many others—these all tend to shorten the respiration and diminish its depth. As a result of this a gradual dilatation of the capillaries takes place. In that part of the lungs where the vesicles are least distended a passive congestion is produced, and thus is furnished a soil that will grow tubercles.

The frequent increase in the force of the heart's action by excitement, by stimulants of any kind, by muscular effort, alteration of the normal tension of vessels by chilling of the cutaneous surface, and many other causes aid in producing a dilatation of the pulmonary capillaries; and thus the blood currents, coursing through vessels which have lost their contractility, come under the influence of this extraneous force—gravity. It is to this immediate influence that we are to look for the explanation of this cough on reclining, which we may distinguish as the gravitation cough. This condition is so important that it seems to me deserving of a distinctive name in our nomenclature of disease symptoms.

Upon the correct explanation of this cough depends the entire treatment of phthisis, whether bacillary or non-bacillary, and I invite your kindly and thoughtful criticisms to this particular point. I have often declared to anxious patients and friends that it is as easily gotten rid of as to walk, and even when the conditions have gone on so far as to produce cough in the morning with expectoration and pain in the subclavicular and interscapular regions from congested pleuræ. These last two stated conditions occur in the order in which they are mentioned—the cough in the morning with expectoration, as a result of a longer continued gravitation blood pressure during sleep producing exudation into the bronchi, which is expectorated on arising. This exudation may not come on until weeks or months have elapsed since the gravitation cough began. The pain in the pleuræ comes on still later as a result of the damming up of the blood currents and vasomotor paresis, producing congestion in that tissue.

I have associated these three symptoms or conditions before speaking of treatment, because they are all removed by the same method, viz., mechanical expansion. The function of respiration, unlike the functions of the other vital organs, is placed under the control of the will, whereby the integrity of the pulmonary apparatus may be preserved by maintaining a perfect function of these organs. This is indeed an important safeguard. It is impossible to maintain a perfect organ without a perfect function. This principle applies to all of the voluntary organs of the body, and more especially to the breathing apparatus, exposed as it is to the vicissitudes of climate and the dangers of infection by bacteria.

Jacobi has truly said that the "tubercle bacillus never attacks healthy tissue," and I believe it to be equally true that when they have found a lodgement in the tissues of the lungs we have as yet no drug that can be administered by way of the stomach or through the blood by hypodermatic injections of sufficient strength to destroy them. We may counteract the effect of their toxins and increase the resisting power of the tissues against their encroachments, and there our drug power ends.

I have used the true mechanical expansion, by which I mean a regular systematic natural method of increasing the capacity of the lungs, maintaining a normal function and regaining it when lost. It is common among physicians to recommend mountain air to their phthisical patients. The benefit to be had by going to the mountains is beyond question, but of the great multitude of patients there are comparatively few who are able to profit by this advice. What shall we do with the thousands who must remain at home? I answer, bring the mountains to them. How can this be done? I answer this question by asking another: In what does the benefit of the mountains consist? When this question is answered we may see in how far we may exert the same influence in homes at sea level. The science of climatology is one of great interest, inasmuch as at the present date it is capable of showing better results in the treatment of phthisis than the more fashionable science of bacteriology or any other. The limits of this paper will permit me to speak only of some of the chief factors, under the head of climatic treatment, bearing upon the disease. We know that there are regions almost entirely exempt from phthisis, others where it is more commonly found, and others where it prevails in great abundance.

Solly, who is recognized as an authority in the science of climatology, says: "Consumption is most prevalent in proportion to the temperature and humidity of the climate: 1st, in damp cold climates, 2d, in damp hot climates; 3d, in dry hot climates; 4th, in dry cold climates: while of curative effects it is true in reverse order. This indicates in a general way that dryness is a benefit and humidity obnoxious to phthisis." He qualifies the statement by saying that "apparently humidity apart from other factors does not in itself produce phthisis." It is my opinion that our phthisis cases here do better in the winter, even with our sudden changes of temperature and humidity, than in the warm, debilitating, moist air of midsummer.

In regard to barometric pressure Solly says: "Statistics show an almost steady rise in the percentage of improvement, from the ocean to the altitudes, and from this we learn that as a rule the consumptive improves the farther he is removed from the sea, as shown in the contrast of percentages of improvement in a large series of cases, to wit: sea voyages, fifty-four per cent.; lowland climates, fifty-seven per cent.; dry desert, sixty-five per cent.; altitudes, seventy-seven per cent. Therefore, while the desert of Arizona will cure more cases of consumption than the sea air of the coast, yet it will not cure so large a proportion as will the mountain air of the highlands."

Hirsch has shown "that decreased barometric pressure tends to confer more or less immunity from phthisis. The marked decrease which is present in all high climates has been demonstrated by Egger and many others to have a remarkable effect upon anæmia, by increasing the amount and quality of the red blood corpuscles and hæmoglobin. That the blood changes are brought about not by the quantities of dryness, sunlight, or other climatic factors in high or other climates, but by the diminished barometric pressure, was proved conclusively by the classic experiment of Regnard, who at sea level kept a rabbit for a month in a bell glass under diminished air pressure equivalent to the atmosphere at six thousand feet elevation. When the rabbit was removed it was found that the same blood changes had taken place as occurred in rabbits transferred from sea level to a climate at six thousand feet elevation." This experiment, instruc-

tive as it is, brings up another question: Would the same changes in the blood have been produced in an animal breathing the same rarefied atmosphere of six thousand feet, with the density of atmosphere pressing upon the external surface of the body as exists at the sea level? That is, was the improvement due to the rarefied air alone which the animal breathed, or was it due to this in combination with the diminished air pressure upon the surface, or was it due to the decreased pressure on the external surface alone?

There are those who claim the improvement in the blood is due to breathing the rarefied air. I do not know of experiments having been made which prove this conclusively. Certain it is that the decreased barometric pressure upon the external surface compels a greater expansion of the chest, opening up a larger surface for the interchange of the gases, and consequently a greater oxygenation of the blood—the greatest of all hæmatinics—with improvement in the digestive system as a result of increased oxygenation.

I believe it is the forced distention of the lungs and bronchi that gives to those who live at an altitude immunity against phthisis. Aside from the barrel-shape chest of emphysema, the full round chest is an acknowledged evidence of healthy lungs; a flat contracted chest is a constant invitation to tubercle bacilli and an evidence of so-called weak lungs. To imitate the effects of altitude has been my practice for over twenty years, and in the lack of suitable apparatus to assist them to teach my phthisis patients the art of mechanical expansion. Among the various ingenious methods which have been devised I could find none that were free from objections, as they almost invariably increase the heart's action, which opposes rather than helps the purpose of their use.

I have practised but two specific exercises, which nature herself teaches. The first is an imitation of the cough, and the second of a person stretching. In practising the first we take in the air through a chink in the lips, about a quarter of an inch in diameter. Some patients do not catch the idea readily or are not accustomed to whistling, and require the use of a tube through which to inspire. When the lungs are filled to their utmost capacity the lips are closed and the cheeks bulged to prevent escape from the nose. The air is held until the excess of blood is driven from the lungs, as evidenced by a sensation of fulness in the forehead and slight reddening of the face. By holding the breath after a full expansion the blood is squeezed out of the lungs into the general circulation, and by frequent practice the lost equilibrium is regained.

This action is equivalent to breathing at an altitude or inhaling compressed air at sea level. The stretching exercise is performed in the same way, with the addition of raising the arms without flexion directly above the head at the beginning of the inspiration and lowering them upon the chest as soon as the lips are closed. The purpose of raising the arms above the head is to lift the chest wall by means of the pectoral muscles. The effect of these exercises is seen in the immediate improvement of the percussion note with lowering of the pitch; a rounding out of the depression under the clavicles; the changing of the voice from a throat to a chest tone; and the removal of the mucous click which has been diagnosed by some pathologists as a sure indication of tubercle. The true respiratory or vesicular murmur, the most significant sign of a normal chest, is restored in its entirety.

A continuation many times a day of these exercises results in a radical cure, with no other medicine than that which is directed toward nutrition and the sustaining of the nervous system. All the symptoms heretofore described may return again as the result of neglect. The price of health is vigilance and effort. To sit quietly and let your boat drift carelessly down the rapids over the falls is suicide. If the phthisical patient would live and be healthy he must work for it, and in the way I have indicated or by some similar method, or he will miserably perish, notwithstanding he may swallow all the drugs in the dispensatory and be injected with all the serums and specifics, so called, which are now obtainable. The expansion method of treatment is nature's method, and it is helpful in every stage of the disease except when there is active hæmoptysis from organic changes, at which time it should be stopped until the bleeding ceases, and then begun again with very slight force at first, gradually increased to the utmost limit after a few days have elapsed.

When pleuritic adhesions have formed, whether bacillary or non-bacillary, the expansion must be so graded as to avoid fresh exudation or inflammation, the sensation of pain being the guide. The greatest obstacle to recovery by this method is ossification of the costal cartilages in a contracted state of the chest. It is like an anaconda; being permanent, it will squeeze the life out. Thus far I have spoken of treatment in the primary stage before organic changes have taken place to any very great extent.

I am often astonished to see what can be done by this method with phthisis cases after they have become tuberculous with muco-purulent expectoration, containing numerous bacilli, with afternoon fever, temperature rising to 101.6° or 102.4° F., pulse of 120, night sweats, anorexia, emaciation, dilated heart. I have seen these cases clear up and remain for years perfectly well, when at the first examination it was impossible to make a diagnosis on account of the foul condition of both lungs, the tubes being filled with secretion giving rise to numerous râles, the pleuræ sore, respiration only tidal, percussion dull. I defy any one to make an exact diagnosis in some of these cases in detail, as to the extent, kind, and location of the disease processes going on, until he has cleaned out the tubes and opened up as many of the alveoli as it is possible by expansion.

An easy diagnosis is made with the microscope, but to drop the diagnosis at that and treat the bacilli instead of the patient is to my mind very unscientific, because we have nothing with which we can destroy the bacilli; and, even if we could destroy them, would it be wise to leave the chest in the same contracted condition, with choked tubes and capillaries, with exudation products in the alveolar walls, and their cavities filled with epithelial elements ready for a new infection? More than twenty years ago, before we knew anything about tubercle bacilli, I treated by this method phthisis patients who had cavities, with all the accompanying evidences which we now know as bacillary phthisis. Some of them are living to-day, well, and performing the duties of an active life. Some have married and borne children.

The following case illustrates the effect of expansion upon hæmoptysis: This patient I saw by request of another physician, in his sixteenth hemorrhage. His disease was purely functional—a case of lazy lungs. I instructed him as to his breathing and he has had no return in the last twelve years, so far as I am aware, he being in robust health.

The following case also illustrates the immediate effect of thorough expansion, without medicine which could affect the fever, in a case which the microscope diagnosed bacillary: The patient had been under treatment about six months before I saw him. Male, aged about forty years; he had considerable cough, had lost flesh and strength, and had some pain in the right chest and back, with diminished expansion. October 12, 1896, I found him with a temperature of 101.6° F., and pulse of 88. October 13th, at the same hour, the temperature was 100.6° F., and the pulse 88. October

14th, temperature, 99.8° F.; pulse, 86. October 15th, temperature, 99.4° F.; pulse, 88. October 16th, temperature, 99.2° F.; pulse, 80. October 17th, temperature, 98.6° F.; pulse, 80. After this the temperature did not rise above 99.4° F. until an attack of grippe on the 28th, when it went to 104.4° F. On the 29th, it was 104.2° F.; on the 30th, 101.4° F.; on the 31st, 100.4° F.

November 1st, it was normal, and so continued, never rising above 99.8° F. during November. His temperature was taken from three to five times a day. During the first half of December the pulse and temperature remained both normal, when my attendance ceased. He continued to attend to his business (which was much in his favor, as he was obliged to walk several miles daily) after his recovery from the grippe, as I could not mend his financial necessities, and I have not seen him as a patient now for nearly a year, during which time he has been about as a travelling salesman, enjoying good health.

The immediate effect of this treatment is often so astonishing to the friends of patients that, in accordance with the prevailing sentiment among the laity as to the incurability of consumption, they will refuse to accept the diagnosis, even of the microscope, and after a time grow careless and forget the advice to keep the chest well expanded, until the same conditions recur, and the patient returns, again to be told the same thing and to go over the same road of treatment, or changes his physician and adopts some other kind of treatment. It is easier to take medicines; it is pleasanter to be told they have "only a little bronchitis" and need a little medicine to stop the cough and ease the pleuritic pain.

A quick confidence is gained in the physician who will thus treat him, but it is a deceptive confidence that lulls the patient to a fatal inactivity, and ere long he turns from one to another until finally he has more need of the undertaker than of the physician. These are the saddest cases we meet. Their day of grace is passed; organic changes have taken place to such a degree that little can be done but palliate symptoms. There are many patients who progress rapidly toward recovery for a few weeks, and hope is high, when all at once they begin to complain of the labor of expansion on account of weakness of the diaphragm and chest muscles.

This is the identical point in their disease at which an immediate change to an altitude becomes (in the absence of suitable apparatus to accomplish the same purpose) an absolute necessity for the removal of a portion of the incumbent atmospheric pressure upon the chest and abdomen, thus lighten the labor of breathing and increasing the nutrition of all the tissues through a better oxygenation of the blood. This is the way in which the resisting power spoken of by others is (in great part) sustained, and it may be aided by the administration of hæmatics—the hypophosphites according to the Churchill method, bathing, suitable food, outdoor life, the patient still remaining under the watchful care of the physician. To those who cannot avail themselves of the altitude treatment, the assertion that they are too tired to expand their lungs marks the beginning of the last stage, when there is no reasonable hope for recovery.

To this class of cases, however, the principles of "pneumatic differentiation" may be applied as an equivalent for altitude, and like effects produced in the patient's home at the sea level as upon the mountains.

The pneumatic cabinet was designed for this purpose twelve years ago, and its action has been proven to be theoretically and practically correct, and it is still held by some of the most distinguished men in our country as second only to altitude, and as "the best therapeutic device ever invented" for the home treatment of pulmonary phthisis.

An insurmountable obstacle to its adoption in general practice has been its great cost. Being a heavy steel cabinet, it cannot be moved from place to place to suit the necessities of the patient; but, being kept at the physician's office, it may be used for twenty or thirty minutes once or twice a day. Those days on which a patient needs it the most he is prevented from using it by the conditions of the weather. What we need is a portable apparatus, of small cost, which the patient can use at his own home under the direction of his physician, using it as often and as long as his case requires. Beneficial as these treatments by the cabinet have been proven to be, in many cases bringing about absolute recovery from bacillary phthisis, their success, it seems to me, is but a finger board pointing to something better yet to be produced, which shall enable the physician to give to his phthisical patients the equivalent of altitude—as much as he requires, with the comforts of home and friends superadded thereto, coupled with his own careful guidance, in everything that pertains to sustaining the vital forces, improving the quality of the blood by food, exercise, bathing, hygiene, clothing, and medicine.

Von Ziemssen, at the Twelfth International Congress at Moscow last August, said: "Looking back over the history of tuberculosis we see a motley conglomeration of methods of treatment. All these have been discarded, and but two agents remain to be considered, viz., tuberculin and climate. Koch's old tuberculin has been forgotten, the value of the new has not been proven, and most people doubt its efficacy. The complexity of the lesions makes a cure by means of a specific seemingly impossible. Fresh air has always been one of the requirements, but it is only of late that the advantage of high altitudes has been clearly demonstrated. Fresh air is not all; it is the altitude that brings about an excitation of the blood-making organs and increases the corpuscular elements in the blood."

Senator regards "altitude second only in importance to fresh air."

Von Leyden says: "So far the only treatment that has given any positive success is the climatic."

The causative relationship of the bacilli to the disease is an important question. Tuberculosis is always produced by the bacillus, but all phthisis is not tuberculous in all its stages. I hold that it is an incident in the course of the disease and not the primary cause of pulmonary phthisis. The tubercle bacillus may be found in the air passages of perfectly healthy individuals. It is not commonly found until after considerable organic change has taken place in the pulmonary structure. It cannot then be rightly considered as the cause of phthisis. Jaccoud enumerates a long list of pathogenic conditions, and says: "These multiple and variable elements are the true causes of the disease; the microbe is only the instrumental agent." Barton says: "Back of the bacillus are causes which are operating to produce malnutrition and a lowered vitality."

The evidence that an imperfect lung function is a causative agent is forcibly shown in the effect of the contraction of extensive scars upon the chest, resulting from burns and scalds, thus favoring a suitable lodgement for the bacilli. Three cases of this sort were reported last year by Dr. Hall, of Denver, in which one side of the chest in each case was scalded during infancy, and pulmonary disease began upon the contracted side.

The night sweats of phthisis need to be considered in this connection, because they are a direct result of insufficient pulmonary aeration and exhalation. The skin with its glands is complementary to the lungs, and supplements their action by elimination of the

water of its exhalation in double the quantity exhaled through the lungs, the daily average being thirty ounces for the skin and fifteen ounces for the lungs.

Now, when for many reasons the function of the lungs is impaired so that the normal quantity of carbon dioxide is not exhaled, the skin supplements their action at a time when the auto-intoxication has become so great as to cause a temporary paralysis of the vasomotors with relaxation of the skin capillaries. The night sweats are always accompanied by increasing weakness of the entire system, and are generally considered the cause of the great prostration which follows them. I do not believe this. The sweat is the result of a specific poisoning, principally by carbonic oxide and the products of metabolism, and is a conservative process, while the exhaustion which follows is a result, not of the sweating, but of the poisoning. We have all seen how quickly the skin responds to the demand put upon it in case of urgent dyspnœa from any cause. If all this be true, as I believe it to be, it certainly is very unscientific to give medicines to check the night sweat, for by so doing the system is still further poisoned, the vitality reduced, and the end hastened. I have not for many years used medicines to control this symptom, but have found that an increase of expansion, systematically carried out, uniformly relieves it.

An instance of this kind was recently seen in a case of phthisis in our own hospital. The action of expansion in relieving and stopping night sweats is the strongest argument I could ask for in substantiating the truth of my statement—that it is the poisoning that exhausts and not the sweating—and I conclude that it is wiser to treat the cause than the effect.

For several years past almost the entire medical profession seems to have been captivated by the discovery of the tubercle bacillus, and has experimented with many methods and drugs with the hope of destroying it by medication. These have all failed. As well try to check the resistless current of a mighty river by catching out the fish in its stream. There is probably not a single case of advanced phthisis in the country to-day under the care of a physician but has been treated with creosote or guaiacol or their carbonates. Creosote and its allies, without affecting the vitality of the bacilli, seem to have a beneficial effect, temporarily at least, upon the general conditions. This I believe to be due to its antiseptic power over germ life in the alimentary canal. The discovery of the bacillus, although an important addition to our knowledge of one of the stages of the disease, has resulted in no therapeutic advantage, but rather has diverted the attention of the profession from the clinical aspect and the various lessons to be learned therefrom to that which is only one of the factors in the disease, one which without doubt may be in some cases primary, but which clinical experience proves to be only a resultant and not the prime causative factor in the greater number of cases of pulmonary phthisis.

To my mind there remains but one method worthy of the undivided attention of the profession, viz., aerotherapy, as indicated in my previous remarks; and although it demands of the physician a greater outlay of time and effort for the benefit of his patient, yet I doubt not that ere long the principles of this science will be understood and practised by the great majority of our hard-working fraternity, because the results which follow are distinct and positive, and because there is nothing else which satisfies the requirements in every case to such a degree as aerotherapy, the science which is destined to take the highest place in all that pertains to the prevention and cure of pulmonary phthisis. As some one has laconically said, "The aerotherapist has come to stay."

SELF-LIMITATION AND IMMUNITY.

By LUKE FLEMING, M.D.,

TARRYTOWN, N. Y.

The limited duration of an infectious disease, miscalled self-limitation, depends upon the extent of soil open to infection and the rapidity with which it is consumed. Immunity is the result of soil exhaustion. In support of this principle which I presume to advance, I rely upon the fact, now generally recognized, that germs are living organisms and are governed by the same laws that govern life everywhere. Among these natural laws we know that there is one well marked, and which rules that different forms of life differ in their needs and choice of soil. The honeysuckle will not blossom in the bottom of the ocean nor will seaweed grow in our gardens. It ought not then to be a mystery that the pneumococcus finds in the perverted lung secretions its most fertile field and that the bacillus typhosus goes to the Peyer's patches as its fittest home. Reasoning by analogy, we can easily see that the difference in choice of soil is due not to any arbitrary instinct in the germ, but rather to its inherent necessities. The physical and chemical properties of a secretion favorable to one kind of germ may be distinctly unfavorable to another. Recognizing this, what is then more logical than that, a secretion necessary to the life of a particular germ becoming exhausted, that germ should die? It strikes me then that we have here in this simple conclusion one of the true reasons why a germ disease runs a course of definite duration. Typhoid fever furnishes a good illustration of the point I wish to make. The germ of this disease finds in the secretions of the Peyer's glands its best and in fact almost its only human culture medium. It passes unharmed and harmless through all the secretions of the mouth, œsophagus, and stomach, down to its favorite spot in the small intestine, where it stops, grows, and propagates a colony of its kind. One of the products of this new life is a toxin which is absorbed into the system and causes symptoms. And as in the vegetable world one form of cell life may produce morphine, and another strychnine, so is it easily possible that this newly discovered form of cell called a germ, so low down in the scale of life that its proper place is not yet assigned, is capable of producing poisons, in their actions equally severe and wide apart. The poison of typhoid is of such a nature that the system is able to withstand its absorption in gradually increasing quantities, as hour after hour and day after day the colony grows and invades new territory. The Peyer's glands, however, being limited in extent, there comes a time when all the available soil is occupied and the disease is at its height. But after three or four weeks, the soil beginning to give out, the colony grows smaller, and, the toxin gradually decreasing in quantity, the symptoms subside, and finally, all food being eaten up, the colony ceases to exist. This ending is due, it would seem, not to any complex theory of self-limitation and antitoxin, but to the simple fact of starvation. If instead of typhoid fever we take pneumonia, the same course may be traced. A patient subject to undue and severe exposure has the protective secretion of his lungs in whole or in part so acted upon, probably through some reflex nervous action, as to pervert its normal character and make of it a fit soil for the development of the pneumococcus. This pneumococcus is capable of remarkable activity, and in two or three days may have occupied all the soil prepared to receive it. The quick extensive involvement of tissue in pneumonia may be due, however, not so much to inherent activity of the germ as to the physical conditions favoring the invasion. In typhoid fever it is probable that only a few germs reach the Peyer's

glands to colonize them, and they may find these glands difficult soil to work; whereas in pneumonia it is possible to conceive of a great crowd of pneumococci being inhaled, to find the delicate villous membranes of the smallest bronchial tube a very easy field to cultivate. These explanations may account partly for the mildness of the onset in typhoid and its severity in pneumonia. Still between these two germs there is a marked contrast. One is slow and plodding, the other rapid and voracious. So much, in fact, are these latter qualities true of the pneumococcus that in the course of a week it has eaten up its entire food supply. In typhoid, because of the nature of the invading germ, the symptoms grow gradually and subside gradually. But here in pneumonia, owing to the intensity of the colonization, the food is suddenly exhausted, and thus cessation of toxin results in a sudden cessation of toxin symptoms, the so-called crisis.

Passing from these two diseases, which are acute, to phthisis, which is chronic, we see that the same principle of food and starvation holds true, and that in the matter of duration all germ diseases abide by the same law. A germ disease lasts while the food supply lasts, becoming acute when the germ is active and supply limited, and chronic when the germ is slothful and the supply unlimited. It might be better still to say that the duration of an infectious disease is in direct ratio to the activity of the invading germ and the extent of soil open to invasion. In pneumonia and phthisis we have examples of two diseases widely different in their nature and attacking the same tissue. The duration of the former may be counted by hours and that of the latter covers a period of months and years. The one comes like a wild beast, to strike and kill in the night; the other creeps in with stealthy tread, bringing false roses to fading cheeks, like the fairy gifts of story. This variation in mode of onset is surely due to something in the germ itself. While speaking of this, however, there comes to mind the fact that the tubercle bacillus may so invade the lungs as to run an acute course very closely resembling pneumonia. This then brings up another feature influencing the duration of disease, which is called individual resistance. It is owing to variations in this resistance that the tubercle bacillus creates an acute disease in one patient and a chronic in another. This variation in resistance is due undoubtedly to variation in nutrition, a weakened resistance being the result of weakened nutrition, leaving the gateways of the system open through the normal secretions. The secretions of the body, like the circulating blood, possess bactericidal powers; but owing to inherited features, coupled with vicious habits, these powers are in many cases lowered or lost. Such persons become the victims of the ever-present tubercle bacillus. The duration of a disease caused by such a persistent germ, while depending ultimately on soil limit, is measured best by the individual resistance. If we could assume a standard normal resistance, might we not say that a patient below par in resistance develops acute phthisis, one at par chronic phthisis, while in one above par the germ is destroyed when it enters the lungs? Can we not also suppose that a system temporarily off its guard, as it were, allows a localized invasion, but, becoming suddenly alarmed by the absorption of toxin, has its glandular system stimulated by the toxin and thus again throws itself above par, causing the disease to abort? We have absolute evidence of abortion in phthisis, hundreds of autopsies proving this. This result is due probably to improved hygienic conditions; but the fact stands, nevertheless, that increased individual resistance shortens the duration of this disease. Considering these things, then, it is not hazardous to say that the stronger the normal resistance the shorter the duration of the disease.

In reference to immunity, we may ask here the question, why does a certain disease usually attack a patient but once and why does a certain other render him particularly liable to a recurrence? Taking again the two diseases, typhoid fever and pneumonia, we find that in the case of the former disease its own specific inflammation sets up an ulceration which completely destroys the ground on which it fed, and that, scar tissue alone remaining where susceptible glands once existed, a reinfection is impossible. Pneumonia, on the contrary, is not attended with ulceration, and it leaves behind a damaged but not extinct normal tissue. This tissue, owing to its weakened state, has its resistance always more or less below par; hence its liability to reinfection. If, however, we take measles, the seat of whose local infection is probably in the air passages, we find that, unlike typhoid, it is not attended with ulceration, and, unlike pneumonia, the first attack is usually the last. We may account for this upon one or both of two suppositions: first, the disease may have destroyed its base of operation without any visible ulceration and loss of tissue; or, second, the toxins of the disease may have stimulated the glandular system to such an extent that the normal resistance to this particular germ is put and kept above par for a variable period, this period carrying the patient into a physiological age in which liability to this infection is small. Again, under this head of immunity may be asked, why does inoculation with cow-pox protect against small-pox? It may possibly be an answer to this question to say that, the symptoms of these two diseases being similar, the toxins may resemble each other, both stimulating the same glandular secretions; and, since a gland, like a muscle, being once thoroughly stimulated, remains for a variable time in a state of hypertrophy, so by inoculation with the milder of these two diseases we protect the patient from invasion by the more severe.

From the above it is seen that I am opposed to the present accepted theory that diseases are self-limited by the action of a substance called antitoxin, and which is claimed to be the result of the toxin acting upon or being acted upon by some blood constituent. It is further claimed that this antitoxin is foreign matter in the blood, that every specific germ has its own specific antitoxin, and that a definite amount of toxin injected artificially or absorbed naturally results in the production of a definite amount of antitoxin which neutralizes the toxin. The chief support of this antitoxin theory comes from the apparent success attending orrhotherapy. There is nothing, however, to disprove that this so-called antitoxin serum is not either a concentrated solution of normal resisting fluid or an irritant which acts by stimulating the normal glandular system. The chemistry of these serums is so absolutely dark as to render their use almost empirical. Still they have virtue, and the darkness which envelops them may be, to use a much hackneyed figure, "the darkness before the dawn." It is a remarkable thing, however, that the antitoxinists attribute this virtue to the germ and not to the system protecting itself through its own glandular secretions. We have in thyroid feeding direct evidence that we can supply a missing secretion; and, since the blood serum is the medium from which all gland secretions are formed and to which they finally return, why should not an injection of a concentrated solution of it add to the material already in the system and thus increase the probability of cure? Furthermore, after the injection, not of toxin alone but of any irritant, why should not the serum be unusually rich in normal glandular secretions? In the preparation of diphtheria antitoxin, the toxin of this disease is injected into the horse until

his serum is supposed to be sufficiently antitoxic. Why is it not possible—yes, probable—that the toxin affects a certain gland or set of glands, the secretions of which are curative or, rather, resistant to diphtheria toxin? We know that different vegetable and mineral poisons have a tendency to affect special tissues of the human body—ergot the uterus, pilocarpine the skin, digitalis the heart; and how can we well deny similar preferences to germ poisons? In fact, the very experiments of those who support the antitoxin theory furnish us with direct proof that the toxin of germ life acts in the same way on the system as does the toxin of plant life. It is found in the preparation of serums that small doses of the toxin must first be given, and these doses gradually increased, there coming a time when a dose which would at first prove fatal may be given with impunity. This process is identical in every respect with the action of morphine. We must at first give a small dose of this poison, but after its continued use large doses give mild results and carry little danger. Will the antitoxinists hold to the same theory in reference to the toxin of the poppy as they do to the toxin of diphtheria? Are we enabled to bear large doses of morphine because the morphine when taken into the blood unites with the blood constituents, and thus forms an antitoxin which is its physiological and chemical antidote? They cannot very well support this theory when confronted with the fact that the same amount of morphine which is injected is excreted by skin and kidneys as morphine. With the toxin of infectious diseases they are confronted by a fact equally significant. In scarlet fever we know, or at least we have the best of evidence to teach us, that the toxin is excreted by the skin and kidneys. Now it is admitted that scarlet fever is a self-limited disease, and, since the toxin is excreted, how is the antitoxin produced?

To my mind one of the fatal errors in the antitoxin theory is that this antitoxin is held to be foreign matter in the blood. The tendency of the blood is to excrete all foreign matter, and the assertion that the antitoxin will remain in the blood from months to years is a standing refutation of the chapter on the blood in every text-book of physiology. If, on the contrary, we assume that the increased antitoxic power of the serum after disease is due to normal secretions in excess, we can easily see how this virtue may last for an indefinite time.

Another feature difficult to understand is this: Since the toxins are consumed in the production of the antitoxin, to what are the symptoms of disease due? If the antitoxin is the result of some action occurring when the toxin comes in contact with the blood, and if a definite amount of toxin results, as is held, in a greater amount of antitoxin, it strikes me that no general symptom should develop. The neutralization of the toxin should be immediate and complete. Why, then—say, in pneumonia—does a patient become thoroughly saturated with the toxin before it is neutralized, and why does this neutralization not go on gradually, but be delayed until the patient is at his worst and then occur suddenly? Again, since the antitoxin depends for its production upon the presence of toxin, would not the former cease to be produced at the moment that the latter ceased to be produced? And since the one is consumed in the neutralization of the other, how could the serum of a convalescent possess antitoxin? Finally, how does antitoxin neutralize the toxin? If by chemical combination, then a new product is the result, and the antitoxin and toxin are both lost; if by physiological action, then one must be as strong to stimulate as the other is to depress, and, both being foreign irritants and equally active, it is absurd to hold that one is retained and the other is excreted.

All these questions are easily understood and can be easily answered, if we but assume that the germ lives only while it finds soil to feed upon, and while it lives it gives off toxin which is absorbed. This toxin in the blood, on its way to be excreted, acts accidentally as an irritant, stimulating normal glands. This stimulation enriches the blood in glandular secretions and the blood serum of disease thus possesses curative powers.

The antitoxin theory of self-limitation is a suicide theory, and nature abhors a suicide, for she stamps on every living cell the impress of her eternal law—not self-limitation but self-preservation. To illustrate the antitoxin theory by a simile, we might say that the blood stream of a patient sick of diphtheria is like a creek upon whose bank a pestilential village rests. The sewage of this village empties into the creek, and, meeting its pure waters, out of them by the action of the sewage an antisewage is formed which flows from the creek to the river and from the river into the sea, thence to come back to the village as antisewage dew and rain. Our eyes, however, in spite of the antitoxin theory, teach us to draw this picture otherwise. The pestilence rages in the village only while filth to breed upon is there. The sewage, although darkening at first the limpid stream and forming nasty green pools here and there, is nevertheless destroyed by the natural forces of fishes, sunlight, and fresh air; when the sea is reached the water is again sweet and pure. So may we believe it to be with the human blood stream in disease: it takes up the toxins and starts with its burden to its sea, the chambers of the heart. The fever due to increased oxidation is but an index to the effort being made to make this blood stream pure. The skin and kidneys are the human filtering sands. The phagocytes and leucocytes are but the fishes of a microscopic world; and, while it may seem to some that this figure is the result of a somewhat poetic fancy, still it is inspired by the same simple truth which inspired philosophers of old with the story of the music of the spheres. Nature through all her works rules in harmony.

CARBON DIOXIDE IN THE URINE.

By J. B. NICHOLS, M.D.,

CLINICAL ASSISTANT, BARNES HOSPITAL, U. S. SOLDIERS' HOME, WASHINGTON, D. C.

The occurrence of carbon dioxide as a constituent of urine is a fact little dwelt upon in medical and physiological literature. While not perhaps a matter of great consequence, its presence confers upon urine physical and chemical properties that are not unimportant, and has a bearing upon the bodily metabolism that is not without significance.

Proust as long ago as 1800 stated that carbon dioxide occurs in large quantity in urine. Brande in 1826 mentioned it as an ingredient, and Brett recognized its occurrence in urine in 1836. Davy in 1839 denied its presence in the urine; he appears to have been the only authority taking this negative position. Since that time a number of observers have made critical investigations of its quantity and variations in urine, while numerous authorities have recognized it as an ingredient of that excretion.

It may be accepted as a definite fact that carbon dioxide is a normal and constant constituent of urine. It occurs in urine in free form and combined as carbonate. Its occurrence in these two states requires consideration from each point of view.

Free Carbon Dioxide.—Carbon dioxide is soluble in about an equal volume of cold water. Its aqueous solution has an acid reaction and taste, due to the presence of virtual carbonic acid, H_2CO_3, which ex-

ists free in no other form. This solution reddens blue litmus paper, which after drying tends to turn blue again. Theoretically it should affect the specific gravity of the water in which it is dissolved. Carbon dioxide exercises some solvent power over certain salts in the urine. It is easily expelled from its aqueous solution by heat, exhaustion under the receiver of an air pump, the passing of a stream of air or other gas through it, or agitation. Even on standing the gas escapes from its solutions. These various properties exist also with respect to the presence of carbon dioxide in the urine.

Urine is capable of absorbing about the same relative amount of carbon dioxide as is water. Planer found that one volume of urine, at a pressure of 760 millimetres of mercury, would dissolve at 33° C. 0.6186 volume of carbon dioxide, at 19.3° C. 0.9072 volume. Water at 20° C. absorbs 0.9 its volume of carbon dioxide.

The acidity of urine is in considerable and material part due to the contained carbon dioxide. In weakly acid urines carbon dioxide is frequently the only acid principle present, and after its removal the reaction becomes alkaline or neutral. As carbon dioxide is a volatile acid principle, all operations by which it is expelled cause a diminution of the acidity of urine. Boiling, which expels the gas, causes a material and marked decrease of urinary acidity. This circumstance, pointed out by Brett in 1836, I have found to occur constantly in numerous trials of acid urines, titrating with decinormal sodium hydrate and phenolphthalein before and after boiling. Occasionally a weakly acid urine after boiling becomes alkaline. As the (alkaline) ammonium carbonate which is formed on boiling solutions of urea is expelled from the fluid by the heat, this loss of acidity is explainable only on the ground of the dissipation of carbon dioxide. I have also been able to effect a perceptible decrease of acidity after vigorous agitation of urine; also after passing a stream of air through it. The withdrawal of the contained gases by an air pump has been known to cause urine of weak acid reaction to become alkaline. When litmus paper reddened by urine turns blue again after drying, the presence of carbon dioxide as the only acid principle is indicated.

Carbon dioxide by its presence in the urine, perhaps by virtue of its acidity, exercises an important solvent power over the phosphates of calcium and magnesium also present. These phosphates are only slightly soluble in pure water, but are much more soluble in solutions of carbon dioxide, as well as of other acids. The occurrence of this gas as a normal constituent of urine has been recognized by many writers in connection with the presence of the earthy phosphates. The expulsion of carbon dioxide by heat is a cause commonly assigned for the precipitation of these phosphates frequently observed on boiling urine. It is, indeed, a prominent factor in the case, but, as I have determined in a study of the subject,[1] the expulsion of carbon dioxide cannot be regarded as the sole or even the chief cause of this precipitation.

Carbonic acid has such weak combining-power that it is expelled from and replaced in its combinations by other acids, whenever present. Theoretical considerations, therefore, indicate that in the more strongly acid urines, in which there is an excess of other acids (chiefly phosphoric acid) over the alkaline principles present, carbon dioxide could occur only in its free and uncombined state; while in neutral or alkaline urines only could carbonates exist without decomposition. From the slowness with which the gas is given off in vacuum, Pflüger indeed believed that the carbon dioxide exists in urine in a state of loose chemical combination (perhaps with sodium phosphate), as in the blood plasma. According to the results of analyses and the weight of authority, as well as theoretical considerations, carbon dioxide occurs practically only in free form in strongly acid urine, while in neutral and alkaline and some weakly acid urines it may occur also in combination.

Carbonates.— By combined carbon dioxide in this paper is meant its combinations in the form of carbonates, either the normal salts or the acid salts (or bicarbonates). Carbamic acid, $HOCONH_2$, and carbamates are related compounds that under certain unusual circumstances appear in the urine, while urea may be regarded as a dehydrated combination of carbon dioxide and ammonia.

The carbonates that may occur in human urine are those of ammonium, sodium, potassium, calcium, and perhaps magnesium. Ammonium carbonate derived from the ammoniacal fermentation of urea is of frequent occurrence in paralytic and inflammatory conditions. The alkaline carbonates are frequently present in alkaline urine, the earthy carbonates only under unusual circumstances.

These salts contribute to the alkalinity of the urine. Ammonium carbonate is volatile and is dissipated by heat with a profuse evolution of gas; litmus paper turned blue by volatile alkali again becomes red on drying. The other carbonates are "fixed" alkalies. The presence of carbonate is indicated by effervescence on the addition of any strong acid; when in very small quantity, however, no effervescence may be perceptible. There is also a slight evolution of gas when urea or uric acid is treated with nitroso-nitric acid, but this is easily distinguished from the effervescence of carbonates, which occurs with any acid.[1]

Methods of Estimation.—The available methods of quantitative determination of carbon dioxide in the urine consist of two or three distinct processes: 1, the separation of the free gas (*a*) by an air pump, (*b*) by heat, or (*c*) by a stream of air; 2, the estimation of the carbon dioxide thus separated, (*a*) from the volume of gas lost after absorption with sodium hydrate, (*b*) from the amount of carbonate precipitated, or (*c*) from the amount of hydrate neutralized after passing it into a solution of barium or calcium hydrate, or (*d*) from the increment of weight after passing it into sodium-hydrate solution; and (3) the subsequent liberation of combined carbon dioxide by strong acid and its estimation separately.

Methods of removing the gases from urine by means of an air pump, similar to those for estimating the gases in blood, have been described by Morin, Pflüger, Ewald, and Thudichum. The urine is drawn by catheter into receptacles free from all gas, so as to avoid any contact or admixture with atmospheric air. When the pump is operated the free gases present separate from the fluid and are collected. Their total volume is measured and the amount of carbon dioxide then determined from the loss of volume after absorption by sodium or potassium hydrate. The combined carbon dioxide is then set free by adding acid, and is collected and estimated as before.

Planer and Purdy have described methods of separating carbon dioxide by means of heat. Planer introduced the urine into vessels so as to avoid mixture of air, separated all the gases present by heat, and collected and measured them. Purdy describes a method, which he attributes to Marchand, by which the vapor from the heated urine is passed, first into an empty flask in which the distillate condenses, and then through several flasks of barium-hydrate solution, in which the carbon dioxide is precipitated as barium carbonate. The amount of carbon dioxide is then

[1] Published in MEDICAL RECORD, New York, October 30, 1897, p. 618.

[1] See MEDICAL RECORD, New York, November 28, 1896, p. 789.

calculated from the weight of carbonate precipitated. The operation is repeated after the urine is acidulated, so as to estimate the combined carbon dioxide.

Any method of separating carbon dioxide from urine by heat is open to the objection that at the boiling temperature urea is converted into ammonia and carbon dioxide, which pass over in vapor, and on condensing combine as ammonium carbonate. The carbon dioxide or carbonate thus produced may form a precipitate with barium or calcium hydrate, and thus destroy the value of the test. In tests of this source of error I found that if the vapor be first passed into an empty flask, as described by Purdy, the ammonium carbonate carried over is usually condensed in it so as not to cause any precipitate with the lime or baryta water. Still this transformation of urea introduces an element of uncertainty in this method; and it is significant that among all the authorities Planer and Purdy are alone in stating that large relative amounts of combined carbon dioxide occur in normal urine.

Beale, Wurster and Schmidt, and Neubauer describe methods for removing the carbon dioxide from urine by passing a stream of air (or hydrogen) through the fluid. This depends on the principle that by the passage of one gas through a solution of another gas the latter is displaced by the former. The air, washed free of carbon dioxide, is drawn through the urine to be tested and then through a solution of barium or calcium hydrate, in which the formation of a white precipitate indicates the presence of carbon dioxide, or through a solution of sodium hydrate. The amount of carbon dioxide is calculated from the reactions effected in the solution of hydrate.

This method effects a complete removal of the gas, is simple, approximately reliable, and is the one which I have employed. The facility with which carbon dioxide escapes from its solutions on agitation, and even on standing, necessitates great care in dealing with the urine before and during the test, to avoid loss of the gas. The urine should be gently passed directly into the receptacle intended to contain it during the test, and the vessel should then be kept tightly stoppered. Air, first washed free of carbon dioxide by being passed through sodium-hydrate or a similar solution, is then drawn through the urine through a tube reaching to the bottom of the fluid. The stream of air and gas removed from the urine is then passed through a series of three or four washing-bulbs or flasks containing solution of barium or calcium hydrate; the current of air is produced by an aspirating-jar attached to the last washing-flask. The carbon dioxide is absorbed by the hydrate solution, from which its amount can be determined.

After estimating the free carbon dioxide in this manner, strong acid is added to the urine to liberate the carbon dioxide in combination, and by repetition of the process the amount of the latter is found. For this purpose nitric acid should not be employed, since, as mentioned above, it or the nitrous acid contained in it will decompose urea and set carbon dioxide free from that source.

The amount of carbon dioxide contained in the urine tested can be calculated either from the weight of the carbonate precipitated or from a volumetric determination of the amount of neutralization of the hydrate.

For determining the carbon dioxide from the weight of the precipitate barium hydrate is the preferable precipitant. The precipitate may be collected, washed, dried, and weighed as carbonate; or after washing it may be treated with hydrochloric acid and reprecipitated by sulphuric acid as barium sulphate, which is then weighed. Of barium carbonate 196.75 parts correspond to 232.72 parts of barium sulphate and to 43.89 parts by weight of carbon dioxide. Or, for every one part of barium carbonate there is present 0.2231 part by weight of carbon dioxide, and for every one part of barium sulphate there is 0.1886 part of carbon dioxide.

The determination of carbon dioxide from the amount of hydrate neutralized—Pettenkofer's method—is easier of execution. The data necessary for this determination are the amount of solution of barium or calcium hydrate employed and its degree of alkalinity, as determined by titration with decinormal acid, before and after the carbon dioxide is passed into it. The loss of alkalinity after the test is carried out corresponds precisely to the amount of carbonic acid introduced, which has neutralized a like strength of hydrate. If alkalinity be quantitatively expressed in thousandths of a normal solution, the strength of a normal solution being taken as one,[1] each thousandth, of a normal solution, of alkalinity lost corresponds to 0.0021945 per cent. by weight, or 1.1159 per cent. by volume (at temperature of 0° C., and pressure of 760 millimetres of mercury) of carbon dioxide introduced. From this percentage and from the amount of the hydrate solution the absolute quantity of carbon dioxide can be calculated. The percentage strength of carbon dioxide in the urine can then be determined from the amount of urine tested.

Another method by which carbon dioxide may be determined—that of Scharling—consists in passing the stream of air and gas, first, through sulphuric acid, which removes watery vapor; then through a solution of sodium hydrate, which absorbs the carbon dioxide; and lastly through sulphuric acid again. The increase in weight of the last two fluids is equivalent to the weight of carbon dioxide present.

Quantity and Variations of Carbon Dioxide in Urine.—Carbon dioxide is always present in fresh normal acid urine, its quantity varying considerably according to circumstances. The following table shows the average percentages of carbon dioxide found in normal human urine under ordinary circumstances, in analyses made by various observers:

Observer.	Average Percentage Amount of CO_2 Found.		Number of Analyses.
	By Volume. (Temperature of 0° C. and Pressure of 760 mm. of Mercury.)[2] Per Cent.	By Weight. Per Cent.	
Planer	9.38	0.0184	3
Morin	1.9	0.0037	21
Pflüger	18.92	0.0372	2
Kerner	3.59	0.0071	3
Ewald	11.64	0.0229	7
Wurster and Schmidt.	4–5	0.0075–0.01	
Nichols	5.68	0.0112	5

Schöffer in six analyses of acid dog's urine found carbon dioxide present in the average proportion of 4.99 per cent. by volume. These figures indicate a certain amount of personal diversity in the results of the different observers; but aside from this carbon dioxide varies much in amount under normal conditions, according to diet, quantity of fluid drank, degree of concentration of the urine, mode and activity of life, etc. The amount of carbon dioxide in normal acid urine under ordinary circumstances may be stated to range from about two to twelve per cent. by volume (0.004 to 0.025 per cent. by weight).

[1] See Medical Record, New York, October 5, 1895, p. 483.

[2] Volume percentages of CO_2 in this article are expressed at a temperature of 0° C. and a barometric pressure of 760 millimetres of mercury, and the volumes as given by the various observers are reduced to this standard. One cubic centimetre of CO_2, at 0° C. and 760 millimetres' pressure weighs 0.001966 gram; 1 gram of CO_2 = 508.5 cubic centimetres, at 0° C. and 760 millimetres' pressure.

Van Nüys and Lyons, in an analysis of the urine for six days on a mixed diet, found this amount of carbon dioxide to range from 0.45 to 0.79 gram per twenty-four hours, averaging 0.588 gram per day; this, if the daily amount of urine were 1,500 cubic centimetres, would make the amount of carbon dioxide about twenty per cent. by volume. From seven analyses of acid urine from convalescents Ewald estimated the amount of carbon dioxide in the twenty-four hours at from 0 28 to 0.44 gram, averaging 0.34 gram.

The analyses show that in normal urine of well-marked acidity all, or practically all, the carbon dioxide present is in free form. Thus Ewald and Pflüger obtained only traces of combined carbon dioxide in their analyses of acid urines. In my analyses no carbonate was found in strongly acid urines. Planer alone found combined carbon dioxide in large proportion in acid urines; Schöffer suggested in explanation of this that the urines tested were only weakly acid and after heating reacted neutral or alkaline. The element of uncertainty attaching to methods of estimating carbon dioxide by means of heat, such as Planer employed, is also worthy of note in this connection. In urine that is alkaline, or neutral, or weakly acid (in which the acidity is due chiefly to free carbon dioxide), it is physically possible for the carbon dioxide to exist in combination, and in such cases analyses show its partial occurrence in that form.

In thin urines, as after free drinking, the percentage amount of carbon dioxide is diminished. In concentrated urines, as after free perspiration, its amount increases. The amount is also increased (according to Wurster and Schmidt about doubled) in weakly acid, neutral, and alkaline urines. Thus in five analyses of strongly acid urine under fairly normal circumstances I obtained an average of 5.68 per cent. by volume of carbon dioxide, all free; in four analyses of weakly acid and neutral urines I obtained an average of 11.45 per cent. of carbon dioxide, of which 9 1 per cent. was free, 2.35 per cent. combined.

Upon a vegetable diet, under which the urine becomes neutral or alkaline, the carbon dioxide in the urine is increased, and may exist in part combined. Thus Van Nüys and Lyons found the urinary excretion of carbon dioxide on a vegetable diet for three days increased to an average of 1.09 grams per day, the average on a mixed diet being 0.588 gram.

After the ingestion of certain salts of sodium and potassium in combination with organic acids (as the alkaline citrates, tartrates, or acetates) there is a large increase of carbon dioxide and carbonates in the urine, which becomes alkaline. Van Nüys and Lyons found the amount of carbon dioxide excreted in the urine increased from two to four times while taking sodium tartrate.

After drinking waters charged with carbon dioxide, Kerner found a largely increased excretion of the gas in the urine, amounting to about twenty-five per cent. by volume, or from 104 to 162 c.c. in actual quantity. The excess of the gas was entirely eliminated within about two hours after its ingestion. The ordinary volume of carbon dioxide in the urine in Kerner's cases averaged 3.59 per cent.

The effects of exercise and rest, other conditions being identical, were investigated by Morin, who found an increased excretion of carbon dioxide in the urine during muscular activity. In three analyses of urine during rest, the amount of carbon dioxide averaged 1.19 per cent. by volume, while during exercise in the same subject and under similar conditions of diet, time, etc., three analyses gave an average of 2.29 per cent. In two analyses made by me under otherwise similar circumstances, 6.09 per cent. of carbon dioxide was found in the urine after exercise, 5.58 per cent. after repose.

Other conditions being equal, more carbon dioxide is excreted in the urine (as from the lungs) during fever than during apyrexia. This was shown by Ewald, who made analyses in seven cases of fevers (relapsing fever, typhoid fever, and pneumonia) during the febrile and afebrile periods. In six of the cases the amount of carbon dioxide, as estimated for twenty-four hours, was materially greater during the pyrexia.

Ewald's analyses also showed a correspondence between the excretion of carbon dioxide and urea in the urine, the amounts of these substances rising and falling together. In all his cases this correspondence was well marked, especially for the same subject. Planer's figures also show this correspondence to a certain degree. My results as to this point were very variable, but it is probable that when other conditions are equal this relation between urea and carbon dioxide will be apparent.

A few of my analyses were in cases of lowered vitality and metabolism. In one case the urine passed about twelve hours after an amputation of the thigh, which had been succeeded by considerable shock, contained only 1.78 per cent. by volume of carbon dioxide and 0.46 per cent. of urea. In the case of a patient moribund from gastric cancer, with subnormal temperature, the urine two days before death contained 3.43 per cent. of carbon dioxide, a slight decrease, but 2.24 per cent. of urea. The morning urine of a very feeble old man, aged eighty-one years, who took a small amount of whiskey daily, contained 14.76 per cent. of carbon dioxide, a marked increase, and only 0.67 per cent. of urea. The morning urine of another old man, aged eighty-five years, not taking alcohol, contained 4.40 per cent. of carbon dioxide and 2.47 per cent. of urea.

Large amounts of ammonium carbonate occur in urine that has undergone ammoniacal fermentation. A bacillus capable of generating carbon dioxide in urine in a similar manner has been described by Schow. After the ingestion of large quantities of calcium hydrate a large amount of carbon dioxide occurs in the urine from the decomposition of calcium carbamate (Abel).

Source of Carbon Dioxide in the Urine.—The carbon dioxide in the urine is mainly derived from three sources: (1) from the products of bodily catabolism; (2) from food and other matters ingested; and (3) from the transformation of urea into ammonium carbonate by ammoniacal fermentation. As the latter is a change occurring subsequent to the excretion of the urine and practically outside the physiological mechanism, it is without interest in this connection and will not be further considered here.

The principal waste products of catabolism, produced by the oxidation or breaking down of the bodily tissues, are urea, water, and carbon dioxide. Urea mainly represents the decomposition of nitrogenous substances, water and carbon dioxide mainly that of carbohydrates and fats. Of these about thirty grams of urea and eight hundred grams of carbon dioxide are excreted daily. Carbon dioxide is being constantly formed throughout the bodily tissues, from which it is taken up by the blood, and excreted mostly by the lungs, but in small quantities also by the kidneys.

These considerations readily explain the correspondence between the amounts of urea and carbon dioxide excreted in the urine, both being parallel products of metabolism. They also show why the amount of carbon dioxide (and of urea) is increased in conditions like fever, active exercise, etc., when there is a heightened activity of metabolism and diminished in conditions of lowered activity.

A portion of the carbon dioxide in the urine is also

to be attributed to ingested substances. Thus most organic salts of the alkalies when taken into the system are decomposed into carbonates and eliminated as such. The large increase of carbon dioxide in the urine after the drinking of carbonated water is another instance in point. After a vegetable diet the increase of carbon dioxide and the alkalinity of the urine are to be attributed chiefly to the vegetable acids (malic, citric, tartaric, etc.) occurring in fruits, which in the system are transformed into carbonates.

The mode by which carbon dioxide passes from the blood into the urine deserves remark. In the blood carbon dioxide exists partly firmly combined as alkaline carbonates, partly free or in loose chemical combination. A portion of the carbon dioxide, especially the carbonates, may enter the urine by a true process of excretion; but another portion, that which is loosely combined or free, exerts a certain amount of expansive tension in the blood and may be forced over into the urine so as to equalize the cabon-dioxide tension between the urine and the walls of the urinary tract (Ewald). The investigations of Strassburg and others indicate that the tension of the carbon dioxide in the urine, and other body fluids as well, exceeds that in the blood. Ewald explained this on the supposition that this excess of carbon dioxide in the urine is derived from the tissues along the urinary tract, in which the carbon dioxide resulting from catabolism being at a higher tension is forced into the neighboring urine.

Another source of the free carbon dioxide in the urine, in addition to its diffusion from the urinary tissues, seems to be this: The free carbon dioxide in the blood is mostly excreted by the lungs: the carbonates are not adapted to elimination by that avenue. While a portion of the free carbon dioxide may be diffused or excreted directly from the blood or tissues into the urine, another portion is probably derived from the carbonates, which are excreted as such from the alkaline blood, but on mixing with the acid constituents of the urine are decomposed with the evolution of free carbon dioxide. In this manner carbon dioxide might be generated in the urine until it has a greater tension than in the blood. Under these circumstances free carbon dioxide would not diffuse from the blood into the urine, but on the contrary it might even be forced back into the blood. On this supposition the free carbon dioxide in the urine represents, partially at least, the excretion of carbonates. If the urine were alkaline, however, there would be less or no decomposition of excreted carbonates and less tension of free carbon dioxide in the urine; more free carbon dioxide would pass from the blood or tissues into the urine, or less would be forced back from the urine into the blood. Hence a larger amount of carbon dioxide would be excreted in neutral or alkaline urine than in acid urine, which corresponds with observed facts.

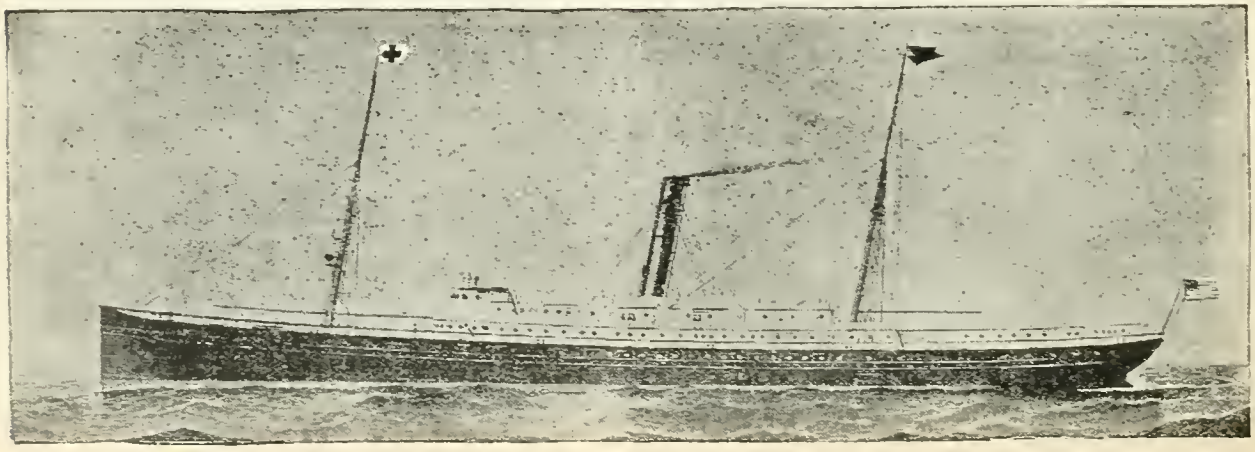
THE NAVAL AMBULANCE SHIP "SOLACE" —HER PURPOSE AND CONSTRUCTION.

By E. S. BOGERT, Jr., M.D.,

PASSED ASSISTANT SURGEON, U. S. NAVY.

Inasmuch as the *Solace* is the first ambulance ship ever commissioned by any government, it is thought a brief description of the vessel may prove of interest to the readers of the Medical Record.

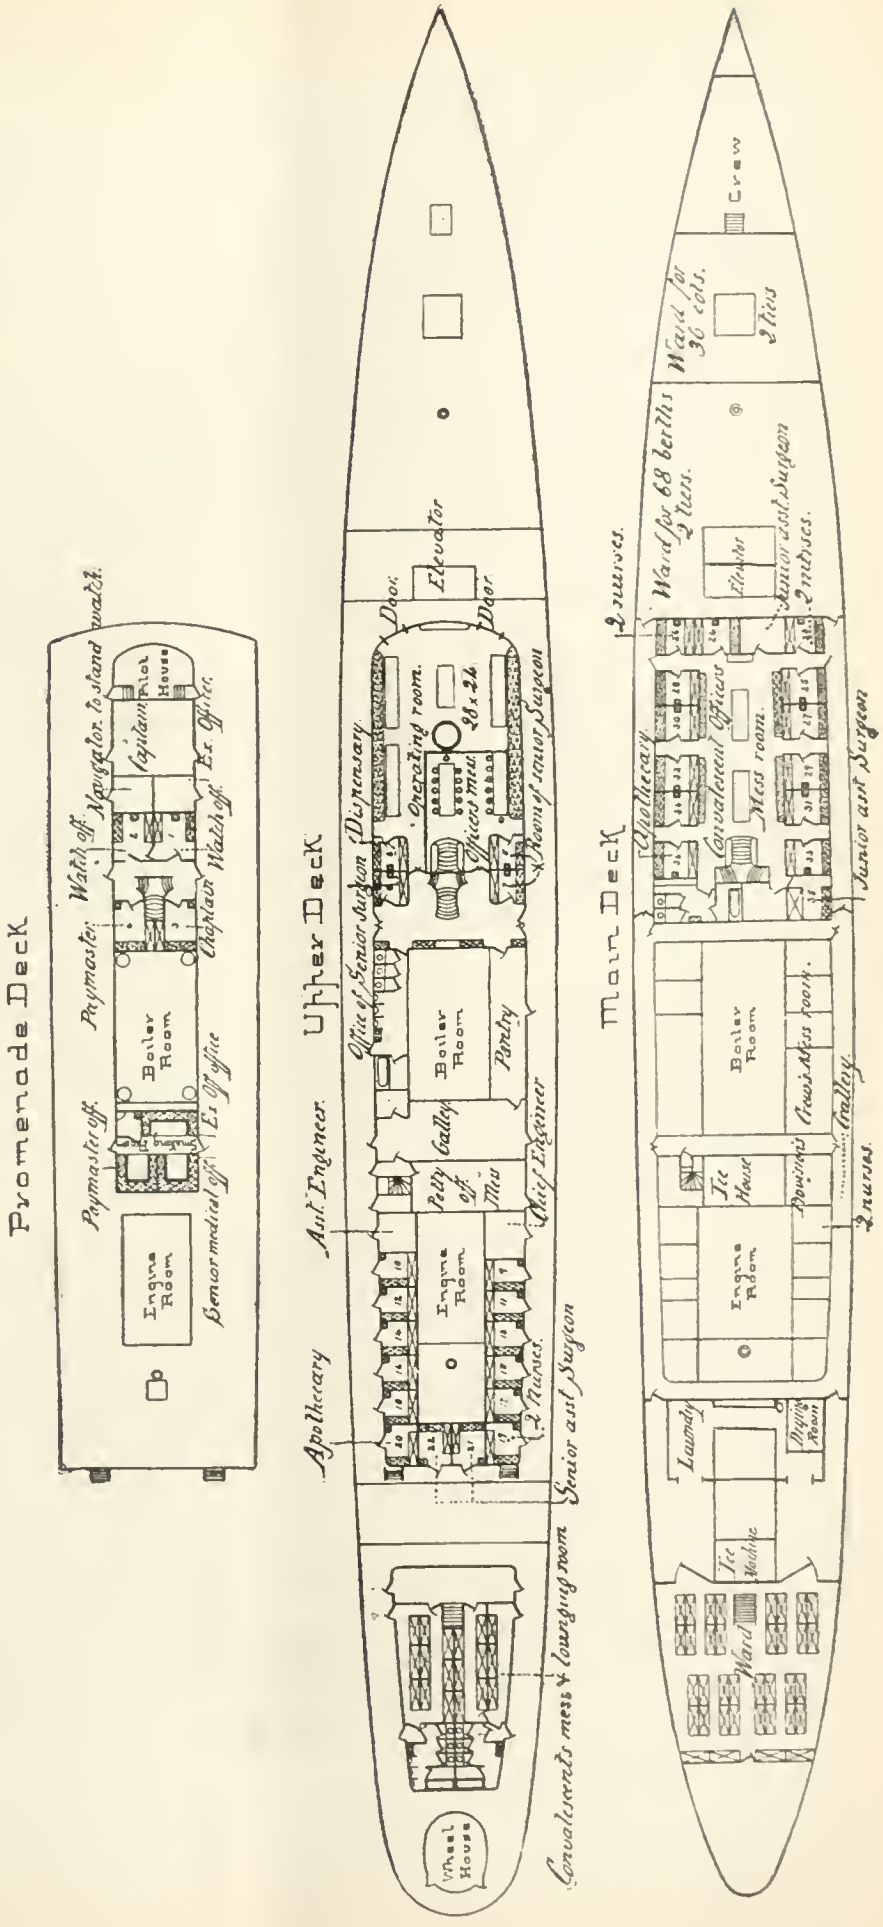
With the constantly increasing destructive power of ships-of-war have come structural changes such that the proper treatment of the wounded on board a modern battleship is wellnigh impossible. When a ship-of-war nowadays goes into action, she is divided into many compartments by the closing of



water-tight doors and the screwing down of battle hatches. These compartments are practically closed cells, and communication between the different parts of the ship is always difficult and often roundabout. For this reason the transportation of the wounded from certain parts of the ship to any central dressing-station is impossible. Again, with the crew of the vessel necessarily divided into small squads in separate non-communicating compartments, men cannot be spared from the guns for transporting wounded. These and other minor conditions, insurmountable without lessening the fighting efficiency of the vessel, render the surgical treatment of the wounded on board a ship-of-war during an action very difficult. The surgeons must themselves move about the ship, rendering aid wherever they may; and this aid must necessarily be limited to checking hemorrhage, the application of temporary dressings, and perhaps some treatment of shock.

It was with a full understanding of these conditions that Surgeon-General Van Reypen, as soon as hostiliites with Spain became probable, sought authority to fit out an ambulance ship. He was heartily supported by the President and the secretary of the navy, and, after much thought and work, the *Solace* is the result.

The *Solace* is a new steel vessel of 3,800 tons displacement, is 375 feet long, and has a speed of from 14 to 17 knots per hour. She has a single screw driven by triple expansion engines, and is extremely economical in coal consumption. She has bunker space for 850 tons of coal, and abundant stowage room for more in case of necessity, and thus has a large steaming-radius. Her holds and lower decks are given up to the stowage of ship stores and provisions, with the ex-



ception of the forward upper cargo deck, on which we find a large steam sterilizer and storerooms for medical and surgical supplies.

On the main deck forward are quarters for the crew of the vessel, the anchor engine, and the blowers for artificial ventilation. Abaft these is the main ward. Here are bunks, accessible on all sides, for ninety-two patients. This ward is well ventilated by numerous air ports and a large hatch, and is well lighted. In addition to the natural ventilation are louvres and ducts connecting with blowers which have a capacity sufficient to insure at all times a plentiful renewal of air. In the ward there is an abundant supply of hot and cold water, and connected with the ward are closets, urinals, and bathrooms. This ward is connected directly with the operating-room above by an elevator capable of carrying a cot or wheeled stretcher. Abaft the main ward is a large saloon with staterooms on either side. This space is intended for convalescent officers. On this same deck amidships are staterooms for nurses, apothecaries, and the petty officers of the ship, and the crew's messroom; also cold-storage rooms, ice machines, and ice houses. Abaft the engine-room is the steam laundry, and still farther aft is the emergency ward, containing fifty swinging cots. In the extreme stern is the steam steering-engine.

On the upper deck forward is the operating-room—large, light, commodious, and well ventilated. It is fitted with two operating-tables of the regulation navy pattern, and all modern appliances for aseptic surgery. The instruments are of the latest and most approved patterns, and of the best construction. The deck is covered with interlocking rubber tiles, which are capable of thorough cleansing, and afford a firm foothold in a seaway. The bulkheads are painted with enamel paint, so as to be capable of thorough cleansing and sterilization.

Adjoining the operating-room are the surgeons' sterilizing and wash room and the dispensary. In the latter, besides the usual fittings, is the central telephone station, with connections to the wards and sick-quarters and to the staterooms of each of the surgeons. Abaft this are, on either side, the quarters of the senior surgeon and the chief apothecary, and amidships is a broad companionway leading down to the convalescent officers' saloon.

Next come the officers' messroom, with connecting pantry and toilet rooms, and abaft these the galley. On either side is a series of staterooms for injured officers, and in the extreme after end of this midship deck house are the quarters for the junior surgeons. In the after deck house is a saloon, connecting with the emergency ward below, for convalescent enlisted men. Abaft this is the wheel house, with hand steering-gear for use in case of emergency.

On the promenade deck are the pilot house and connections, the quarters of the captain and deck officers, and offices for the executive officer, the surgeon, and the paymaster. The after part of this promenade deck is arranged so that it may be entirely screened off by awnings, and will be devoted to the isolation of contagious diseases, should such develop.

Beside a large distilling-plant, the *Solace* has tanks for fresh water of a capacity of over twenty-seven thousand gallons. On the forward upper deck the *Solace* carries two steam launches, which can be fitted with platform decks on which the injured in cots or in hammocks may be lowered.

In conformity with the additional articles of the Geneva convention, the *Solace*, as well as each of her steam launches, is painted white with a broad green stripe. She flies the Geneva cross at the fore, and thus her peaceful character should be always apparent.

The personnel of the surgeon's division of the *Solace* includes at present four surgeons of the navy, three apothecaries, eight nurses, four mess attendants for the sick, and one cook for the sick. She carries, in addition, a captain, executive officer, three watch officers, and a paymaster—all of the navy—and a crew of sixty men. The nurses are male nurses and are all graduates of the Bellevue Hospital Training-School.

The *Solace* is expected to remain near the fleet while in action, and as soon as any ship withdraws, or at the close of the engagement, she will take all the wounded on board and steam away for a naval hospital, thus fulfilling distinctly the duties of an ambulance ship and not those of a hospital ship. The injured will be lowered from the battleships either into the *Solace's* steam launches or into barges towed by the launches, or will be landed directly on the *Solace's* deck by a trolley sort of litter, which will run on a cable stretched from the battleship to the ambulance ship. The wounded having been received on board of the ambulance ship, those requiring immediate operation will be placed on the tables at once and sent down to the wards later, thus involving the least possible handling; those that do not require operative treatment will be sent at once to the wards.

This is the first time that this humane project has ever been attempted, and if the ship enacts the part for which she has been designed her surgeons will be the first to have the opportunity to practise aseptic field military surgery. That the United States should be the first nation to adopt such a humane adjunct to naval warfare, all the country should be proud of. That the vessel is the product of the brains and energy of American surgeons, should cause a widespread interest in the vessel's work by the entire medical profession of the United States. That the navy of the United States should be the first to suggest and to put into execution this project, our navy in general, and the naval medical corps in particular, may take pride in. Honor to the President and to the secretary of the navy, who authorized the expenditure of public funds for such a purpose, and honor to the surgeon-general of the navy, who by his tireless energy has brought this project to a successful completion.

Progress of Medical Science.

The Spastic Night Cough with Vomiting and Coryza in Young Children.—According to Dr. P. Gastow (*Der Kinder-Arzt*, 1897) this very common affection is of reflex origin, sometimes due to intestinal parasites, sometimes to other causes, but usually the result of a coryza posterior. The cough has the following characteristics: it is spasmodic, similar to whooping-cough; it causes nausea and vomiting, and it occurs at night when the child is in bed, never when it is up, and rarely by day. It occurs only in very young children, because they do not expectorate and cannot clear the nose: the mucus therefore drops backward into the pharynx and the irritation of the pharyngo-laryngeal mucous membrane thus produced causes a reflex cough. The cough is spasmodic, because the mucus collects in the region of the arytenoids and the vocal cords, causing glottic spasm and attacks of suffocation. The cough occurs at night, because then the position of the head favors the gravitation of mucus to the pharynx and larynx. Treatment consists in the application three or four times daily, through the whole length of the nasal cavities, of tampons saturated with borovaseline. This at first causes sneezing, but later the infant bears it well. The snuffling causes the vaseline to flow into the pharynx. Astringents, such as tannin or alum, and especially antipyrin, may be added to the vaseline.

MEDICAL RECORD:

YELLOW FEVER AND THE WAR.

THE report published last week that yellow fever had developed in members of a prize crew on one of the captured Spanish vessels held at Key West naturally causes some apprehension at this particular time. "Yellow Jack," always a most unwelcome guest, would be especially so now, despite the excellent facilities at the command of the Marine Hospital service for preventing or stamping out an epidemic. The great importance, however, to the United States of the yellow-fever question lies in the fact that there will probably be an invasion by our troops of territory in which the fever prevails each year with considerable virulence. It will be well for us, therefore, to learn our lesson from past rather than from present and future experience. We must not forget that armies have been decimated in the West Indies without a man being lost at the hands of a human enemy. A century ago, according to John Hunter, who was a surgeon in the English army in Jamaica, scarcely a man was left in some regiments at the end of a year, although the number killed in battle was almost nothing.

All authorities are agreed upon this point: that it is the newcomer, and especially the unacclimated soldier, who suffers to the greatest extent. The ravages of former times among European troops are hardly to be anticipated in an American army of invasion, because we now know that hygienic conditions which military authorities can control have much to do with keeping down the death rate. Our soldiers would, for example, not be landed in an impaired state of health after long voyages in overcrowded vessels. The food supply would be much superior to that of former days, and quarters would be so far as possible chosen at a distance from swamps, while the water supply would be much more carefully controlled. Overcrowding and lack of sufficient air space have been important causes of the high death rate in barrack and hospital in former West Indian campaigns—conditions not now so likely to exist, since their danger is so well appreciated.

In spite, however, of all that is known of the dangers of yellow fever and of the means of prophylaxis, many deaths might occur among our men from a lack of knowledge of proper personal conduct under the new conditions of life. It would be well, then, that each man should receive instruction as to his mode of living. In a little book just published in London, on "Yellow Fever in the West Indies," the author, Dr. Izett Anderson, states that after an experience of more than thirty years he can say that undue exposure to the sun in the heat of the day is the most potent exciting cause, and next to this are intemperance and debauchery.

Earth freshly upturned, as in the digging of trenches, is a source of danger which it might at times be impossible to guard against. Past experience, however, should guide in sending troops into a yellow-fever region to engage in such work, since it has been found that the most susceptible subjects come from the more northerly and colder regions, while colored-skinned races are but slightly endangered. Then, too, those who have acquired immunity by previous exposure should be first utilized.

We cannot here enter into the importance of an early diagnosis of the first cases in a community, or of the difficulties at times attending the detection of the affection by physicians who have had no practical experience with the fever. The author above referred to dwells especially upon the dangers of faulty diagnosis—in instances in which the disease is seen for the first time by the physician—in the stage of depression or decline of the fever, when the symptoms may be limited almost to cutaneous capillary hyperæmia and conjunctival injection, and when the patient expresses himself as feeling well again. The treatment he recommends embraces an attempt at abortion of the process by administering twenty grains of calomel, together with twenty or more grains of quinine, and repeating the dose if necessary at an interval of three or four hours; and if the fever remains high, even a third dose may be given. This must be employed early in the first stage, and is particularly suited to sthenic cases in plethoric soldiers, especially those who have recently arrived in the infected region.

As a routine treatment he has employed for many years:

℞ Acidi carbolici ..... gr. xviij.
Potassii bicarbonatis ..... ℥ iij.
Aquæ ..... ℥ xij.

Of this two ounces are to be given well iced every two or three hours, a dessertspoonful of freshly squeezed lime juice being added to the effervescing mixture at the time of taking.

Among other measures recommended are wet packs to the body; "iced drip" to the head; dry cupping to prevent or relieve suppression, together with drachm doses of spirits of nitrous ether every hour; and bromide of ammonium in full dose given in iced milk for insomnia. He speaks favorably, too, of Sternberg's formula:

℞ Hydrargyri bichloridi ..... gr. ½
Sodii bicarbonatis ..... gr. cl.
Aquæ ..... ℥ xl.
M. S. Three tablespoonfuls every hour, given ice cold.

It is gratifying to note that the government is taking most active measures to solve this great war problem, and that an officer of the Marine Hospital service has been detailed to accompany the army of invasion, whose special duty it shall be to secure for our soldiers all the protection possible from this hid-

den enemy. Among the measures to be carried out are the establishment of a base of supplies at a distance from any yellow-fever centre, and prevention of communication between the army and infected localities.

The latter will naturally be a most difficult thing to accomplish. The only absolute safety would seem to lie in terminating the war in Cuba before June, when the annually recurring epidemic in and about Havana makes its appearance, or in so far accomplishing this end that the native army, assisted by immunes, could complete the work and permit susceptible Northern troops to return to the States.

We have the utmost confidence in the ability of our Marine Hospital service to accomplish by vigilance and scientific sanitation all that it is possible to do in the matter of detecting early evidences of danger and carrying out segregation. A disease, however, which presents such an appalling mortality in severe epidemics and under certain conditions, should likewise be regarded as an enemy to be combated until conquered. No doubt this will be one of the results of the present warfare, for it may be predicted that with Havana under United States control the unwholesome conditions which have permitted this yearly visitation of yellow fever will be done away with and the city made as safe from June to November as it is from November to June.

It has been pointed out by authorities, and former experience in our own country has shown it to be a fact, that old wharves with their rotting timbers, unpaved streets, collections of decaying vegetable matter, and lack of proper sewerage all contribute to epidemic outbreak. Such sanitary defects are abundant in Cuba's capital, and it will become our duty at no distant day to fortify the city by modern hygienic improvements for the benefit of humanity at large.

MAKING GAME OF THE MEDICAL JOURNALS.

The proprietor of a much-advertised patent medicine, who is himself thoroughly familiar with the art of advertising in all its branches, has been having lots of fun with some of our esteemed contemporaries. Being of a jovial disposition, he has mercifully not kept the joke to himself, but has shared it freely with the doctors in the land, somewhat to the disgruntlement, we fear, of the fish who too greedily snapped at his bait, to find it nothing but flannel.

This amusing gentleman wrote out a flamboyant advertisement of his patent remedy, which remedy, he said, was on sale "in many grocery stores, restaurants, saloons, and other places where it is not usual to find a medicine." A copy of this was sent to each of one hundred and nineteen medical journals in the United States and Canada, and accompanying it was a letter inquiring whether the advertisement would be acceptable as written; if not, what changes would be necessary; and if accepted, what the price would be for one insertion or for a full year. Sixty-six of the papers addressed probably suspected something or else regarded the inquiry as an impertinence, and sent no reply whatever. Of those that did vouchsafe an answer, twenty-three rejected the proposition, some with scorn, others with regret. The remaining thirty yielded to the tempter, most of them unconditionally, a few asking for more or less immaterial alteration in the wording of parts of the advertisement. All the replies, both affirmative and negative, are published, and it is humiliating to note the avidity with which the bait was gulped down—bob, hook, and sinker—by some editors who boast of the huge circulation and lofty moral tone of their journals. Of the fourteen journals approached in Chicago, the headquarters of the American Medical Association and supposed to be sodden with ethics and high principles, six accepted the patent-medicine advertisement, one of these being the *Journal of the American Medical Association*. On the other hand, in New York City, the alleged hotbed of heterodoxy and lair of unethical brigands, thirty journals were tempted and only six fell, and of these six only *Pediatrics*, *The Medical Examiner*, and *The Polyclinic* have any standing as legitimate medical journals.

Many other interesting comparisons might be made in a study of this entertaining pamphlet. For example, not a single homœopathic or eclectic journal, so far as we can see from a careful reading of the list, lowered its flag for the sake of the patent-medicine man's money; the sinners were "regulars" all. Philadelphia also made an honorable showing, only one periodical of any importance having yielded to temptation. Fortunately the youngest of the local journals was not approached, only papers with a circulation of one thousand and upward being considered worthy game; we say fortunately, for this serio-comic weekly, while always protesting it would ne'er consent, has usually consented, and so it is possible the editor would have fallen in line with the other gold seekers had the opportunity been offered him, stipulating perhaps for the insertion of a few orthographical peculiarities in the ad. The advertising manager of a house which publishes one journal in Philadelphia and another in New York accepted the advertisement, subject to the approval of the editors, which he thought might be fully counted upon; he was disappointed, however, for both journals are in the list of those which refused to sacrifice principles for cash.

The ingenious gentleman who got up this trial of virtue deserves our thanks, for he has contributed largely to the mirth of medical journalists, and has suggested a subject pregnant with amicable discussion for the Denver meeting of the American Medical Editors' Association.

PATHOLOGY OF FEVER.

Later-day science has for its mascot the guinea-pig. Like the little lamb of Mary, everywhere that science goes the guinea-pig trots in her footsteps, and but few great pathological investigations have taken place for many years without the aid of this prolific little beast.

Some of the later experiments with the guinea-pig and his allied tribe of experimental animals lie along

the lines of research in the histological changes in the nervous system due to increase of temperature. Nearly a year ago Goldscheider and Flatau experimented on this subject by placing animals in an incubator and exposed them to the influence of various grades of temperature for varying intervals of time. More recently a pupil of theirs, Dr. Moxter, *Fortschritte der Medicin*, vol. xvi., 1898, pp. 121 *et seq.*, varied the experiments somewhat by placing the animals under conditions of increased temperature after exposing the brain by trephining. After the wounds had healed and all signs of reaction had disappeared, the animals were exposed to the action of the heat and the effects on the cells of the nervous system studied after the newer histological methods. They found changes in the chromophylic bodies of the ganglion cells in the anterior horns of the spinal cord, more marked in the cervical region, these changes varying with the intensity of the heat and the length of the time of exposure. Moxter finds "that after twenty-two hours, with a temperature between 40.5° C. (104.9° F.) and 41.5° C. (106.7° F.), there was a marked loss of the chromophylic substances in the ganglion cells of the anterior horns; following intermittent changes in the temperature, which ran from 38° C. (100.4° F.) to 41.3° C. (104.3° F.), no changes were found, and twenty-three hours' exposure to temperatures ranging from 39.2° C. (102.5° F.) to 40.7° C. (105.2° F.) produced no changes." These results in great part substantiate the researches of Goldscheider and Flatau, though Ewing has shown that the subject is difficult of interpretation and that we are not yet in a position to assert what is and what is not within the range of the normal.

Following Moxter's experimental work, Goldscheider and Flatau give the results of an examination of two cases of fever in tetanus and scarlatina. In the case of tetanus the temperature rose to 39.9° C. (102.8° F.), and ranged from normal to 39.9° C. for three days. The chromophylic granules were destroyed in the ganglion cells of the anterior horns, and all traces of their arrangement were lost. In the case of scarlet fever, in which the temperature rose to 40.9° C. (105.2° F.), much the same kind of change was found. Thus the experimental work on animals (Goldscheider, Flatau, Moxter, and Ewing) has been duplicated in conditions of high temperature; in pneumonia by Dejerine, and in tetanus and scarlet fever as set forth in the present communication.

The American Laryngological Association.—The twentieth annual meeting of this society will be held in New York City, borough of Brooklyn, on May 16, 17, and 18, 1898. The sessions will be held in the hall of the Long Island Historical Society, corner of Pierrepont and Clinton Streets. The president of the association is Dr. Thomas R. French; the secretary and treasurer Dr. Henry L. Swain, of New Haven, Conn. The programme contains thirty-one titles of papers in addition to the president's address. The annual dinner of the association will take place on Tuesday, May 17th.

News of the Week.

Appeal of the Red Cross.—At a meeting of the American National Red Cross Relief Committee, held at the rooms of the Chamber of Commerce, it was decided to issue the following appeal: "The American National Red Cross Relief Committee, acting under the auspices of the American National Red Cross, has for its object the collection of funds for providing medicine and surgical attendance, nursing, medical supplies, food, clothing, and such necessary assistance as may be required by the American National Red Cross upon call of the United States government, in order to unify all endeavors to that end during the present war. Under provisions of the Geneva conference, from which every national Red Cross society derives its authority, the American National Red Cross is directed to provide such relief as may be required by all, without recognition of friend or foe, who may suffer from the calamities incidental to war, pestilence, or famine. The Red Cross here and throughout the civilized world, by a wide and varied experience in recent wars, recognizing by international treaty the sacred obligations of helpfulness for the suffering, wherever found, has so perfected its organization that it becomes the recognized and legitimate channel for contributions from all classes of individuals and every variety of auxiliary association. For the purpose of properly systematizing the benevolent impulses of the general public and of giving proper direction for efficient Red Cross work, the committee solicits the co-operation of individuals and auxiliary associations throughout the country, confident that through such means the various funds and articles collected can most safely and most directly reach their ultimate destination." Mr. Levi P. Morton, Bishop Henry C. Potter, Messrs. Alexander E. Orr and William T. Wardwell, and Drs. George F. Shrady and A. Monae Lesser were appointed a committee with instructions to place the matter before the United States government at an early date, and also to invite its co-operation.

Railroad Fare to Denver.—The announcement is made that the rates to Denver and return for the meeting of the American Medical Association will be one full fare plus $2. The cost of a round-trip ticket from New York will therefore be $48.50 or $50.50, according to the road selected from New York to Chicago or St. Louis. This provides for the railroad ticket only, the sleeping-car rates and charges for meals being unchanged.

American National Red Cross.—Dr. A. Monae Lesser has been appointed surgeon-in-chief of the American National Red Cross, and Mrs. Bettina-Hofka Lesser sister-in-chief of that organization.

Dr. Aristides Agramonte, of this city, assistant bacteriologist of the health department, has been appointed acting assistant surgeon in the army. He is temporarily on duty at the Army Medical Museum in Washington, but will, it is supposed, be sent later to serve with the army of occupation in Cuba.

Disease at Dawson City.—The latest advices from the Klondike state that pneumonia and scurvy prevail to a very alarming extent at Dawson City, large numbers of the inhabitants being ill and many having died. It was expected that when the snow had disappeared, by the 1st of May, the danger to public health would be increased, owing to the wretched sanitary condition of the town.

Women Nurses Not Wanted by the Army.—It is officially announced that no women will be accepted as nurses for Cuba. Surgeon-General Sternberg is reported as saying: "We have a hospital corps of trained men, whose duty it is to go with the troops in the field, and if we need additional assistance in Cuba or on the Gulf coast I shall accept only those who are immune from yellow fever, from having had the disease, or passed through one or more epidemics. In case hospitals are established farther north, we may require the help of trained women nurses. Many have volunteered. All applications are placed on file for future reference. A large number of patriotic women, who have had no special training as nurses, have also volunteered. While I fully appreciate their motives, there is no probability that their services can be utilized."

The Spitting-Nuisance.—A committee of the Woman's Health Protective Association recently interviewed the president of the board of health in regard to the prevention of spitting in the street cars. Mr. Murphy said that the board would be glad to co-operate with the ladies in the work, and showed them a letter from the president of the Metropolitan Street Railway Company, in which it was said that arrangements have been made to place a framed copy of the ordinance against spitting in every car belonging to the system. The Woman's Health Protective Association also proposes to inaugurate the card system, by which each conductor will be supplied with printed cards, calling attention to the board of health ordinance, one of which he shall quietly hand to any person discovered violating the ordinance.

A Suspicious Fever at Key West.—It is reported that there have been two cases resembling yellow fever among the crew of one of the prizes recently captured by the Cuban blockading fleet. No fear is felt that the disease will be carried into the town, but it is thought that some isolated place will be designated for the detention of the captured vessels, where they will not be in close proximity to the other ships in Key West harbor.

The University Medical College.—Only four of the present medical faculty will, it is said, be with the university next year—the dean, Dr. Egbert Le Fevre, adjunct professor of medicine; Dr. H. G. Piffard, professor of dermatology; Dr. E. D. Fisher, professor of nervous diseases; and Dr. Cornelius Coakley, professor of laryngology and lecturer on physiology. All the other members of the faculty have been appointed to the faculty of the new medical department of Cornell University. Four lay members of the council of the university have also resigned, on the ground that the university violated the conditions under which the property of the medical school was ceded to it. The protest of the directors of the medical school to the council of the university was in part as follows: "The control of the medical department has been taken by you from the medical committee; the expenses and salaries of the officers of the medical department have been fixed without their consent, and without consultation with the medical committee; the personnel of the medical committee has been changed by you, and one of the gentlemen selected by our faculty to guard and protect their interests has been dropped from your council in direct opposition to the wishes of those who represent our faculty and in direct violation of the understanding." On these grounds the medical school asked for the restoration of its property. The president of the council appointed a committee to investigate, and this committee reported that the university ought not to retain property obtained on certain conditions which had not been fulfilled. The majority of the council refused to accept this report of its committee, however; hence the resignations from the council and from the medical faculty.

The Plague in China.—Much alarm has been caused by the spread of the bubonic plague at Hong Kong, Swatow, Canton, and Macao. Each of these cities except Canton has established a quarantine against the other plague cities. Hong Kong has cabled to Bombay for a supply of Haffkine's prophylactic lymph. Official reports place the new cases at Hong Kong at from twenty to thirty a day. Smallpox as well as plague prevails at Canton and Macao.

The Society for the Prevention of Cruelty to Children.—The State board of charities has instituted judicial proceedings to establish its authority over the Society for the Prevention of Cruelty to Children in this city. The attorney-general has obtained an order requiring the society to show cause before the supreme court in New York why it should not submit its affairs to the supervision of the State board. The constitution of 1894 directs the legislature to provide "for a State board of charities, which shall visit and inspect all institutions, whether State, county, municipal, incorporated, or not incorporated, which are of a charitable, eleemosynary, correctional, or reformatory character," excepting only such institutions as the constitution makes subject to the visitation and inspection of the State commission in lunacy or the State commission of prisons.

The San Francisco Polyclinic was recently the recipient of a present of $5,000 from Mrs. Hearst, the money to be used to pay the mortgage on the property of the school.

The International Congress of Hygiene and Demography.—The attendance at this congress in Madrid was about two thousand. Of this number thirteen hundred and fifty were Spaniards, one hundred and ten French, fifty English, and as many Germans. There was but one member from Portugal, but the United States had two, and possibly more.

Society Reports.

CONGRESS OF THE GERMAN SOCIETY OF SURGERY.

Held at Berlin, April 13, 14, 15, and 16, 1898.

(Special Report for the MEDICAL RECORD.)

Friday, April 15th—Third Day.

Œsophagoscope.—Dr. Kelling, of Dresden, exhibited and demonstrated his œsophagoscope. He described it as consisting of a jointed metal tube covered with rubber. It was introduced curved, and then by a mechanical arrangement was straightened. The patient was to be on his back with his head hanging over the edge of the table. The tube was illuminated by a small electric light attached to the outer end.

Empyema and its Operations.—Professor Jordan, of Heidelberg, described his method of operating on an old empyema cavity. He recommended a combination of the Schede and Delorme procedures. In other words, he believed in removing the whole of the chest wall covering the cavity (Schede) and the breaking up and loosening of the contracted pleura (Delorme). Of twenty-three patients so treated in the Heidelberg Clinic nine were completely cured and capable of doing their former work; six were almost cured, a very small fistula only remaining; they, too, were capable of working; four died, and several were still under treatment. Of four cases in which the operation was done on tuberculous patients three were fatal. He insisted that the extent of the resection depended on the size of the cavity, that the whole wall should be resected. Small resections, he said, were worse than useless. He presented two cured patients. One was a boy, aged twelve years, in whom five years ago he resected five ribs; since then there had been an entire and complete regeneration of the ribs. In the second patient through the cicatricial tissue the heart could be seen beating closing in the former cavity. Physiological studies as to the heart's action, he said, were being made in this case.

Dr. Perthes, of Leipsic, exhibited an instrument for the treatment of empyema and pneumothorax. It consisted of a water-vacuum pump, by means of which the cavity was aspirated. He claimed to have cured a number of patients by this procedure.

Dr. Karewski, of Berlin, declared that there was very little danger in operating after adhesions had formed around the empyema. In a series of eighteen cases of his, only one was fatal. He presented two patients, one of whom had been operated on, the other not, much to the advantage of the former, both in appearance and health. He predicted a great future for operations on the lung itself. In the general discussion that followed, cases were referred to in which five, six, seven, eight, and even nine ribs had been resected in their entire or almost their entire length, with cure.

Dr. Gerulanos, of Greifswald, described a case and exhibited the specimens of a tumor, suspected to be sarcoma, in a child in whom he resected the whole side of the thorax. The patient lived twenty-two hours after the operation.

Dr. Joachimsthal, of Berlin, exhibited a case of double-side hernia of the lungs. The tumors extended above the clavicle, causing a marked prominence on each side.

Professor König said he did not believe the case was one of hernia of the lungs, that the tumors were more likely myxomatous tissue. He added that he had seen but one case of a hernia of the lung in that situation.

Surgery of the Liver and the Bile Passages.—Dr. Petersen, of Heidelberg, said that in his clinic the staff had operated with only six deaths in one hundred and sixty-two cases, among which there were six cases in which a biliary calculus was found, though other conditions had been diagnosed, such as floating kidney, cyst of gall duct, etc. He said, in relation to peritonitis resulting from effusion of bile, that if the bile was not previously infected it would not of itself cause peritonitis. This was a point which an operator could not determine either by the clinical symptoms or by an examination of the bile itself during operation. He stated that in several cases it had been necessary to resect portions of the liver, and it was found that the best means of stopping hemorrhage was hot air.

Professor Poppert, of Giessen, described his method of cholecystotomy. Having opened the gall bladder, he put in a rubber tube and held it in place by a Nélaton stitch. He stitched it in the same way to the abdominal wound, and closed the latter up to the tube. He said it took but a short time for adhesions to form so firmly that when the tube came out it would leave behind it a permanent fistulous tract. He reported a total of fifty-seven cholecystotomies done in this way.

Professor Heidenhain, of Worms, exhibited a gall bladder with a carcinoma, the size of a cherry stone. It had been removed by operation, and the liver and surrounding structures had seemed perfectly healthy. The patient died in a very short time, of carcinoma of the liver. He concluded that after operation for carcinoma, no matter how small the tumor, one could not be sure that there were not other foci.

Dr. Haasler, of Halle, described the technique of operation for choledochotomy. In the Halle Clinic they had eighteen times removed stones from the ductus choledochus. He said they had always stitched the wound in the duct, and when no stone could be felt in the gall bladder they did not open. For opening the abdomen he advocated the incision parallel to the ribs.

A Hot-Air Hæmostat.—Dr. Holländer, of Berlin, reported a case of complete extirpation of the gall bladder with resection of the liver for carcinoma, which he had done several weeks ago. He announced that the patient was well and entirely over the effects of the operation. He exhibited the device for supplying hot air, by means of which he had stopped the hemorrhage. He recommended it strongly for such cases, and also for stopping hemorrhage elsewhere, as in the uterus. The device consisted of a small Bunsen burner, with two arms extending up from it. These arms supported a small coil of tube, so that they would come just within the flame. A long tube extended from this coil and terminated in a point. On the other side the coil was connected by rubber tubing to two bulbs, like those of a Paquelin cautery.

The Results of Serum Therapy in Diphtheria.—Professor Krönlein, of Zurich, said that the most evident thing he could show as to the good effect of the serum was his statistics. He explained that since the serum was introduced, toward the end of the year 1894, he had used it in every case of diphtheria that came into the hospital. Since bacteriology had become a science, every case was examined bacteriologically, and was not pronounced diphtheria unless the bacilli were found. In case any one questioned his statistics on account of their extending back to before the days of bacteriology, he wished to say that he believed that the large majority of the cases of diphtheria, even to within two or three out of a hundred, could absolutely be diagnosed clinically. The statistics were those of his clinic, from 1880–98. Total number of diphtheria cases before introduction of

serum, 1,336; total number of deaths, 534; percentage of deaths, 39. Total number of cases after introduction of serum, 437; total number of deaths, 55; percentage of deaths, 12. Number of cases operated on (tracheotomy, etc.) before serum, 662; number of deaths, 438; percentage of deaths, 66. Number of cases operated on after introduction of serum, 101; number of deaths, 36; percentage of deaths, 35. Number of cases without operation before serum, 674; number of deaths, 96; percentage of deaths, 14. Number of cases without operation after introduction of serum, 336; number of deaths, 19; percentage of deaths, 5. He also exhibited a diagram showing the relative mortality at different ages before and after the introduction of the serum. It showed the same results in favor of the serum. He called attention to several points: 1, the general decrease in mortality; 2, the decrease in mortality of the cases operated on; 3, the decrease in the number of cases in which operation was necessary. They thought they noticed, the speaker said, a decided improvement in the majority of cases after the first injection. This improvement consisted in (1) a fall in the temperature; (2) the membrane became looser and began at once to be thrown off; (3) there was a decrease in the glandular swellings; (4) there was no further extension of the process. For the canton of Zurich, the speaker continued, the statistics were even more remarkable. In the canton there were one hundred and sixty thousand inhabitants. These statistics represented the number of cases of diphtheria and the percentage of deaths for every year since 1880.

Year.	No. of Cases.	Deaths, Per cent.	Year.	No. of Cases.	Deaths, Per. cent.
1880	1,000	24	1890	700	18
1881	1,500	21	1891	900	16
1882	1,900	15	1892	1,300	15
1883	1,400	12	1893	1,400	21
1884	1,500	16	1894	1,450	19
1885	900	14.5	1895	900	12
1886	800	12.5	1896	1,000	7½
1887	700	14	1897	1,500	6
1888	675	15	(Number of cases given in even hundreds.)		
1889	1,100	18			

A reduction in mortality, the speaker insisted, of from between twelve and twenty per cent. to six per cent.

Saturday, April 16th—Fourth Day.

Inhuman Bullets.—Professor Bruns, of Tübingen, exhibited a number of parts of dead bodies on which he had tried the effect of what he called "inhuman bullets." These, he said, were made by filing down ordinary bullets on stones. The effect of such a bullet was terrible, as he could show by his specimens and as was proven in actual battle. He showed that when it struck a bone such a bullet splintered it from top to bottom or took pieces out of it twenty or thirty times its own size. When it struck only soft parts it carried away immense pieces, often so large that if it struck, for instance, the calf of the leg, amputation would be necessary. The injury was so extensive that in no case could one imagine it was caused by a bullet. Therefore he believed that he was justified in naming them inhuman.

Shot Wounds of the Brain.—Professor Tillmanns, of Greifswald, detailed some experiments done on animals. They demonstrated that the track of the bullet was not smooth, but showed tearings of the brain substance irregularly. The gray substance was usually more torn than the white, from which he concluded that the latter was firmer, more compact.

Treatment of Lupus with Roentgen Rays and Concentrated Light.—Dr. Kümmel, of Hamburg, spoke on this subject. The method had succeeded only in selected cases, and the indications and contra-indications were not yet soundly established. He exhibited two patients almost cured, whom he expected a continuance of the procedure to cure completely.

A Few Observations on Brain Surgery.—Dr. Doyen, of Paris, took this for his theme and exhibited a whole series of new instruments. He stated his results in a number of cases of hemicraniectomy. He reported a number of idiots and microcephalics whose improvement after the operation was beyond cavil. The first patient on whom he did the operation, a girl idiot with Graves' disease, showed a marked change at once. Four days after the operation the exophthalmos and goitre had disappeared. He mentioned several epileptics markedly improved. One had had no attack in five months, another in six months. In two cases of Jacksonian epilepsy in which he found no lesion, he excised the epileptogenic centre. The first case had proved successful; the second operation had been done but a short time ago and the patient was still under observation. He claimed excellent results in one case of a large subcortical tubercle and in the opening of several deep-lying abscesses, which would not have been discovered but for the extensive resection. In a case of meningitis occipitalis the patient was apparently moribund when the operation was done. There was complete recovery. He closed with the statement that he was now endeavoring to reach tumors at the base of the brain.

Empyema of the Frontal Sinus.—Professsor Barth, of Dantzic, described his method of operating, and said that he trephined the antrum and enlarged the opening toward the nose. Then he reclosed at once the outside wound. He claimed good results, both cosmetically and in regard to the ultimate cure of the disease process. He detailed one case in which in this way a cure resulted in fourteen days.

Purulent Otitis Media.—Dr. Ludewig, of Hamburg, spoke on this subject, and exhibited many ossicles removed for this condition. He said that the radical treatment required their removal, and it would be good practice to do it oftener.

Cancer of the Face.—Dr. Grosse, of Halle, gave statistics of twenty-four cases, some very extensive, in which operation was done; sixteen patients completely recovered. He exhibited a woman operated on in 1893. A mole which she had always had began to increase rapidly at the age of forty. When she came to the clinic the disease was widespread. They were obliged to remove the superior maxillary and malar bones, the eye, the zygoma, the ear, and to chisel away the petrous portion of the temporal bone as deep as the tympanum. The patient made a complete recovery, and, considering the extent of the operation, the cosmetic effect was excellent.

Temporary Resection of the Alveolar Process.—Professor Partsch, of Breslau, described this operation and exhibited a cured patient. The procedure consisted in chiselling off the anterior portion and turning it back on a flap of soft tissues.

Resection of the Œsophagus.—Professor Garré, of Rostock, spoke of three cases in which he resected portions of the upper part. In one he was obliged to remove the posterior wall of the larynx, but left the mucous membrane of the same, and with it made an anterior wall for the new œsophagus.

Dr. Rehn, of Frankfort-on-Main, thought there was no reason why one could not operate on the thoracic part of the œsophagus as well. He had in one case successfully entered on the right side from behind, but the patient died.

Syphilitic Goitre.—Dr. Küttner, of Tübingen, described two cases which had been diagnosed as malignant thyroid tumor and had been operated on. He could find nothing in the literature similar and so took occasion to report them. The first case was that of a

woman thirty-nine years old, who had given birth to a dead child shortly before the growth began. It increased in size rapidly and was thought to be malignant. It was extirpated, and on microscopical examination there were discovered only centres of caseation surrounded by round cells, epithelioid cells, and giant cells. The diagnosis now rested between tuberculosis and syphilis. No tubercle bacilli could be found and syphilis was diagnosed. Six months later typical tertiary lesions appeared, which were cured by specific treatment, confirming the diagnosis. The second case was in a man, twenty-seven years old, who had had syphilis a few years before. A right-side thyroid swelling developed, growing rapidly. Cancer was diagnosed and an operation was performed. The operation was particularly difficult and could not be completed. The tumor grew again in a very short time; but from an examination of microscopical sections the speaker had by this time diagnosed syphilis, because he found, in addition to what had been seen in the other case, markedly thickened blood-vessels. Under iodide of potassium and mercury the recurrence had disappeared and the man was now completely well. The speaker said that ordinary gummata of the thyroid, which were not uncommon, led to no enlargement of the gland and gave no symptoms, though there were other cases in which syphilis of the organ led to serious disturbance, such as myxœdema, etc.

Traumatic Separation of the Epiphyseal Head of the Femur and its Relation to Coxa Vara; Skiagraphic Errors.—Dr. Sprengel, of Brunswick, described two cases in adults, and showed the specimen in which coxitis had been diagnosed from the clinical symptoms and Roentgen-ray photographs. Post mortem, however, they were found to have been instances of separation of the head of the femur.

Dr. Hofmeister, of Tübingen, exhibited a number of skiagraphs of a single normal pelvis, in which could be demonstrated a dozen abnormal conditions. There were fractures of the pelvis, a variety of pathological conditions of the bones, variations in size of the pelvic canal, and every sort of angle of the neck of the femur, from 90° to 180°. He said that the different appearances had been produced by moving the light or moving the patient, or both.

Treatment of Arthritis by Means of Heat.—Dr. Wilms, of Leipsic, described an apparatus of tubes through which hot water was conducted, by means of which the application of heat to inflamed joints could be regulated.

Dr. Krause, of Altona, employed for the same purpose with good results hot air.

Employment of Steam as a Hæmostatic.—Professor Dührssen, of Berlin, said that he had found steam very efficient in controlling uterine hemorrhage, especially excessive menstruation. The injection must not be continued for too long a time or injurious consequences might follow. He demonstrated his apparatus for carrying out the procedure, and a protective device to prevent injury to the neck of the uterus.

At the close of the congress Professor Garré, of Rostock, in the name of the society thanked President Trendelenburg for the satisfactory way the congress had been conducted.

Professor Hahn, of Berlin, was elected president for the ensuing year.

Bunion.—Never operate during an attack of acute inflammation; always treat the deformity and never operate on the bursa, for it will take care of itself after its cause is removed. The exceptions to this rule are the removal of callosities from the bursa when they exist, and the incision of the bursæ when they suppurate.—Parker Syms.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 5, 1898.

Edward G. Janeway, M.D., President.

The Climatic Treatment of Tuberculosis.—Dr. S. Edwin Solly, of Colorado Springs, read a paper on this subject. He said that the climatic treatment of tuberculosis seemed to him not to have been rooted in science and fact in the past, but had hung in mid-air. The basis of all climatic therapeutics was hygiene, and the only way one could judge of any particular climate was by the meteorological data—a point frequently overlooked entirely by the physician. A large amount of the desired data had been accumulated, and if properly digested would be found in condition for assimilation. It was possible now to estimate the value of a particular climate without relying upon personal statements. Much valuable information had been secured by the United States Signal Service. In the choice of a climate the disease was only one part of the problem, the individual being an exceedingly important factor.

The Soil more Important than the Germ.—Although tuberculosis was known and admitted to be a germ disease, it seemed to him that physicians in cities were inclined at the present time to go too far in their statements regarding the infectiousness of tuberculosis. It was known from laboratory experiments that the tubercle bacillus could be inoculated into animals, and that they would die as a result of this; but it seemed to him very doubtful if the majority of cases of tuberculosis arose from without, except in the sense that the germ was received into the body. The development of the disease seemed to be the result chiefly of the germ, which must be almost omnipresent, falling upon favorable soil. This was often observed in children in whom the disease first gained a foothold as a sequel of traumatism. In the West and in many sparsely settled countries typhoid fever appeared to arise *de novo*, and not from direct infection. His theory was that the typhoid bacillus was very widely disseminated, but did not produce its characteristic phenomena except under certain favorable conditions, such as after excessive muscular exercise, possibly followed by a chill. In the few cases of tuberculosis developing in Colorado the question of infection did not seem to be a prominent factor. Another element which must be taken into account was the virulence of the germs. Dr. E. L. Trudeau had for many years been experimenting with a view to making the tubercle bacilli less virulent.

Classes of Tuberculous Patients.—Looking upon the soil as the chief factor in the production of tuberculosis, it was evidently important to inquire very carefully into the mode of origin of the disease. In one class of cases the physique seems to be such as to make the person very susceptible to tuberculous infection; in another class there was a preceding catarrhal condition of the mucous membranes; in still another class tuberculosis seemed to be engrafted upon recurring attacks of catarrhal pneumonia. These three classes should be taken into consideration in selecting the climate for the individual case. As the climatic treatment was rooted in hygiene, it could be said in a certain sense that this treatment could be begun at home. For example, if the poor and ignorant were impressed with the importance and necessity of having an abundance of fresh air and sunshine in the living-rooms, more could be accomplished than by fussing over disinfectants and laying a great deal of stress upon the communicability of the disease. Therefore, before sending a tuberculous patient away from home, one should consider carefully what had been the hygienic surroundings previously.

"A Stitch in Time."—A very significant fact developed by an analysis of his last one hundred cases was that in fully fifty per cent. of the cases coming to him any properly educated physician should have been able to recognize the existence of pulmonary tuberculosis very much earlier than had been done. In these neglected cases the average delay in sending the patient to a proper climate had been two years. It needed hardly to be added that the proportion of recoveries was very much greater in the other cases in which the disease had been recognized early, and the patient given at an early stage the benefit of a proper climate. If the people could be educated up to the idea that tuberculosis in its early stages was a curable disease, it would be very much easier to manage these cases, and according to the best-known principles.

Common Mistakes.—Undue haste in making a change of climate was also responsible for much unnecessary worry, and frequently for a miscarriage of otherwise well-laid plans. Tuberculous patients often left home hurriedly, urged on by the first fright engendered by a knowledge of the true nature of their malady, and in doing so they failed to take time to make the necessary arrangements as regarded their business and family, which alone could insure the requisite peace of mind. A very common mistake among consumptives was regarding the amount of exercise to be taken. This observation applied with special force to persons in high altitudes. The sanatorium treatment of consumption was undoubtedly the ideal one, and one great reason for this was to be found in this very matter of the control of the patient, and in the avoidance of imprudences as to exercise, diet, etc. In catarrhal cases a large field for preventive measures was to be found in the treatment of diseased conditions of the nasal passages. A climate to be suitable for consumptives must be dry, warm, and have a sufficient altitude. The pneumonic cases were particularly susceptible to sudden changes in the weather; they required a moderate elevation and a moderately damp and warm climate.

The Blood Changes in High Altitudes.—Experiments on animals by Paul Reinert had plainly shown that diminished barometric pressure caused marked changes in the red blood corpuscles and in the hæmoglobin. The blood could take up oxygen only under a certain pressure, and hence the quantity of oxygen introduced in a definite quantity of air was less in high altitudes than at the sea level. To offset this nature increased the number of red blood corpuscles, and after some days the hæmoglobin also was increased. Thus, a person residing at an elevation of six thousand feet above the sea would ordinarily have about one million more red blood corpuscles in a cubic millimetre than one at the sea level, and about sixteen per cent. more hæmoglobin. These changes began immediately, within the first twenty-four hours after a high altitude was reached, and were fairly complete in four weeks. Until this condition had resulted, the person would breathe more rapidly, and the heart action would be stronger and more rapid, true compensatory hypertrophy of the heart taking place. When the person went down again to the sea level this compensation disappeared, and the former condition was restored. Persons who were ill and anæmic gained in red blood corpuscles and hæmoglobin more rapidly, and on their return to the sea level held what they had gained—up to the normal amount at the sea level. From some experiments now being made it would seem that high altitudes tended to increase the bactericidal power of the blood. Cases of neurasthenia, in which the nervous irritability was dependent upon weakness, were generally benefited by a sojourn in high altitudes. The observations of Mercier and others showed that the blood count was easily affected by slight indiscretions, and was quickly lowered by too much exercise.

Effect of Different Climates.—Dr. Solly said that an analysis he had made of seventy-seven hundred and ninety-five cases of pulmonary tuberculosis showed that of those remaining at home, in England, twenty-five per cent. were cured: of those who went to reside in the islands of the sea, the percentage of recoveries was fifty-two; of those who went to the coast or to the lowlands it was fifty-five; while of those who took up their abode in high altitudes seventy-five per cent. were cured. This analysis also showed that dryness was an important factor. The very large percentage of recoveries in high altitudes he explained by the marked blood changes which occurred there. The change to a high altitude was especially beneficial to those exhibiting marked anæmia. Those who had weak heart, who were old or prematurely old, those who had arterial sclerosis, or those in whom a large area of lung was involved, did badly in high altitudes. It was not necessarily wrong to send patients with extensive cavities to a high altitude, or those threatened with hæmoptysis, but a high altitude was bad for very active or imprudent persons, because by slight indiscretions they could do themselves so much harm.

The Weaklings of the Flock.—Dr. Irwin H. Hance, of Lakewood, said that sanatorium physicians could more fully appreciate the points made in the paper than physicians in ordinary practice. Much could be done for the children of tuberculous patients—the weaklings of the flock—without sending them to any distant locality. An important duty of the physician was to secure proper hygienic surroundings, and especially to insist upon their spending most of their time in the open air, and sleeping in well-ventilated rooms at night. A matter often overlooked in these children, and with disastrous results, was the condition of the tonsils and pharyngeal vault. Hypertrophied tonsils and adenoid growths in the pharynx, if not removed, favored the development of tuberculosis.

The Danger of Exercise.—It was not an unusual experience to find athletes and those of admirable muscular development becoming the victims of pulmonary tuberculosis, probably owing to indiscretions and excessive muscular exertion. The disastrous effects of ill-judged exercise could hardly be too much insisted upon. It was a safe rule to insist that tuberculous patients should not exercise.

Early Diagnosis by the X-Rays.—Dr. J. E. Stubbert, of Liberty, said that it was absolutely necessary to diagnose tuberculosis in the very early stage if much benefit was to be derived from the climatic treatment. There could be no doubt that the *x*-rays rendered valuable assistance in certain cases, particularly in young subjects. For example, a young man had been brought to him suffering from tuberculosis of the larynx and having a slight infiltration at the right apex. The man had four brothers, all of them apparently healthy, but on close inquiry it was evident that the family was susceptible to the disease. These brothers were subjected to the *x*-rays without the father being questioned regarding their condition. The *x*-rays showed slight infiltration in three of them, and in two of these the presence of the disease was detected later by ordinary physical examination.

Pure Air More Important than High Altitude.—We should be careful not to send tuberculous patients to high altitudes unless they evidently had great vitality, and it could be fairly assumed that they did not possess great vitality if the family history was decidedly phthisical. He had found that the percentage of good results in pulmonary tuberculosis was almost as great in low as in high altitudes. Again, he had seen excellent results in the tropics, in damp forests,

and on the sea. He was inclined to believe that, after all, the most important factor was pure air. Patients who have any functional disorder of the heart should not be sent to a high altitude, and all the pneumonic patients did badly. He had records of a number of cases of tuberculosis contracted in a high altitude, and which did not do well until removed to a low altitude.

Rule Regarding Exercise.—His rule about exercise was if the temperature was not above 99.5 F. to allow moderate exercise. Those who were able to exercise seemed to improve more rapidly than others.

Tuberculous Joint Disease Does Best on the Coast.—Dr. S. A. Knopf said he could not accept the statement made in the paper, that in cities the development of tuberculosis depends more upon bad soil than on contagion, for certainly any one familiar with tenement-house life must admit that contagion, irrespective of the soil, was a powerful etiological factor. He was of the opinion that tuberculosis of the joints did better along the seacoast, and hence he could not accept the statement that a climate which was suitable for pulmonary tuberculosis was appropriate for all other forms of tuberculosis.

Favors the Rest Treatment.—As to the question of exercise for consumptives, he felt very strongly that rest was most important, and that even the most moderate exercise should not be allowed for some time after the arrival of such a patient at a new place. Under rest alone the temperature would fall.

The Prognosis.—The prognosis in pulmonary tuberculosis was extremely difficult, and depended upon many and complex factors. A valuable hint as to the prognosis was contained in the saying of one of his former teachers, that "the patient died of his character."

Change Rather than Climate Does Good.—Dr. J. H. Girdner said that an idea which still had a firm hold on the laity was that the air of certain localities had an intrinsic virtue and was capable of curing tuberculosis. He had spent the first twenty years of his life near Asheville, and could assert positively that the percentage of tuberculosis among the natives of that region was fully as great as on Manhattan Island. This should not be if there was any intrinsic virtue in that climate or elevation. Patients sent there from other places often improved, but it was not to the climate so much as to the change of life and scene that this was due. His father, who practised medicine in that region, had been in the habit of sending cases of pulmonary tuberculosis away from there to the sea or to other parts, and these patients would improve while away from their native place. About a year ago, the speaker said, he had experimented with tuberculin among the cattle in the mountains of that region, and had found them to be tuberculous almost without exception. As the people lived largely on milk, butter, and cheese, he had been led to think that the milk was an important factor in the production of tuberculosis among the inhabitants. Additional factors were the general lack of attention to hygiene and the custom of inter-marrying.

Favors Exercise for Consumptives.—Dr. Wolff Freudenthal said that tuberculosis was now prevalent in some of the very best herds in Massachusetts, because the cattle had been badly housed during the winter. He favored giving the patient as much exercise as possible, providing there was no elevation of temperature. If there was a possibility of recovery at all, it would be under exercise. The frequent occurrence of tuberculosis in the cervical glands in children seemed to him a confirmation of the theory that pulmonary tuberculosis originated in the upper air passages, and especially in the retropharynx.

Dr. Solly closed the discussion. He said that the question of exercise seemed to be a matter largely of common sense, and a broad guiding line would be found in the temperature and pulse. The patient should be very gradually accustomed to taking exercise. He did not believe in the rest cure for consumptives any more than he believed in total abstinence for every one. Golf playing was one of the best forms of exercise for consumptives. The endeavor should be to get the patient out of the rest cure as soon as possible. The argument against climate founded on observations in the neighborhood of Asheville hardly applied, because the elevation there was only about twenty-five hundred feet, and the advantages of elevation were not usually apparent until higher altitudes were reached. The salubrity of Liberty and the Adirondacks depended very largely upon the sunny slopes of those regions, which gave a maximum of sunshine and most excellent drainage.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirteenth Annual Meeting, Held in Washington, D. C., May 3, 4, and 5, 1898.

Tuesday, May 3d—First Day.

The Presidential Address was delivered by the president, Dr. F. C. Shattuck, of Boston (see page 649).

Congenital Stenosis of the Pylorus in Infants was the title of a paper then read by Dr. S. J. Meltzer, of New York. After a brief review of the literature, he said that he had had four cases of this trouble. It seemed to be now becoming more common or else the cases were more easily recognized. After the first case recorded was recognized there was a long interval, and then many cases seemed to have been observed within a short period. In five cases the diagnosis was made and operation was done, and the lives of the patients were saved. Several physicians had been able to make a diagnosis by having seen cases post mortem. The speaker then referred to a case in which he had made the diagnosis, and showed a very beautiful specimen from a child which during life had vomited occasionally and had had great trouble with its nursing and feeding. Free hydrochloric acid was present in the matter vomited. It took its food greedily. By the use of diluted carbolic acid and bicarbonate of sodium the food was held for some time, but gradually the child was again afflicted with vomiting and then succumbed. He found a stenosis of the pylorus and atony and dilatation of the stomach. The child was forty-four days old when it was operated on by Dr. Willy Meyer. He did a gastro-enterostomy and used the Murphy button. The child lived a very short time after this. The speaker then explained the gradual change which took place in the stomach in this trouble, and discussed briefly the diagnosis and the treatment.

Dr. I. Adler, of New York, also showed some specimens of this same malformation and explained his method of treatment. He did not use the Murphy button. In his cases he had found hypertrophy of the circular fibres, but the longitudinal fibres were but slightly altered.

Dr. A. Jacobi, of New York, referred to a case which he had seen very recently, and mentioned other cases. He said that the contraction of both ends of the stomach was probably the cause of this hypertrophy.

Dr. Meltzer, in conclusion, said that he had mentioned the hypertrophy of the muscles in relating his case.

Gastric Carcinoma Associated with Hyperchlorhydria.—Dr. D. D. Stewart, of Philadelphia, related a number of cases of this trouble and spoke especially of the position of the cancer. He said that a positive

diagnosis was very difficult, especially when the cancer included an ulcer in which a certain amount of gastric fluid persisted, even after the symptoms of this disease had been marked for a long time. He related at length a case of unusual interest, in which the operation was made before the patient came under Dr. Stewart's care, which showed that there was apparently a diffuse carcinoma, the stomach being too much involved for a gastro-enterostomy. One of the omental glands was found to be cancerous. In spite of all this the patient recovered from the operation and apparently became well. The symptoms returned later on and Dr. Keene was consulted. The case would have been considered one of chronic ulcer had not the gland been examined. The patient died after the second operation. The autopsy showed a very large cancerous ulcer with a thickened cancerous pylorus. He had sent specimens to different pathologists for examination and had received a variety of opinions, some saying it was tuberculous and some asserting it was cancerous. The latter opinion was the correct one.

Dr. William H. Welch, of Baltimore, in discussing the diagnosis of Dr. Stewart's case, said that he had examined two nodules, one from the lymphatic glands and the other from the omentum, and the diagnosis seemed clear. It surprised him that it was diagnosed as tuberculous by another physician in Philadelphia. He supposed that the follicles must have been mistaken for a tubercle. Notwithstanding this discrepancy, the fatal end came. There was no difficulty in making the diagnosis, and the clinical results must make physicians sceptical as to the value of microscopic examinations. The apparent recovery was interesting. Multiple cancer was explained by its being due to implantation rather than to metastasis. It was due perhaps to contact. The specimen seen at the autopsy was in such a stage of decomposition that it was difficult to make out, but it was clearly an adenoma. There was a diffuse thickening of the exterior wall of the stomach.

Dr. W. W. Johnston said that the improvement in these cases was so marked that there must be some explanation, and it might be in part that the gastric catarrh which accompanied these troubles was improved by the treatment. A patient with cancer of this kind got better under treatment, and often went back to solid food and gained flesh, but in the end died. This went to show that, while our treatment was not curative, it was beneficial.

Dr. F. P. Kinnicutt, of New York, said it was remarkable that even without a change of diet cases improved. In one instance he noticed a gain of twenty pounds and the man was getting better.

Dr. E. G. Janeway, of New York, referred to two cases of gastric carcinoma in which there was a gain of forty pounds after the stomach was washed out and proper treatment given, but four months later the patient declined, had severe pains, returned to liquid diet, and in three months died. The usual diagnostic rule of urea excretion failed in this case; the temperature for eight months was from 101° to 102° F. In one case there was also a change in urea secretion, and the patient, who was in bed, could always take food better when sitting up than when lying down—the position probably removing the cancer from contact with the food.

Dr. Charles G. Stockton, of Buffalo, said that it was remarkable that in some cases of gastro-enterostomy successfully performed there was improvement. There might have been food stagnation with loss of weight, for if the stagnation ceased from whatever cause the patient would gain in weight.

Dr. A. H. Smith, of New York, referred to a case of his in which there was hydrochloric acid, but no lactic acid. The patient was very miserable and could not get out of bed, but on treatment he rapidly grew better and acted as assistant in the ward. He returned to his home and for five months had fairly good health, but later on grew worse and died. Evidently he had a cancer.

Dr. D. D. Stewart said in conclusion that his patient was exceptional, in that he did not have to go to bed, and he gained sixty-five pounds.

Gastric Syphilis with the Report of a Case of Perforating Syphilitic Ulcer of the Stomach.—Dr. Simon Flexner, of Baltimore, had collected the histories of cases reported by Chiari. In two hundred and forty-three cases of syphilis which came to autopsy, two were evidently cases of ulcer of the stomach due to this trouble. Some cases of this disease, he said, were hereditary and some were acquired. In a case he referred to the history dated from 1892; the death occurred in 1896. The patient had ascites and œdema of the lower extremities and the scrotum. The ascites was tapped, grew less, and the fluid was inconsiderable. Death came suddenly after the man had eaten a hearty meal. Just before death there were great abdominal pain and tympanites. The autopsy revealed a sero-fibrinous peritonitis. There was a perforation in the base of the stomach with several organisms in the peritoneal contents, among which were the bacillus aerogenes capsulatus and the colon bacillus. The liver contained a large gummatous mass. The diagnosis was based on microscopical examination.

Some Observations of Cardiac Syphilis.—Dr. I. Adler, of New York, spoke of the various forms of syphilis in the heart, such as gumma, endocarditis, etc. The anatomical diagnosis was not infrequently doubtful. In the hearts of four babies a few months old he had found signs of syphilis. It was hard to make this trouble out, for to the naked eye the heart was apparently normal. In his cases he hardened the heart tissue in formalin and stained and examined it. In two specimens there were no signs of syphilis; in the other two characteristic lesions were found. In one infant who was two years old one small patch was found in the internal coat and also a slight infiltration. The other child died at the age of three and one-half years, from what was apparently catarrh, and to the naked eye there were no signs of disease in the heart. He thought that the blood-vessels were often the primary seat of the disease and the muscles were attacked later. In many cases the disease might be arrested early if a diagnosis was made, but as a rule the disease was advanced too far when the clinical symptoms appeared. There were really few symptoms sufficiently diagnostic to the naked eye to distinguish it from other troubles. Often traces of syphilis could be found in other organs than the heart. He thought it necessary to make methodical examinations of each patient and to suspect syphilis in every case of heart disease; it was necessary also to give the iodides and mercury, as well as digitalis and other such drugs, and if the disease was not syphilis no harm would have been done.

Error in Diagnosis between Chronic Syphilitic Fever and Tuberculosis.—Dr. E. G. Janeway, of New York, briefly reported a number of cases in which this error was made. One case was that of a young man who had been sent to a sanatorium for consumption. He continued to grow worse, came to him, and an examination revealed syphilis. No tuberculous symptoms could be found, and hepatitis had been the cause of his ill-health. The patient promptly recovered under treatment. In another case there were fever, sweating, and pain in the side; the patient also had been advised to go to the country on account of supposed tuberculosis of the right lung, but a later examination showed two ribs to be diseased and a small sinus was apparent. Antisyphilitic treatment removed this trouble. The specialist might be able to

recognize these cases, but it must be remembered that the majority of them fell into the hands of the general practitioner. In obscure cases of apparently tuberculous miliary sepsis, syphilis should always be borne in mind as the possible cause.

Dr I. E. Atkinson, of Baltimore, said nothing showed more clearly the lack of accurate attention on the part of the medical profession than this very frequent presence of syphilis, complicating all sorts of obscure conditions. It should be looked for. This was especially true of the class of cases referred to. The disease might simulate continued fever, although fever might be remittent in character and thus cause suspicion. He referred to a sailor from Calcutta, who had an enlarged liver and a severe cough, but no tubercle bacilli could be found. Albumin and casts were both present. The man denied having syphilis; hepatic abscess was suspected, and he was aspirated several times, without result. The plasmodium of malaria was looked for, but not found. The right testicle began to enlarge. Iodide of potassium was prescribed, and in three or four days he had no fever. He recovered entirely. It was in the late cases that the fever was apt to be obscure.

Nephritis of Malarial Origin.—Dr. William S. Thayer, of Baltimore, read a paper with this title, in which he referred to the frequency of albuminuria in malarial fever. In looking over the statistics and in his own cases he had found that a large proportion of cases of malarial fever had albuminuria and casts, but principally the cases of æstivo-autumnal fever. Of seven hundred and fifty-eight cases of malarial fever there were albuminuria in three hundred and twenty-one and casts in one hundred and twenty-one. Albumin was present in nearly one-half the cases. He had had nineteen cases of acute nephritis, of malarial origin. He had found in general that his own statistics agreed largely with others he had collected, except in some few cases. In scarlet fever there was, of course, a certain number of cases of albuminuria and casts; also in diphtheria and typhoid fever. Albumin was probably present in about one-half the cases of scarlet fever, and malaria seemed to be the cause of more cases than was generally supposed, but not so often as in yellow fever, and for this reason we could not place too great reliance on the presence of albumin in yellow fever. In one hundred and fifty-two cases of malaria, there were fifty-two cases of nephritis; seven were tertian, ten æstivo-autumnal, and three of varied type. There were thirteen recoveries and four deaths. Nine cases were doubtful. The speaker also gave statistics of the age, sex, and color in these cases. He thought there was a possible etiological relation between nephritis and malarial infection.

Dr. F. Forchheimer, of Cincinnati, wished to corroborate the statement as to nephritis in æstivo-autumnal fever. There were many such cases in Cincinnati. The kidney rarely escaped, and he had found the majority of cases to occur in children. He had also found in a certain number of cases of nephritis the presence of a pigment, which probably came from the blood. The urine was light above and dark below. There were blood pigment and casts. In most of the cases the pigment was reddish-brown in color. The cause was described to be the plasmodium, but he had studied a number of these cases and had found the pigment in connection with malarial fever. He showed a specimen from a child, sixteen months old. He had no suggestions to make. He had made no complete chemical analysis, but thought the pigment might be melanin.

Dr. William Osler, of Baltimore, in referring to the interesting cases of Dr. Thayer, said that the importance of albumin in the differentiation of yellow fever from malaria lay in the fact that in yellow fever the albumin was found early, in the first twenty-four or forty-eight hours. And this was a strong point. It was interesting to note that in the hospital there had been no single case of malarial hæmaturia which could be attributed to the use of quinine, and many physicians in the South hesitated to use quinine on account of this complication.

Dr. Jacobi asked if the findings of Dr. Thayer were the same for every year. A number of observers had said that they found no albumin for a number of years, and then in a large number of cases it was found. He had seen many cases, but none had had albuminuria.

Dr. I. E. Atkinson had for years felt convinced that malaria was an important factor in nephritis, and it had been pretty constantly found in every outbreak of malarial fever—more so than was usually granted. One of the difficulties in the way of decision was to know whether the nephritis was due to the malaria or the malaria to the nephritis. Another point to note was whether in localities where mortality statistics were kept it was found that kidney complications were more common than where malarial fever did not exist In Maryland as a whole there had been no vital statistics until the present time, but in Baltimore the records were carefully kept.

Dr. Thayer, in answer to Dr. Forchheimer, said that he had seen very few cases in children; that only recently had there been a children's ward in the Johns Hopkins Hospital; but he had had an interesting case referred to him by Dr. Northrup. As to the pigment referred to, he had never seen it; it was quite unlike anything he had found in the blood and its occurrence was extremely interesting. He had not had a case in which quinine was of influence. Dr. Rampoldi, of Rome, the speaker said, wrote that he had never seen a case of quinine hæmoglobinuria recorded from the Roman Campagna. He had noticed that there were epidemics in different years. Of twenty-six cases he had observed sixteen occurred in 1896, and last year there were very few.

Acute Interstitial Nephritis.—Dr. W. T. Councilman, of Boston, read this paper. He described the disease as being an acute non-suppurative inflammation of the kidney, characterized by cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent upon, degeneration of the epithelium. The interstitial lesion was marked by the presence of cells similar to those described by Unna as plasma cells. These were due to emigration of the parent cells from blood-vessels and their subsequent proliferation. They were formed in other organs, chiefly in the spleen and bone marrow, from lymphoid cells, and were carried to the kidneys by the blood. Accumulations of plasma and lymphoid cells could be found in the blood-vessels of the kidney without interstitial lesions. Such cases of acute interstitial nephritis were frequently found in the infectious diseases of children, notably in diphtheria and scarlet fever, but they might be found under other conditions.

A Case of Myxœdema and Albumosuria; Treatment with Thyroid Extracts.—Dr. R. H. Fitz, of Boston, reported the case for the purpose of calling special attention to the occurrence in myxœdema of albumosuria. It was therefore desirable, in examination of the urine in myxœdema, to bear the above fact in mind, since albuminuria was relatively frequent and albumose might easily be mistaken for albumin, unless the customary tests with heat and nitric acid were duly controlled. The communication had an additional interest, in showing that, despite temporary improvement under the use of thyroid extract, this remedy was not infallible in myxœdema. The addition of nitric acid to the urine caused the precipitation of albumose, which heat dissipated, and the application

of cold caused it to return. This was an interesting test. He showed several illustrations.

Dr. V. C. Vaughan said that these were remarkably interesting and rare cases, and were rarely recorded. The presence of a small amount of albumose was very common; some authorities claimed that normally it was always present in small amounts. So far as he knew this was probably true, but the occurrence of large amounts as noted was quite rare.

Dr. Fitz said, in conclusion, that his paper contained references to these illustrations of small amounts, and he had mentioned the work of Bence Jones. There had been seven cases recorded in Germany and Holland. He thought that often these were mistaken for cases of albuminuria, and that they were really more common than was supposed.

Wednesday, May 4th—Second Day.

Bacillus Icteroides (Sanarelli) and Bacillus X (Sternberg).—Surgeon-General George M. Sternberg, U. S. A., referred to his paper on this subject in which he replied to Sanarelli's article in the *Annales de l'Institut Pasteur* and in the *Centralblatt für Bakteriologie*. The latter's paper copied in part his work and had done him great injustice. He regretted that it was necessary to correct written statements made by Sanarelli. He quoted what Sanarelli alleged him to have said and then stated what he really did say. His work had not been taken up anew, but was a continuance of what he had begun some time ago. His bacillus X was found in the contents of the intestines in some cases, but Sanarelli did not find any bacillus there. It was very bad teaching to say that the organism could not be found in the contents of the intestines, for if it was not there there would be no necessity for disinfecting the clothing, etc. The alvine discharges of the sick were very dangerous. Sternberg had not made any clinical notes, because he had not had the time; but he had had great experience, while Sanarelli had had no experience in the disease. Dr. Sternberg said that he had had the yellow fever in 1875, and he had seen a great many cases. It had been his practice always to make an autopsy and collect material for bacteriological examination, and while in Havana he had personally made forty-three autopsies in four months, always from two to five hours after death. This was against the law in Havana, but the authorities had connived at it and had assisted him greatly in the work. He had obtained the cultures from Dr. Roux, in Paris, of Sanarelli's icteroid bacillus, and there was a difference between this organism and his bacillus. The organism of Sternberg, the bacillus X, was motile in Havana but here it was not, although the flagella could be seen stained. He had passed the culture through guinea-pigs and had found that the bacilli became motile again. If neither organism was the specific organism of yellow fever, then one was just as good as the other. Sanarelli had experimented on man, but the speaker had not yet done that.

Dr. A. C. Abbott, of Philadelphia, asked, for comparison's sake, if Dr. Sternberg had had a parallel experience with the colon bacillus and others of that kind. He felt personally that the organisms were identical. The colon bacillus was sometimes virulent and sometimes not.

Dr. V. C. Vaughan, of Ann Arbor, said that Dr. Novy had begun work on Sanarelli's germ a year ago; he had obtained no proof that Sanarelli's germ was the cause of yellow fever. The latter's experiments on man were simply ridiculous. He did not know what was the matter with the men he used in the hospital, and when he said that he observed marked effects it was not clear what he meant. Marked effects could be obtained from other germs. Sanarelli's germ was not affected by freezing and thawing; his observations of agglutination were made in a test tube, but it was absurd to study agglutination in that way. The blood of the speaker's students in the university had caused agglutination, and they were healthy men.

Dr. William Osler, of Baltimore, said that much stress had been laid on the work done by Dr. Archinard in the recent epidemic that seemed most favorable to the claims made for the Sanarelli bacillus. The experiments of Sanarelli on man were not ridiculous; that was not the proper word. Almost every dose of medicine was an experiment. It was not known, for instance, what effect iodide of potassium would have in certain conditions. It was only an experiment. Experiments in medicine should be recognized. Sanarelli's experiment on men was not ridiculous; it was criminal, however, unless he had obtained the men's sanction.

Dr. Sternberg said that comparative experiments with the colon bacillus were needed. This might be a fæcal disease. The typhoid bacillus might be an offshoot of the colon bacillus. Yellow fever had a toxin and the tetanus bacillus was also hard to find. Investigators were not ready to accept Archinard's work, because it was so much better than Sanarelli claimed.

Comparative Studies of Bovine and of Human Tubercle Bacilli.—Dr. Theobald Smith, of Boston, read a paper based upon the results of cultures of tubercle bacilli from human sputum and from cattle.

Bacterial Infection.—Drs. S. J. Meltzer and T. M. Cheesman, of New York, read a paper entitled "An Experimental Study of the Direct Inoculation of the Spleen with Micro-Organisms, and a Contribution to our Knowledge of the Importance of the Lesion of a Body Tissue for the Settlement and Development of Bacteria within it." It was the result of a long series of experiments, in which organisms were injected into the spleen, and after a few hours autopsies were made which showed that the organisms had disappeared from the spleen and were found in other organs of the body, while cultures from the spleen were usually sterile. Were these bacteria destroyed in the spleen or were they carried out? The tying of the portal vein did not prevent the spleen from being sterile. When certain parts of the spleen were ligated they were found to contain bacteria, and when the bactericidal power of the blood was exhausted the bacteria multiplied very rapidly.

Dr. Welch said that this demonstration was very welcome, but hardly seemed conclusive evidence that bactericidal substances were of less frequent occurrence in the spleen than elsewhere. The ligation of the spleen caused the appearance of the bacilli. It was likely that the bacteria in the ligated areas were analogous to the bacteria found in cauterized areas. They were there because the spleen was damaged.

Dr. A. Jacobi, of New York, in referring to these statements, said that when the tissues were normal bacterial invasion was not found. Diphtheria organisms would not grow in any part of a healthy throat, with the exception of the tonsil. Tuberculosis would settle in the ends of the bones, because there circulation was slower. The spleen changed in the course of the day. After meals it was larger and there were many organisms in it. A person had chronic malaria and was given a large dose of quinine, and there came a severe chill because the quinine contracted the spleen and it was squeezed like a sponge; the chill was the response. He had noticed the same thing in giving ergot in malaria.

Acute Leukæmia.—Dr. M. H. Fussell, described two cases of his own. Fifty-six cases had been collected in all, and statistics showed that the disease was most common between the tenth and thirtieth years.

Five patients were over forty year sold: thirty-three were males and twelve were females. He gave a careful clinical history of his own cases and showed the specimens under the microscope.

Two Attacks of Temporary Hemiplegia.—Dr. E. G. Janeway, of New York, reported this case. The patient was a man forty-one years old, and right handed. He had pleurisy on the left side. A year and a half later it was necessary to take out one of his ribs on account of a sinus. This was irrigated with peroxide of hydrogen. Some time later while using this material he became unconscious. His right arm and leg and one of his feet were paralyzed, but he recovered in twenty-five minutes: he got well in every other way, but was very much frightened. Three days after this, under similar circumstances he had another attack. He lost power in his neck this time and his head dropped over. The attack lasted twenty-five minutes. The sinus eventually closed. Physical signs were few and not easily found. His respiration was somewhat more free on the affected side. Large râles were found to follow coughing.

Uric-Acid Diathesis.—Dr. Victor C. Vaughan, of Ann Arbor, Mich., said that uric acid was eliminated when the nuclein was broken up. It used to be thought to be the product of imperfect oxidation. The formation of uric acid was the measure of nuclein metabolism. He asked what were the chemical constituents of the nuclein cells. No two cells of nuclein had definite composition. Some light had been thrown on this subject by the study of lymphocytes. Nucleinic acid was the most important constituent of nuclein, and this contained much phosphorus. He cited the work done by Lilienfeld, and went very thoroughly into the chemistry of nucleinic acid. Nuclein disintegration was necessary for the production of nucleinic acid. The nucleus was the important part of the cells and that which made life potentially continuous. Some cells existed only for the formation of other cells. Thus, the nucleus, having formed the red blood corpuscles, disappeared. The leucocytes were the quantitative or varying source of uric acid in the body. There might be hypoleucocytosis with an increase or an elimination of the alloxuria, but there was no increase of uric acid. It was not claimed that the xanthin base was broken up and so yielded uric acid.

Dr. William H. Draper, of New York, reviewed the older ideas on the subject of uric-acid diathesis, and spoke first of gout, referring to Garrod's work. He said that uric acid might be in the blood when there was no gout, and there might be gout with no apparent presence of uric acid in the blood. Inflammatory rheumatism was now considered a specific disease, perhaps of bacterial origin. The joint structures were especially vulnerable. Men seemed to be inclined to gout and women to rheuematism. Th disease was hereditary. Uric acid did not seem to be the cause of gout. Rheumatism was hereditary, but the tendency to it might be aroused by errors in food and diet. Gout was especially liable to affect persons who had a tendency to it; also such diseases as tonsillitis, pharyngitis, and urticaria were complications, and these might be brought on by eating strawberries, apples, drinking wine, beer, etc. Pruritus was another symptom often observed in cases of weakened constitution. Skin diseases often occurred in diabetes. How did the salicylates act? They probably had a paralyzing effect on the metabolism. Clinical observation alone was necessary to solve these problems, but the clinical observer of the present day must be better prepared than was the practitioner of twenty-five years ago. The instruction in chemistry was better now in the schools than it used to be. If there were fewer drug-stores and better laboratories for helping physicians in making diagnosis, the results of treatment would be much better.

Dr. James Tyson, of Philadelphia, said that the uric-acid diathesis was hard to define. It was generally a weakened condition showing scant, highly colored urine, which deposited a copious sediment of uric acid mixed with urates and oxalates. Later on there were some albumin and casts. This did not tell what the uric-acid diathesis was, but it gave certain points from which we might infer its presence. The tendency of the uric-acid diathesis might lead further on to uric-acid gravel and calculus, with consequent irritation of the urinary tract, perhaps with cystitis and nephritis. It might mean even more than this. It might cause depression of spirits. The pulse was low and there was marked lithæmia. Measures should be used to eliminate and get rid of this latter. Migraine might be another symptom of the uric-acid diathesis. The speaker related a case of migraine which was cured by large quantities of Célestine Vichy. Eye strain and other reflex causes might be active factors. Again, the uric-acid diathesis might be the cause of endometritis, degeneration of the blood cells, and hypertrophy of the left ventricle: it might cause vertigo in the most distressing forms. Uric acid and its congeners played an important rôle. It was not known whether it produced glycosuria, asthma, bronchitis, and other such conditions, or whether it caused rheumatism and gout. The speaker did not think that uric acid had anything to do with rheumatism. Gout usually attacked well-to-do persons past forty who had lived high. Muscular rheumatism usually attacked younger persons. Haig thought that rheumatism could be cured by making the blood alkaline. The term rheumatic gout was not a happy one, and rheumatic arthritis also was an expression that should not be kept up. Another form of gout was found among the poor; it was not hereditary and it was not like the other form of gout. Mixed diet was necessary. Persons so affected should be well fed and they usually got well; food was better than medicine. Rheumatoid arthritis or deforming arthritis was a very distressing form of the disease. It occurred between the ages of twenty and thirty and might be caused by grief or anxiety. It was doubtful whether epilepsy could come from uric acid. Uric-acid sediments had been found in diabetes, but with this the resemblance of the latter to the uric-acid diathesis ceased. The specific gravity was high, but this was usually from the sugar. Excess of uric acid could be caused by overstudy. It was not so common in this country as abroad. In a certain number of cases of supposed diabetes tests had shown uric acid to be the trouble.

Dr. C. A. Herter, of New York, said that his observations in the last seven years were that the best test for uric acid was that of Ludwig and Salkowski, which method of determining uric acid he had used almost exclusively. He had observed disturbance of the digestive organs, disease of the kidney, epilepsy, migraine, etc. He generally used the urine of twenty-four hours, as a smaller quantity was not sufficient. It was also different at different times of the day. Many patients excreted more uric acid than had been mentioned, some even one to fifteen of urea. There was nothing characteristic in the symptoms of these patients. In many cases the increase of uric acid seemed to be related to the disturbance of digestion, in others it was chronic and continued from month to month. The condition most usually met with was some form of disturbance of digestion. This might account for the great majority of cases in which the uric acid was more marked. It was very marked in pneumonia after resolution. Diet would increase it still further, as would also alcohol. It might be present in very large quantities. Excessive fatigue and

overstudy might cause it. The mere deposition of uric acid was no indication of increase of uric acid in the body. He did not believe uric acid had any connection with uræmia. It was not found in the blood in this condition.

Dr. A. H. Smith, of New York, said that this discussion would lead to error in that it was sought to make reactions in the test tube correspond to reactions in the human body. What Dr. Herter had said illustrated this very well. Glycosuria might be due to this acid or it might not. He appreciated this chemical research; it should not, however, be allowed to mislead as to these affections of the human body. In his early days he used to think that uric acid was affected by heat. His experience was the same as Dr. Draper's. The speaker referred to a bad case of gout, with spontaneous amputation. The man took all sorts of drugs, such as colchicum, etc., but finally recovered on diet alone. Some cases would result favorably on diet but would get worse by starving. He had found in attempting to reduce flesh in obesity that sometimes the rheumatism disappeared. He spoke of a patient of his own, who had inhaled considerable quantities of oxygen and had then excreted less uric acid.

———

Thursday, May 5th—Third Day.

Antitoxin Treatment of Pneumonia.—Dr. A. H. Smith, of New York, read a paper with this title. He thought that pneumonia infection was from a continuously changing set of microbes; while old ones were dying out new ones were growing up and infecting the body. There must be an antitoxin which had its share in the resolution of the disease, and thus began its action from the beginning of an attack. He had made a culture broth of these organisms, peptonized with ammonium sulphate, and had injected it into rabbits and given them immunity. He had then killed the animals and injected the blood into other rabbits, and so on until all were immune. Blood from a man ill with pneumonia killed a rabbit at once. The speaker then reviewed the subject of pneumotoxin and antipneumotoxin. Toxins, he said, were not always of the same strength, and might be either worthless or extremely dangerous. Washburn had been endeavoring to produce a reliable toxin, and the New York health board was also trying the same thing.

Dr. William H. Welch, of Baltimore, said that he had been experimenting with these toxins and had published his results. The work of Klemperer had been disproved. He had repeated all of the latter's experiments and had found it very difficult to demonstrate a toxin in the blood of those who had recovered from pneumonia. He had injected a stronger culture into rabbits and it did not kill them. It was not true that antitoxin appeared in the blood of a person in the crisis of pneumonia; on the contrary, the toxin was stronger at that time. Thus one and one-half cubic centimetres of the blood of a person convalescing from pneumonia three or four days after the crisis was rapidly fatal in small amount to rabbits. By the method of Washburn no one could tell what the result would be, but if one could judge by analogy the injection of living cultures was not likely to lead to the formation of an antitoxin.

Dr. V. C. Vaughan, of Ann Arbor, Mich., said he had read a paper on this subject in 1894 at the International Congress of Hygiene, at Buda-Pest, and in the recent abstract of this work by Lewy and Richter his paper had been included. He agreed entirely with Dr. Welch that the pneumotoxin was preventive only to a certain degree and this only temporarily so, but the difficulty was to know what amount of antitoxin to use; the result, too, depended on the leucocytosis that existed at the time. There was no promise at the present time of making the pneumotoxin of therapeutical effect. The action was germicidal and was not antitoxic in character.

Dr. Charles G. Stockton, of Buffalo, said there was a feeling that a degree of leucocytosis had something to do with the decline of pneumonia, and the safety of a given patient depended on this degree. He showed the blood and temperature charts of a case which he had had in a child, eight years old, that had a recurrence of lobar pneumonia; it had had three distinct attacks in six weeks. There was no expectoration, so the sputum could not be examined; but the physical signs were classically distinct and there was evidence of intoxication. There was a complete absence of the usual symptoms and the physical signs were those of catarrhal pneumonia. The point of interest was that the blood was counted in these attacks, and just at the end of each attack it was found to have very few of these white cells; but at the end of the last attack there was a greater degree of lymphocytosis. There was nothing peculiar about the blood in this case; fifty-six days after the end of the last attack the blood was normal. This case was unusual. It might fairly have this interpretation, in the absence of the normal number of leucocytes, especially of the multinuclear cells. The child did not gain the immunity which an ordinary attack would give, and this might be a certain amount of proof that only in the last attack did the blood reach the normal immunity.

Dr. William S. Thayer, of Baltimore, said that in his experience the great difference was in the behavior of the leucocytes. During the crisis it depended on the clearing up of the lung rather than on the temperature. When the lung consolidation was retarded the leucocytosis lasted longer. In some cases there was a fall at the time of the crisis.

Bacteriology of Cheese.—Drs. V. C. Vaughan and Julian T. McClymonds presented a communication on this subject. They had been interested in food poisoning and cheese poisoning for a long time, and had long wished to study cheese. Last October they began this work, and had examined bacteriologically the cheese from sixty-eight manufacturers. Each cheese examined was treated in about the same way. They bought a pound or more of cheese, made a note of its physical properties, its appearance, its color, how old it was, and then broke it through the centre and with a sterilized platinum needle took up a small quantity and made cultures of it. They first made eight cultures of each cheese in different ways: two cultures aerobic at 38° C., two aerobic at room temperature; two anaerobic at 38° C., two anaerobic at room temperature. But they found that it was not worth while to make so many cultures, as they all grew about alike, and they then used only anaerobic cultures at 38° C. About fifty of these cheeses (not poisonous) were ordinary American cheeses. In every one of them the writers found a germ which was pathogenic to white mice, guinea-pigs, rabbits, and white rats. They carried these germs through many cultures and thought the organism found was always of the colon group. It was an ordinary non-motile organism, giving the indol reaction, reddening litmus paper, and not producing any soluble toxin. Cultures of beef tea were injected into a rabbit and did not kill it for forty-eight hours. Five were not killed for seventy-two hours, and one lived ninety-six hours. It was thus evident that large quantities would not kill, showing that in liquid cultures every inoculation decreased the virulence of the germs. Boiling did not alter the germ, for the dead germ was just as toxic as the living one. In no sample of old ripe cheese did they find any pathogenic germs. In imitations of Limburger they found an organism, but in imported Roquefort,

Camembert, and other such cheeses no germ was found. They discovered a group of germs which were rapidly peptonizing.

Serum Treatment of Chronic Infective Endocarditis.—Dr. W. H. Thomson, of New York, reported a case of this kind occurring in a man, thirty-six years old, who was affected for seven months with definitely periodical daily attacks of an intermittent fever, ushered in by chilliness or by pronounced rigors. At other times he would have attacks of severe periodical neuralgias in the forehead and in the left hypochondrium without rise of temperature. No recent cardiac lesion could be demonstrated, on account of a loud murmur due to congenital malformation of the right heart obscuring other heart sounds. He never showed ecchymoses or other local lesion which would point to infective endocarditis, but an examination of the blood drawn from the median vein showed the presence in it of numerous streptococci pyogenes. He was then treated with injections of antistreptococcus serum, with no benefit, his rigors increasing in severity and death finally supervening with symptoms of acute nephritis and suppression.

Serum Treatment of Tuberculosis.—A paper prepared by Drs. E. L. Trudeau and E. R. Baldwin, of Saranac Lake, entitled "Studies of Antitoxins for Tuberculosis," was then read. The paper described the attempts of the writers to produce an antitoxic and curative serum for tuberculosis, and to test on animals the efficacy of serums already produced by others. The results of the experiments showed that with one or two exceptions, in which the serum had a slight degree of antitoxic power, the tests were negative. In none of them could any germicidal or curative influence be demonstrated. The authors, however, had a full appreciation of the uncertainty of correct conclusions from these tests. They also felt that, in the light of recent contributions to our knowledge of the mechanism of immunity and antitoxic production in the body, the outlook for an efficient antitoxin was by no means a hopeless one.

Officers.—The following officers were elected for the ensuing year: *President*, G. Baumgarten; *Vice-President*, E. G. Janeway; *Recorder*, I. Minis Hays; *Secretary*, Henry Hun; *Treasurer*, W. W. Johnston; *Councillor*, J. C. Wilson; *Representative on Executive Committee of Congress of American Physicians and Surgeons*, William Osler; *Alternate Representative*, C. F. Folsom.

The following were elected to membership: Honorary member—William M. Polk, of New York. Active members—J. W. Brannan, C. A. Herter, B. Sachs, of New York; F. A. Packard, J. K. Mitchell, S. Solis-Cohen, A. Stengel, of Philadelphia; H. F. Vickery, C. F. Withington, F. B. Mallory, F. Pfaff, of Boston; N. S. Davis, Jr., J. N. Herrick, of Chicago; F. F. Wesbrook, of Minneapolis; A. D. Blackader, of Montreal.

Iodoform-Calomel in the Treatment of Wounds.—This is especially efficacious in the treatment of tuberculous wounds and in tracheotomies necessitated by diphtheritic membranes. A chemical analysis of the compound produced shows that the action of the wound secretions forms a biniodide of mercury, which is a powerful antiseptic. Before it is applied, the wound must be thoroughly dried; this can be accomplished by packing the wound with sterilized gauze and letting it remain for a few minutes. In tracheotomies the powder is strewn over the inner surface of the trachea, between the diseased area above and the wound and healthy tissues below. In two hundred cases there were from forty-five to sixty per cent. of recoveries.—Sprengel.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENTARY MEASURES OF MEDICAL INTEREST—THE NEW BRITISH PHARMACOPŒIA—INEBRIETY AND THE ARMY—MEDICAL AND DENTAL REGISTERS—REMOVED FROM THE REGISTER—"DEATH BY MISADVENTURE" OF A DOCTOR—SURGEON-GENERAL CLEGHORN—DEATHS OF DRS. W. G. SHEPHERD AND J. PAUL.

London, April 22, 1898.

The measures of medical interest in the house of commons have made very little progress. The London University bill is postponed until the Irish local government bill is out of committee, and that may prevent its passing this session. The vaccination bill occupied the commons for three and one-half hours on Tuesday, and then the debate was adjourned. When it is resumed there is likely to be more opposition; it is hardly likely to come on for another three weeks and may have, therefore, a hard struggle against time. Sir W. Foster supported it, but he thought that, as repeated penalties have failed to enforce vaccination, it is not worth while to keep up agitation by retaining two penalties. He would therefore allow a statutory declaration of conscientious objection to suffice for exemption. Sir William Priestley also spoke, and rather demurred to remitting fines. If people would not protect their own children by vaccination, he thought they might perhaps be made to contribute to isolation hospitals. Further the administration of the law should be taken from the guardians, who have grossly neglected their duties, and intrusted to the sanitary authorities.

The midwives registration bill seems to be doomed, as the day for its second reading will almost certainly be taken up for the principal government measure. This need not be regretted, but we shall probably be worried with discussions about the midwives question for another year or more.

Advance copies of the new British Pharmacopœia have been distributed to journals and a few individuals, and the work will probably be on sale in another fortnight. There is naturally a considerable number of changes necessitated by the lapse of thirteen years, and some which, if not necessary, will prove acceptable. For instance, the index is much more elaborate, and gives, besides the names of the drugs, their doses and chief preparations, with the strength of these latter. This will be found very useful for reference, and will often save the trouble of referring to the body of the book. It will also be useful to students if examiners continue to frame their questions on the old lines. Another change is the increase of matter thrown into the form of appendices, of which there are no less than eleven. This permits the grouping of many important facts. Thus in one the chemical tests for impurities are described once for all, instead of being repeated under each of the substances. This plan saves space in the body of the book, and will facilitate the study of the subject; in another we have the composition of various lozenge cases described; in another alternative preparations sanctioned for use in India and the colonies.

It was expected that the new British Pharmacopœia would adopt the metric system, but compulsion is not in favor just now, and prescribers are left to their own option in this matter. They are further considerately told that the drugs may be dispensed when so ordered in non-official forms, such as capsules, cachets, granules, and the like. This permission not being re-

quired, I suppose its insertion may be due to the pharmaceutists on the committee, or a wish to recognize the merits of some of the manufacturers. There are other indications of the influence of pharmacy, and a few critics will perhaps suggest that the subsidiary art has gained the upper hand.

There is a long list of omissions, no less than one hundred and eighty-eight, while the additions number eighty. In each of these classes the preparations as well as the drugs are of course counted. Comparatively few new drugs are admitted, preparations and compounds going to make up the number. Among them I notice two preparations of thyroid, bismuth salicylate, hyoscine hydrobromide, hyoscyamine sulphate, morphine tartrate, salol, strychnine hydrochlorate, naphthol, and terebene. Preparations of various kinds make up the eighty admissions.

In the long list of articles omitted, extracts, decoctions, infusions, plasters, poultices, and ointments account for fifty, and eleven tinctures are also expunged. Concentrated infusions and decoctions have been in use for a generation, but only now obtain admittance to the pharmacopœia. This, of course, makes up for some of the fresh infusions and decoctions admitted, and is perhaps a further concession to the convenience of dispensers. Although eleven tinctures are omitted, others have been added, so that they now number sixty-seven against the seventy of the last edition. The strength of forty is altered, chiefly with a view of making the doses of these fluids more uniform. In some cases changes of strength are very important; *e.g.*, tincture of strophanthus is reduced to half, to bring the dose to correspond with that of tincture of digitalis. The strength of the hypodermic injections also varies considerably. You will see, therefore, that for a time we shall have to be on the *qui vive* in prescribing. Changes of name are easily assimilated, but changes of strength of important remedies make attention imperative. Consequently there are already some mild remonstrances among the seniors, but there is a general disposition to look kindly on the labors of the committee which has produced the new British Pharmacopœia. When it gets into use, criticism will have fair play. Hitherto the British Pharmacopœia has been behind that of the United States. Whether this edition will lessen the difference it is too soon to say.

The annual meeting of the Society for the Study of Inebriety was held on the 14th inst., when Dr. Norman Kerr took the chair, and Lady Elizabeth Biddulph, who has lately returned from Egypt, stated that the battle of Atbara was fought without alcohol. Her ladyship said some cheap German spirit had been smuggled in, but the sirdar, on this being discovered, poured it out on the sand before the paraded troops.

Speaking of this, I may note that on Wednesday the Duke of Connaught took the chair of the Army Temperance Association, which he declared had largely diminished the number of inebriates in the ranks, and he gave an emphatic testimony to the value of the association and the excellent and large-minded way in which it works.

"The Registers" (medical and dental) are out. The number of names in the former is 34,642; in the latter, 4,937. No less than 504 have been omitted in consequence of no reply having been received by the registrar to a registered letter. It seems likely that many of these persons are still in practice. If so, it is their own carelessness which will give them the trouble of getting once more inscribed on the official list of qualified men.

A man whose name was struck off the "Register" in 1891, and who was sent to penal servitude for five years, was fined £5 on Wednesday for unlawfully using the title M.D. Several other men who have been struck off the "Register" are still practising. One was before the magistrates on Wednesday on a charge of procuring abortion, and was remanded.

Dr. Douie, of Sevenoaks, met his death by "misadventure." Going to his surgery he took up a glass, filled it with water, and gulped down a mouthful before noticing that the glass was one which had been used for tincture of nux vomica. A neighbor was called in, but death took place in half an hour.

Surgeon-General Cleghorn of the Indian service, staying at St. Ives, met with a serious cycling accident. He was found by the roadside in an unconscious state, and with injuries to his head, face, and arm. He has now recovered consciousness.

Dr. W. G. Shepherd died on the 30th ult., aged eighty-three years. He was a lieutenant-colonel in the Victoria rifles and one of the first surgeons of volunteers to instruct by lectures and drill his bearer companies.

The death is announced also of another aged practitioner, James Paul, M.D., who began his medical education at Aberdeen University in 1821. He was in the naval service of the East India Company, 1825–30. His health suffered from hard work during the cholera epidemic of 1849, when he was in general practice in South London. In 1856 he was obliged to retire. He has been blind for a number of years, and at length succumbs to old age.

THE DIFFERENT FIELDS OF OPERATIVE SURGERY AND GYNÆCOLOGY IN EUROPE.

To the Editor of the Medical Record.

Sir: Vienna, the capital of the empire of Austria and residence of the Emperor, has 1,400,000 inhabitants, with a garrison of 22,700 soldiers. It is surrounded by picturesque mountains, from which the city may be viewed with a dreamy charm commensurate with its remote origin and ancient appearance. The great basin bisected by the historic Danube and adorned with this cultured city was dotted with the domiciles of a community of Celts when the shepherds of Judea sang to the star which proclaimed a new light to the world. Marcus Aurelius died here, A.D. 180. Napoleon fought, camped, and married here, and his only son died in the same room (1832) in which his illustrious father had his headquarters (1805 and 1809).

Vienna is disputing to-day with Paris for first place in modern art, and one needs but visit its picture galleries to know the reason. The largest and most elegant playhouse in Europe is the Burg Theatre of this city. It was built by the Emperor at a cost of 11,000,000 gulden, and remains his property.

The university was founded in 1365, nineteen years later than the University of Prague, and next to that institution is the oldest school of learning now in existence in Europe. It has six thousand students and three hundred and fifty professors and lecturers. The university fund supports the K. K. Allgemeines Krankenhaus, which is the largest hospital of Europe or of the world. The abundance of clinical material of this hospital and the polyclinic, supported by the same fund and less than two hundred yards away, is nowhere equalled. Professor Gussenbauer is the successor of Billroth and has the largest clinic in general surgery, with Dr. Albert a close second. They observe scrupulous cleanliness and operate with the usual aseptic precaution of the German surgeon. Americans attend here in numbers and are certainly not discriminated against, and in the pathological rooms near by all conversations one hears among attendants are in English. In a class of thirty I found only one German, outside of assistants. The latter were mostly, though not all, German.

The Frauenklinik of the Allgemeine Krankenhaus is divided equally between Professors Chrobak and Schauta, each of whom has a third of the obstetrical department assigned him, Professor Braun having the other third of "Geburtshulfe" without gynæcology. Each of these has an able corps of assistants and one hundred and twenty beds, and the two former directors have each forty beds in a separate department purely gynæcological, making in all eighty gynæcological and three hundred and sixty obstetrical beds.

The Allgemeine Krankenhaus was founded in 1815 and covers ground variously estimated at from twenty-five to forty acres. Austrian measurements are so entirely different from ours, saying nothing of the untranslatable names therefor, that it appears impossible to put them into acres. The buildings are of stone, brick, and cement, and are substantial but in no sense modern. They run at right angles, with square courts between, and appear to be thirty-five or forty-five feet wide and a quarter of a mile or more in length in a straight line, if one does not count the five or seven intersections as interruptions. Medically there are thirty-five sections or divisions, presided over by twenty-two directors or physicians-in-chief, who have seventy-seven resident assistants, two hundred and twenty-two female nurses, thirteen male nurses, and more than two thousand beds. Of the 77,061 patients treated in the royal hospitals of Vienna in 1895, the Allgemeine Krankenhaus had 25,149 in its wards.

While I attended Chrobak's clinic, twenty-nine children were born in the one large room or ward used for obstetrical purposes, and twenty-seven during another twenty-four hours. This labor ward has usually sixteen or eighteen beds, though it has capacity for twenty-four. In three hours after delivery the patient is removed to the lying-in ward, where she remains nine days, when she is sent home or to the foundling hospital. If she goes to the latter she must agree to wet-nurse two children if necessary, as many of these mothers leave their offspring behind when departing. They come alike from country and city.

Schauta is a favorite with the German students, having been German professor in the University of Prague until six years ago, when he was appointed to the position he now occupies. He is tall and slender, with the long and tapering fingers of an artist, and these do not belie their appearance, for Schauta operates with artistic nicety and he is very dexterous and speedy.

Chrobak has been officially connected with the service of the general hospital for twenty-nine years and for ten years has been chief of his department. He is short and stout, and as cool a man under most exciting and trying circumstances as can be found among German-speaking people. He is as free from scolding his assistants as I could find any other among the same class. He is reverenced and liked by his subordinates and loved by his patients. Chrobak begins operating at 8 A.M., and usually continues until 11:30 or 12 M. From 12:30 to 2 P.M. he gives clinical lectures in the amphitheatre, which is in another part of the hospital. Saturdays and Sundays there are no lectures. Schauta begins operating at 10 A.M., giving clinical lectures on the same days and at the same hours. Chrobak does not operate himself so often as Schauta does, but the former is especially strong in the ability of his assistants, three of whom—Ludwig, Konour, and Savor—give private courses in operative gynæcology and obstetrics. The most nimble and dexterous fingers in cutting and sewing I have thus far seen are Savor's.

There are no private hospitals in Vienna, in the same sense as in Berlin, though there are so-called private hospitals. I could not learn of an instance where a celebrated operator owned and conducted his own hospital. The private hospital of Vienna is more nearly a hotel, the difference being chiefly in its having an operating-room with proper appliances and the rooms arranged for the sick rather than for guests in good health. Such a sanatorium may be owned by a surgeon or gynæcologist, who will himself perform minor operations, but I believe in no case the major ones; the most skilled operators bring their best-paying patients to such sanatoriums where the best of everything is obtainable—room, board, nursing, heat, and light.

The best-constructed, most modern, and most perfectly arranged gynæcological hospital I saw in Europe is the Botina Pavilion of Elisabeth Hospital at Vienna. Baron Albert von Rothschild gave 600,000 gulden for the construction, equipment, and maintenance of this elegant pavilion or hospital. More than half was used in the construction of the building, and the remainder of the fund was turned over to the committee for permanent investment, the proceeds to be paid annually toward maintenance of the hospital, the rest of the yearly expense to be paid by the empire of Austria, to which the property and endowment were formally presented by Albert von Rothschild while I was in Vienna—on condition that no patient treated within its wards be allowed to pay for operation, room, or board, and that no one should be discriminated against by reason of nationality or creed.

The floors are mosaics, enamelled tiling, and cement. The inside walls and partitions are glazed brick or tiling, in the operating and disinfecting halls as well as in the laboratories. These are of light color and agreeable shade. In some of the rooms the walls and overhead ceiling are hard finished in cement or plaster of Paris, painted, and glazed. The structure is of stone outside. There are two operating-rooms without communicating door, one for septic, the other for aseptic cases. There are separate rooms for sterilizing instruments and appliances, still others for anæsthetizing. In the operating-rooms water is turned on and off, hot and cold, and washbowls are emptied without anything being touched with fingers all by pedal attachments easily worked by foot. There are forty-two rooms for patients, with sixty-two beds. After operation only the physician and the nurse are allowed to see the patient for several days, and for three or five days there is only one patient in a room. If she is then still aseptic she may be placed in the same room with others. Four is the maximum number ever permitted in any room. On the upper floor are pathological, histological, and chemical laboratories, well equipped with the most approved and most modern appliances, without regard to cost. In the hall on the first floor near the entrance is a fine piece of statuary, heroic in size and of appropriate design—a nurse ministering to a suffering woman. This alone cost 10,000 gulden, and Albert von Rothschild paid an additional 2,000 for a bust of his deceased wife, after whom the hospital is named; this crowns the statue most gracefully. Impressive inscriptions further adorn this work of art. The professional wisdom of arrangement and perfection in structure and material, as well as the ornate, can be studied to the edification of any one contemplating the erection of a hospital for women.

Professor Wertheim is chief, with two resident and two visiting assistants, all of whom assist at operations, and I met physicians and gynæcologists of prominence from all parts of Europe and America among the attendants of these clinics.

Next to Vienna Buda-Pest is the largest and most important city in Austria-Hungary, having more than a half-million of inhabitants. It stretches nearly three miles along the banks of the Danube, and adorns one of the most picturesque parts of that historic stream with its military forts, King's palace,

ornate capitol for the national Diet, and its many other structures and monuments of artistic splendor. It is the capital of the kingdom, and the Emperor of Austria is King of Hungary and resides much of his time in this city of romantic beauty and Oriental luxury. It has a garrison of eleven thousand soldiers. The educated classes speak French fluently, often Italian, and occasionally English. If they know German they are loth to admit it. They have a feeling of bitterness against the German people exceeding that of even the French. Four-fifths of the people speak Magyar.

The gayest society season is during their carnival, and in its closing week at the Grand Hotel Hungary there were two or three halls occupied nightly by as many sets of the select for dancing and feasting. The dancing usually began at 10 P.M., and supper at 2 or 3 A.M.; at 5 A.M. the ladies would go home, but if the latter are to be regarded as the *Hamlet* of this play, certainly some of the young bloods prefer that drama with *Hamlet* left out, for they remained and enjoyed their wine and song as late as 9 or 10 o'clock. In addition to the very excellent band that gave daily music during meals and from 8:30 P.M. until after midnight, we now had two or three additional bands in the dancing-halls. The musicians used mostly string instruments, including violins, but their national instrument is most noteworthy—the cymbal (pronounced *stymbal*). Hungarian music is the most pleasingly thrilling I have ever heard, and their ladies are the most graceful, charmingly winning, and beautiful I saw in my entire journey.

During the carnival the King resides here in his palace, which stands on a high bluff directly across the river from the Hotel Hungary, in full view and almost within hearing-distance. On a higher point overlooking the palace, on the same side of the river, is an immense military fort, giving a grandeur and magnificence to the view seldom equalled.

Buda-Pest has a system of underground electric railway. The streets, light, and all means of communication are better and more modern than in Vienna, and its hospitals are the most perfect public hospitals to be found in Europe. There is a university here supported by the kingdom of Hungary, with thirty-five hundred students, of whom twelve hundred are medical. The required time in medicine is five years, and, like the German schools, the university does not admit medical students to clinics until after two years' attendance and satisfactory examination.

The professor of gynæcology can be such only by being also professor of obstetrics, though there are professors of the latter who are not professors of the former. At Buda-Pest the professor of the university is also director of the clinic in gynæcology, and the same as to general surgery. Professors Kézmárszky and Tauffer have equal rank, but conduct separate hospitals and clinics in the Frauenklinik on diseases of women, including both gynæcology and obstetrics.

Kézmárszky has just moved into the new hospital built for his work. It is of buff-colored brick, black mortar, two story and basement, with seventy obstetric and forty gynæcological beds, each on different floors. There is an amphitheatre with seating-capacity for one hundred and fifty students, before whom difficult and instrumental deliveries and obstetrical operations are performed. This amphitheatre is as steep as that of St. Luke's and the Presbyterian hospitals of New York, and all students have a clear view of the operations. For gynæcological surgery there are separate rooms, and only a few are admitted to the operation. The ambulant patients are treated in still another part of the hospital. In the obstetrical department there is a large room with eight beds, where all deliveries with normal labor are made; and in three hours the patient is removed to the lying-in ward for nine days when she is sent home. About one thousand births are yearly recorded, and three hundred gynæcological patients are treated in the wards. In 1896 his books showed treatment of twenty-one hundred and forty ambulant patients. There are sixty or seventy patients treated in the ambulant department daily, where there are five gynæcological chairs or tables, with as many operators, who do massage and the smaller operations almost continuously. Here is where diagnosis is taught, and also the ordinary methods of treatment by the assistants.

For retrodisplacement with fixation Kézmárszky does not believe in surgery. He has never done ventral fixation, only one Alexander operation, and three vagino-fixations, and objects to all alike, giving his reasons: If the uterus is adherent operation will not cure, and when mobile he prefers a Hodge pessary. If there are adhesions he will treat by massage for three or five months if necessary. His method of massage was shown me and appears very simple, unobjectionable, and rational. The index and middle fingers of the left hand are introduced into the vagina and held firmly by the points resting against the promontory of the sacrum. The right hand is placed over the abdomen and pressed down and behind the fundus, where the ligaments and adhesions can be caught and rubbed between the fingers of the two hands, but by motion of the right hand only. The clitoris is not rubbed or touched with the introduced hand. The external hand presses on the adherent fibres by rubbing first longitudinally, then transversely, so as to thin out adhesions; then there is a tremor of the hand with continued pressure which shakes loose the attachments.

Kézmárszky was consulted by civil engineers and architects in the construction of this model hospital. The pipes conduct all fluids from the building into a reservoir, and from there, by a system apart, into the sewer, thus avoiding communication between sewer channels and the hospital. The air-supply system for the wards begins with a dome about fifty feet from the building in a court at the rear. This dome is perhaps fifteen feet in height and six feet in diameter. It has a tin roof, and open sides surrounded with two layers of wire netting with a small space between the layers. Outside the wire and immediately under the eaves of the roof are two rows of pipes forming a complete circuit around the dome. These are perforated at their lower border with many pin holes, through which water is forced in jets which make almost a spray. This fine rain surrounds the dome in two rows, with a few inches of space between, and prevents entrance of dust. It further purifies the air, cools it, and enriches it in oxygen. About six feet below the surface the piping turns at right angles and goes horizontally to the building. In the foundation wall is a large circular electric fan, which drives this air in through a long narrow hall with numerous openings, through which it is distributed by conductors into the various wards above. In the summer this is done continuously. During winter air is heated in the basement and conducted to the wards by pipes within partition walls, with registers making ventilation ideal. A brass chain is pulled a specified distance, giving hot air only; a little more gives medium, while the last notch yields cold air only. Near the floor opposite the above there is a pipe admitting air from without the building direct, in any amount desired and easily regulated. Steam or water radiators are in every ward and hall. Windows and skylights admit the greatest abundance of sunshine and daylight. There are gas and electric light in every room.

The floors in the operating-rooms and greater part of the hospital are glazed tiling, in other parts mosaic

or cement; there is very little if any wooden flooring. The inside walls are of glazed brick, tiling, and cement—the latter always painted and glazed.

Dr. Béla Walla, Kézmárszky's assistant, attended the Congress of American Physicians and Surgeons at Washington in May, 1898. He visited the better cities and clinics of the United States, and knows the comparative ability of American gynæcologists wonderfully well. He reads and speaks English fluently, and is a good operator and accomplished teacher in diseases of women.

Nearly all the professors and teachers of medicine at Buda-Pest speak English fairly well, and I found no place in Europe where the American is treated with the marked consideration and cordiality manifested by these accomplished people.

Professor Tauffer's new hospital is largely of the same pattern as that of Kézmárszky, with a few noteworthy points of difference. In addition to the public fund, there was some private endowment for this hospital, which was applied in extending its dimensions and in elaborating and beautifying. There are one hundred and twenty-eight beds, half obstetrical and half gynæcological, and separate operating-rooms for septic and aseptic operations. In the basement at a rear corner of the building is a room which does not communicate with other rooms. In this are placed for delivery obstetrical patients with contagious diseases —scarlet fever, erysipelas, etc. For these there is a lying-in ward or pavilion in a separate building some distance away. I am assured that any obstetrical patient who has exalted temperature when brought to the hospital is suspected of sepsis or contagious disease, and placed in this basement room.

The hospital is replete in laboratories. There are a museum of many interesting specimens, and a glass-covered tank in which are twelve full-term fœtuses kept in preserving-fluid. These are used for diagnostic purposes in manikins and pelves in teaching obstetrics. But with all its excellencies I notice the absence at this hospital of the dome for purifying air, and the conductors from the building connect with the sewers direct. Tauffer's obstetric record shows six hundred and thirty-five births within the hospital and nearly two thousand out-patients in 1897. In the gynæcological wards there were one hundred and sixty patients, and in the ambulant department two thousand. The day preceding my visit there were fourteen births in the ambulant obstetrical record within twenty-four hours. Besides the three regularly appointed assistants, who reside permanently in the hospital, ten visiting assistants attend daily. In the obstetrical department one assistant remains thirty days continuously, eating and sleeping within the hospital, as do two additional ones for twenty-four hours at a time, and then retire until their turn comes again. These work mostly in the ambulant department.

The patient in the gynæcological department is given a bath the day before operation, after which the part to be cut is scrubbed with a brush, first, in soap and water; second, in alcohol; third, in sublimate, 1 to 1,000; after which a sublimate cloth is applied until the morning of the operation, when it is removed and the scrubbing is again repeated as described. The operator scrubs his hands and nails with soap and water for ten minutes, with alcohol (ninety-five per cent.) for half a minute, and with sublimate for one minute.

For carcinoma of the cervix Tauffer does vaginal hysterectomy, cutting with knife and scissors and using clamps, which latter are removed in twenty-four hours. The deeper packing is of iodoform gauze, and is left in for eight or ten days. If there is odor when this is removed, he douches with carbolic-acid solution, two per cent.; if aseptic, sterilized water alone is used. The day preceding a vaginal hysterectomy the patient is given a bath and vaginal douche, and on the morning of operation a sitz bath, after which a vaginal douche of carbolic acid, two per cent. Brushes are not used within the vagina. Tauffer does no ventral fixations and has done only one Alexander operation, preferring massage and pessaries. He has been director of this clinic for fourteen years and will celebrate his one thousandth laparotomy next week.

After serving for twenty-eight years as professor of surgery in the university and director in the hospital, Professor Kavacks died, in August of 1897, and Professor Dollinger was appointed his successor. This brilliant young surgeon was then director in a city hospital, which position he still retains, though his principal work is in the university hospital, where he did two hundred and ninety-seven major operations the first one hundred days of his directorship. He has fifteen assistants and nearly one hundred beds, and besides treats about sixty ambulant patients daily. He is the author of a fixed dressing for fracture of the femur, and he was good enough to send for me to witness the application of his method when he had a case of this much-dreaded fracture. He had no difficulty in convincing me that no splint can be better as to result, for he has absolutely no shortening, the fragments being put in perfect juxtaposition and easily held so during the process of healing, whether the fracture be square or oblique; and, what is still more remarkable, the patient not only may, but is required to, walk immediately after the dressing is applied, and then daily until it is removed five or six weeks later. No anæsthetic is given. It requires considerable time to complete this dressing, which is of plaster of Paris, but when it is finished there is nothing more for the surgeon to do until he removes it. Dollinger was one hour in adjusting a fracture and completing the dressing. The details would exceed the limits of this letter, but no one interested in fractures ought to remain unadvised of this method, which Dollinger published, with the history of his first nine cases, several years ago; he will soon publish an account of his first one hundred cases. The case I saw was that of a boy, seventeen years old, and at the completion of the application of the dressing he walked out of the arena into his ward and said he experienced no pain, though he had complained repeatedly during the adjustment and was very awkward in the use of his crutches. Dollinger has done Wagner's circular osteoplastic section of the skull five times. The fifth case I saw, and five days after operation there was still oozing of blood. The flap was lifted daily and dressed with sterilized gauze. The frequency of convulsions is diminished but not stopped. In operating adhesions were found in the membrane, with pus and débris beneath, which were scraped away. Dollinger thinks this will be his last operation after Wagner, as the method has effected no cure, though there has been improvement in every case for a short time. The most marked improvement was in a case of stuttering, in which the patient repeated words four and even five times. After operation the repetitions were few and were not made more than once, but in four months the patient relapsed to his previous condition. Dollinger thinks well of the operation of Chipault, who reports fourteen cases or operations, with eight recoveries. I saw Dollinger do his first "Chipault." He was twelve minutes in completing it. Behind the ear at the lowermost point of the skull the incision was begun and carried downward and slightly forward about three inches. After the skin and fascia were cut, a blunt-pointed instrument was used in pushing the muscles apart until the carotid artery could be distinctly seen pulsating, and behind it the sympathetic was exposed

running parallel with it. About one and one-half inches of nerve was cut away, including the ganglion. Neither the nerve nor anything else under the skin was united. One small artery was cut and was ligated, after spurting violently, with silk, which was cut off short and left under the skin. The incision was sewed with continuous suture of silk; the blood was pressed from beneath by rolling a rolled bandage from above downward over the parts after sewing and before the bandage was applied around the neck. I am promised a history of this case for publication in the MEDICAL RECORD.

In the best residence part of the city is the private hospital of Dr. Herzel. From the street it has the appearance of a palatial residence. In midwinter I found a perfectly clean carpet spread from under the large balcony out to the sidewalk, fifty feet away. Oriental rugs were spread over the floors of the spacious halls and over the many lounges and luxuriant divans throughout the building. Herzel was two years building this hospital, of which he is the owner. The ground cost 110,000 and the building 350,000 gulden. The hospital is about one year old, and Herzel believes it to be the most luxurious in Europe. I have nowhere seen its equal in elegance. It has two stories and basement. There are thirty beds for patients in as many rooms, and each room has an adjoining space communicating, with a lounge on which the nurse may sleep the first three nights after an operation, when lounge and nurse are removed. He keeps eight nurses in the hospital, besides female help in the kitchen and the laundry, and nine men as helpers. There are gas and electric light in every room in the building, and the elevator is run by electric power generated within the building. Herzel tells me his yearly expense for maintaining the hospital is about 80,000 gulden.

In addition to the fee for operating, he gets 10 or 12 gulden a day for patients of the first class; 7 or 8 gulden for those of the second class. He has a few in the third class, who pay 5 gulden daily. When a patient cannot pay five gulden Herzel treats her in the city hospital, where he is director and also teaches, giving operative courses in gynæcology and general surgery. He was Czerny's first assistant at Heidelberg for four years, and that celebrated surgeon was his guest the day before my first visit. Dr. Herzel and his wife reside in the hospital. There are two resident assistants and three visiting assistants, who help in the daily professional work, including laboratory, and assist at operations. There are two operating-rooms, one for laparotomies alone, and also laboratories for pathological, histological, and bacteriological work. Herzel is perhaps thirty-five years old, and does most difficult operations, having twice done total extirpation of the bladder and fastening of the ureters into the rectum. These operations were done nine months and three months ago respectively. Both women are living and comfortable, one of them retaining four ounces of urine before passing it.

J. PRESTON MILLER, M.D.

Badly United Fractures.—Dr. Alfred Willett (*The Lancet*, December 18, 1897) says: "I would just mention that it is very essential for success that the fragments should be disengaged very thoroughly, and after careful adjustment I have generally found it necessary to employ very much more extension weight than in ordinary simple fractures to insure full length being maintained; in one instance I used as much as thirty pounds of shot in a canister. The ultimate results, as regards not only union but also position, are, in my experience, extremely satisfactory, although constant supervision is needed to insure success."

Medical Items.

Specialism Appreciated.—At one of our large dispensaries having special departments an applicant recently took tickets for each class, and spent the day obtaining expert opinions on the condition of his eyes, nose, throat, internal organs, and skin, and it is said even had a little surgery done and got a tooth pulled.

A Definition of Medical Practice.—John Hunter said that "definitions are the most damnable things," and certainly the definition is often by far the most troublesome part of a proposed legal enactment. A Kentucky judge has recently given a definition of medical practice which seems to be fairly satisfactory. In pronouncing sentence upon an "osteopath" who was convicted of having subjected a child suffering from tuberculous disease of the hip-joint to cruel and unnecessary torture, he laid it down that "any person who for compensation professes to apply any science which relates to the prevention, cure, or alleviation of the diseases of the human body, is practising medicine within the meaning of the statute." This concise definition is probably comprehensive enough to include every form of quackery.—*British Medical Journal*, March, 1898.

New Use for Roentgen Rays.—Some interesting particulars of a new application of the Roentgen rays for curative purposes were communicated by Dr. Edward Schiff, lecturer at the Vienna University, at the last sitting of the Imperial and Royal Medical Society. A series of experiments conducted by Dr. Schiff and his assistant proved that these rays could be used for the cure of disease in a manner capable of perfect control by means of a more or less intense application for a longer or shorter period, producing reaction in the exact degree required. In this way it has been possible for the lecturer, on the one hand, to remove hair from parts of the body where it constituted a disfigurement without causing the slightest inflammation; while, on the other hand, he has been able to treat lupus with uniform success by means of an artificial inflammation, the intensity of which he was in a position to increase or reduce at will.—*London Times*.

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the United States Marine Hospital service, during the week ended May 7, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Mobile	April 22d to 30th	10

CERTAIN POINTS OF INTEREST IN PHTHISIS.

BY HENRY P. LOOMIS, M.D.,
NEW YORK.

THERE are certain points of interest in the treatment of phthisis, its diagnosis, and prognosis, which are not set down in any text-book that I know of, and yet which are of great value in the care of this only too common disease.

Grouping these points under three heads—1, prognosis; 2, diagnosis; 3, treatment—and assuming that what the text-books have to say on these three subjects is well known, I pass to some facts as to the elements of prognosis, which are drawn from careful records kept of several hundred cases, upon which I have passed as one of the examining physicians for the Adirondack and Liberty sanatoriums—records showing the kind of cases which end in recovery under the best climatic advantages; and later to some points of interest on the new serum treatment, gained after a year's experience.

An accurate diagnosis of phthisis, so necessary to the scientific observer as the basis for his treatment, falls very far short of being all the patient requires from his medical adviser. If the patient himself is satisfied that the nature and the extent of his disease are known, and its treatment is scientifically planned, his friends have a series of questions to be met: Will the disease be eventually fatal? How long can life be prolonged? When will the patient be able to return to his work? Is a change of climate absolutely necessary? These and an infinite number of problems, connected with the habits, engagements, and social environments of the patient, arise, which tax the skill of the physician to the utmost.

Our general knowledge of the disease, accumulated by experience, helps toward a satisfactory prognosis, but each case is after all unique and must be considered in all its personal equations. Prognosis must be reached in every case from the study of the constitutional condition of the patient, as well as of his lung condition. As you know, there is frequently not only a want of correspondence between these two conditions, but actual contradictions will very often be found. In every case the physician must regard and carefully balance the evidences to be derived from both sources, as only in this way can even an approach to accurate prognosis be reached.

Under the two heads, constitutional condition and lung condition, I have jotted down a few points which have been of help to me in estimating the future of a case of phthisis, and which later results have borne out as accurate.

As one of the examiners for the sanatoriums referred to, a large number of applicants for admission come before me. I am expected to decide: 1st, whether they will recover completely under climatic advantages; 2d, whether they will make that recovery within a year. Careful records of the course of these cases are kept, and I have reached at the present time from my past experiences and mistakes the following conclusions:

I. Constitutional Conditions.—Under this head I will mention only a few facts which seem to me important in estimating the prognosis of any case.

1. Gastric symptoms. Being asked what one point would influence me more than any other in giving a prognosis in a case of phthisis, I should answer, "The condition of the patient's stomach." I do not mean when a patient's digestion is disturbed from some good cause, such as injudicious feeding, cough mixtures, etc.; but when, in spite of careful attention to diet and method of feeding, it is impossible to keep a patient's digestive organs in any kind of condition for the proper assimilation of food. Many of these cases go along well for a few days, and then quickly lose what they have gained. These are the bad cases. One sees many of them. They are generally persons of high neurotic temperament. It matters not what the lung condition is, these patients seldom recover. Climate avails little when the patient is daily losing ground because of unassimilated food. Medication is worse than useless, because of an enfeebled digestion which is constantly disturbed.

Again, when the assimilation of food is good, the prognosis is always favorable, often even with desperate lung conditions.

2. Rapid heart action. The second condition that always renders the prognosis bad, in my opinion, is a rapid heart action noted at the beginning of a tuberculosis. In the advanced stages of the disease we expect to find a rapid and often feeble heart, but when there is only slight involvement of the lung, and the heart action is always above normal even at rest, and when on the slightest exertion it goes up to 110 or 120 beats, the outlook is always unfavorable.

This condition is seen generally in young subjects of high nervous organization. In my experience it is not more common in women than in men. The rapid pulse in these cases is not dependent on any fever the person may be having; for at the time of day when the temperature is normal the pulse is still rapid.

3. Age. I have never found age to be a very important element in the prognosis of phthisis, as far as the curability of the disease is concerned; but as an element in estimating the probable length of life of one advanced in the disease it is a very important factor. The age at which the disease is most prevalent is settled. It is not so generally understood that phthisis is far from uncommon in people of advanced years. My experience has been that the phthisis of advanced age is often latent in its beginnings, slow in its advance, tending to the destruction of limited portions of the lungs, and is found with few secondary derangements accompanying it. A few years ago I had opportunities to make autopsies on a large number of old people who died at the almshouse. I was impressed with the great frequency with which an unsuspected pulmonary tuberculosis was found; I should think fully sixty per cent. had chronic phthisis. Age, then, is a modifier of the type, and exercises a controlling

Read before the New York Clinical Society, February 25, 1898.

influence over the progress of the disease. The patient often lingers for years, especially if provided with the comforts of life, with food adapted to his requirements and appetite, and a fair allowance of stimulants.

4. Fibroid diathesis. The importance of the fibroid diathesis is generally overlooked in prognosis, especially when the disease develops in middle life. In people with this inherited condition, irritations have always a tendency to start up fibroid changes. Should we not expect it to be so in phthisis, when the quiescent stage comes as it does in nearly every case? The tendency of the pulmonary lesion to heal is very marked. I know a number of cases in which this condition seemed to be the principal element that arrested the disease and led to a relative cure. For instance, a prominent physician who had active phthisis for over ten years, who is now a comparatively well man, doing a large amount of professional work each day, is thoroughly convinced that as he advanced in years his fibroid condition became well marked and he began to have slight gouty attacks; and then his pulmonary condition which was extensive took on a retrograde process at once and began to heal. Interested in his own case, he studied this element of prognosis thoroughly, and I have often talked with him about it. He is confident that this diathesis is an element of favorable prognosis, that is little understood and often overlooked.

5. Hæmoptysis. Opinions in regard to hæmoptysis vary. Certainly the popular idea is that hemorrhages make the outlook discouraging. On the other hand, some authorities go to the other extreme and claim that it renders the prognosis favorable, and that there is a larger percentage of recoveries when frequent hæmoptysis occurs. A very interesting and systematic study of this subject has just been completed in the German army and the results have been published by Stricker. During the past five years nine hundred patients were admitted to the military hospitals, suffering from pulmonary hemorrhage. His conclusions after analyzing these cases are as follows: 1st, of soldiers attacked with hæmoptysis without cause, eighty-six per cent. became tuberculous; 2d, when from a cause, as military drills, seventy-four per cent. became tuberculous; 3d, when from injury, only fifty per cent. developed tuberculosis. My experience has been that hæmoptysis early in the disease does not affect the prognosis one way or the other, especially if it is not followed by fever which lasts a number of days. This last point I consider very material in deciding the importance of hemorrhages in each individual case.

Out of twenty-three patients discharged during the past year from the Liberty Sanatorium in whom the disease was cured or so arrested that the person was able to return to his or her former occupation, six had had pulmonary hemorrhages at some time.

As is well known, hemorrhages occurring later in the development of the disease are of much more serious import.

6. Heredity. Only when one has endeavored systematically to obtain the family history of a large number of persons suffering from phthisis has he any idea how inaccurate the information given by the sufferer and his friends often is in regard to the previous occurrence of tuberculosis in the family. I have noticed again and again how this fact is concealed, whether intentionally or unintentionally. Whatever conclusion the medical profession of today has reached as to the importance of heredity in phthisis among the people, it still holds the first place. So powerful has this influence been considered that, as you know, it has been used as an argument against the proposals for prophylactic measures which are advocated by sanitary officers and others. It is not to consider the importance of heredity as a causal agent in the development of phthisis that I speak of it now, but to note whether persons with a tuberculous family history are handicapped in their struggle to regain health when placed under suitable climatic conditions. My experience has led me to believe that tuberculous heredity has very little to do with the question of a person's recovery, all other things being equal. Of twenty persons known to me who have recovered from phthisis during the past year alone, nine of them have pronounced tuberculous histories. One had two brothers and one sister die of phthisis.

Habits.—It has been my experience that alcoholic subjects do badly when they contract phthisis. The resisting power of their tissues seems to be at a minimum. Their course downward is generally rapid. Climatic advantages may stay the process for a time, but there is no real gain in the case, no matter how long they remain away from unfavorable conditions. These cases after the phthisical process has developed have generally very rapid hearts and are often troubled with constant dyspnœa. If they are sent to a place of any altitude these symptoms are aggravated and the hemorrhages so constantly seen in these cases increase in severity.

Loss of Flesh.—Loss of flesh, so common in phthisis, is dependent upon so many causes, such as gastric disturbances, fever, worry, etc., that it becomes a very important element when a person is placed under suitable climatic conditions. The axiom ought to be laid down that unless a person gains in weight he is not improving, no matter which way other symptoms point. I think it is one of the best tests that we have for improvement in phthisis. Before a patient can gain flesh many things must happen of a beneficial character; the fever must diminish or disappear, the assimilation of food must be good, sleep must be fair, and the sweats must stop. Besides this it is the one test which patients can apply themselves. It is wonderful how cheerful they become when the scales show a gain of a few pounds.

Every one of the twenty-three cured cases I have referred to at Liberty gained in weight from eight to twenty pounds.

Character.—There is an element in the prognosis of phthisis, of which mention is never made and yet which seems to me to be one of the most important points to consider. One may call it the "personality" of the patient. Take for instance a person with a strong, determined character and a happy disposition, who has made up his mind to get well; put that man under suitable climatic conditions, whether it be in camp, alone in the woods, or at a hotel with attractions for late hours and mild dissipation, that man will recover even though the disease be quite advanced. Put another patient, of a nervous temperament, with slight pulmonary changes, but one easily influenced by surroundings, with no inherent reserve force, depressed by every light and temporary change in his symptoms, in the same surroundings, and he hardly ever does well. If he is fortunate enough to be benefited by any one locality, he is forever anxious to seek a change, follow his own inclinations, but not the instructions of his physician. Such people wander about from place to place, restless and dissatisfied, until they soon succumb to the disease. The tediousness of recovery from tuberculosis, at the best, requires all the fortitude and perseverance of which a strong character is capable. How handicapped therefore at the very outset are they of weak will and mental irresponsibility!

II. Lung Condition.—The pulmonary element more than any other, to my mind, that renders prognosis

favorable and makes arrest and final cure of phthisis possible, is the localization of the pulmonary lesion. I should prefer to see a man in the third stage of phthisis, with a cavity at an apex and the rest of the lungs normal, than another with the slightest imaginable tuberculous change, but that scattered here and there; for the first condition, if the patient's energy is kept up, can cicatrize in time and will soon become walled in by fibrous tissue, but the latter is so liable to extend in every direction that at any moment an acute tuberculous process may start. It has often surprised me how well the former cases do under climatic advantages. Naturally in this kind of a case it takes a long time for the patient to get well, but it has always seemed to me that the cure was permanent when once it was established.

Naturally in the majority of cases the slight extent of the localized lesion is a most important element in a favorable prognosis; this, however, only emphasizes the still greater importance of an early diagnosis. One month in the beginning is worth six months at a later day. Remembering this, we should look with suspicion on localized bronchitis at an apex, and should make it a routine practice to examine the sputum of every case of cough with expectoration which has lasted over two weeks, especially in one during the tuberculous period of life.

In reference to the prognosis of that large class of patients in whom tuberculosis develops secondary to a subacute pleurisy or is coexistent with marked changes in the pleura, it has always seemed to me that these cases uniformly do well when placed under suitable climatic conditions, and recovery is the rule rather than the exception.

Even with no advantages of climate many recover, and in almost all cases the advance of the disease is slow and marked by stationary periods in development. While I do not believe as some do that all pleurisies are tuberculous, still, if we can follow to the end all cases of subacute pleurisies, we will find, I think, that in time, it may be after years, phthisis will develop in the vast majority. I can recall two cases of pleurisy with effusion in which the patients completely recovered, but in which phthisis developed at the base on the side where the pleurisy had been; in one case after five years and in the other after ten years had passed. My experience with those cases of phthisis which begin at the base of the lungs has been bad. Seldom under the best conditions has there been any permanent arrest of the process. But I have seen a number of times in my life these cases and also advanced cases of ordinary apex tuberculosis suddenly start to improve, and the patient from being in a desperate condition become comparatively well, this change following upon the filling of the chest cavity on the affected side with effusion, the result of a tuberculous pleurisy. These cases have always surprised me, and a few years ago I worked for a number of months trying in animals rendered artificially tuberculous to fill the chest cavity with fluid or to start up artificially a simple pleurisy so as to compress the affected lung and then watch the results upon the tuberculosis. But after a large number of experiments I was forced to give it up. I could find no innocuous fluid that would remain in the pleural cavity, and in trying to start up a simple pleurisy I always caused an empyema. Cacao butter was the only material that would show any inclination to remain in the pleural cavity without doing harm. Sterilized plaster of Paris proved too irritating for the lungs. It has always seemed to me that possibly the compression of the lung in these cases of pleurisy by shutting out the air, keeping the lungs quiet and still allowing the circulation to go on, changed the tuberculosis from an active process to a conservative one and favored the development of fibrous tissue. I think this to be a fact of which possibly at some future time advantage may be taken in the attempted arrest of tuberculosis. There are many points to which I might call your attention in considering the relations which the various lung conditions have to the element of prognosis, but the time will not permit. I have here the history of twenty-three patients with cured or arrested phthisis who have left the sanatorium at Liberty during the past year. In the arrested cases the patients were practically well, for they were able to return to the cities and to their ordinary occupations. In analyzing these cases on the lines just alluded to we see: 1st. In all but one were the stomach and digestive condition good; three suffered only at times slightly with gastric disturbances. This bears out what I have already said, that a good digestion is a very favorable element in prognosis. 2. All the cases gained in weight, one case twenty-two pounds; the average gain for the twenty-three being eleven and one-half pounds. 3. The average length of time sixteen of the cases had phthisis previous to admission, as near as could be learned, was eight months; in seven the histories were too indefinite to be of value. 4. The average age of the patients was twenty-four. 5. Nine of the twenty-three had a tuberculous family history. In nearly half, then, the matter of heredity was of no importance in rendering the prognosis unfavorable. 6. In the matter of hæmoptysis, seventeen of the twenty-three never had any hemorrhages, three had only one hemorrhage each, and three a number of slight attacks of hæmoptysis. 7. The lungs of all twenty-three cured patients were in the first stage of the disease, with the exception of three, which were in the early second stage. 8. One point which surprises me in analyzing these cases is that ten out of the twenty-three had evidences of a tuberculous process in both lungs; possibly an involvement of both lungs is not a bad element in prognosis, as we are otherwise led to believe.

Diagnosis.—Physical diagnosis: Many times on making autopsies I have found an active tuberculous consolidated area, say an inch or two in diameter, at one apex of otherwise healthy lungs, and with the bronchial tubes in and about the localized consolidation also affected; but on account of the minuteness of the lesion I should defy anybody to make a diagnosis during life, if the lungs were examined in the ordinary way.

There is a way of examining the lungs which will reveal a lesion not much larger than the one just alluded to, and possibly as small as an inch in diameter. If a patient's arm is brought forward, the hand placed on the opposite shoulder, the ear placed over the portion of lung which is now uncovered by bringing the scapula forward, viz., just above and external to where the bronchial tubes are given off, there will be heard prolonged tubular breathing and fine râles on coughing. This is the very first physical evidence of tuberculosis—an evidence which will enable a diagnosis to be made weeks before the physical signs can be appreciated in front, where they are ordinarily looked for.

The reason for this is evident; it is an established fact that the majority of pulmonary tuberculous cases start at the apex, and commence as a peribronchitis with localized consolidations around the minute bronchi, which are the continuation of the smaller tubes. The reason these areas are not appreciated by listening beneath the clavicle in front, as is ordinarily done, is that they are covered over with two or three inches of normal lung tissue. I should almost be willing to make a positive diagnosis of tuberculosis if I heard fine cracklings, localized beneath the scapula and heard behind, at one apex, and accompanied by a prolonged tubular breathing. Quite often it is

necessary to have the patient cough two or three times before the fines râles are clearly evident. These physical signs generally antedate any expectoration that can be satisfactorily obtained, and are therefore of especial importance in the diagnosis of phthisis as coming before the presence of tubercle bacilli in the sputum. I am not aware that this fact in reference to the earliest physical signs of phthisis is mentioned in any text-book, so I venture to bring it to your attention.

Another point to which I would call attention is the method of examining the chest. We were taught as students that there were four methods of eliciting the physical signs—inspection, palpation, percussion, and auscultation. But how often does the busy doctor take up each of these methods in their order? He percusses and listens and draws his conclusions and makes his diagnosis, and I venture to say that inspection and certainly palpation are omitted in five cases out of six. He may be absolutely right in his interpretation of the lung condition in five cases out of six, but I believe if he would make it a routine practice to employ all of these different methods in regular order in every case the physical exploration would be complete and accurate in the six cases out of six. In my opinion, in no condition of the lungs is this routine examination more important than in phthisis. For example, you inspect the chest of one in whom an apex tuberculosis is just beginning; the result may be negative. You palpate at the same time beneath the clavicle on both sides. You are surprised at the marked increase in vocal fremitus, say at the left apex. You percuss, and you learn nothing; you place your ear first at one apex and then at the other, and you hear perhaps wavy respiration and a few râles at the left apex only. Your whole attention is now directed to the left apex, just as you were suspicious of it when you first noticed how marked was the vocal fremitus on that side. You complete the examination by listening behind, beneath the scapula, and hear a large number of fine râles on coughing, perhaps tubular expiration. You are now justified in making a diagnosis of beginning tuberculosis at the left apex, which you could not have done accurately by percussion and auscultation alone. This is not a fanciful case. Many persons whose life you may save by an early diagnosis belong to this category. I believe that palpation helps in diagnosing early phthisis fully as much as percussion. I know what I have just said in reference to the importance of using all the methods as a routine practice is nothing new, but it is of such absolute importance that I feel justified in speaking of it with emphasis.

There is one help in the diagnosis of phthisis which the physician has at his disposal, and of which he very seldom makes use, an aid which is especially important in doubtful cases—cases, for example, in which there is no expectoration and the physical signs are only negative. I refer to the tuberculin test. It is now so thoroughly settled that tuberculin is a positive diagnostic agent that even the courts recognize it, and in many States animals which show the tuberculin reaction can be killed at once and no appeal can be made for damages. I do not think it is so generally known that tuberculosis can be diagnosed in the human subject just as accurately: but the result of the last two years' work in this line has settled the point. Let me give you two illustrations of the practical use of this fact.

1. A patient has apparently recovered from phthisis: his expectoration has ceased and his cough has almost disappeared: he has no constitutional disturbances: his weight is above what it was before he was taken ill. Physical signs are still present in his lungs, but they are principally the result of fibroid changes, and everything is quiescent, as we believe. Shall that patient return to his home and his regular occupation? The question is a very important one to decide. I should answer it by the result of the tuberculin test, applied in the following way: Having taken the patient's temperature for a few days, say every six hours, to make sure that he has no diurnal elevation above what is normal, I should then give him an injection of one-half milligram of tuberculin, and have his temperature taken every four hours during the twenty-four hours following. At the end of two days, if still there was no rise in temperature or only an elevation less than a degree, a second injection of two milligrams should follow; and if still no reaction, after two days more, a third and final injection of five milligrams. If there was still no reaction, I should say that the patient is cured and could return to his work. If after any of the injections the temperature should rise one degree or over, I should consider that there was enough active tuberculosis in that patient's lungs to cause trouble if neglected. Practically this method is followed by Dr. Trudeau, at Saranac Lake, and he tells me that he finds it of the greatest aid and a reliable test for tuberculosis in ninety per cent. of cases.

2. Let me give you one more illustration of how tuberculin is of help. Take, for example, some of those obscure cases of beginning pulmonary tuberculosis. The constitutional symptoms are very suggestive; possibly there has been a slight hemorrhage. There is no expectoration that can be examined, so we find no help here. The physical signs are negative, or, if marked, suggest from the way the condition was ushered in, a pneumonia. The prognosis and to some extent the treatment will depend upon deciding whether there is any tuberculosis whatever. The tuberculin test will often aid us to decide this point. I say "often," for sometimes the fever from the diseased condition is so irregular that the test is negative or only presumptive: but where it can be used I believe it is positive. I cannot see why this test would not be of help to the surgeon just as it is to the medical man—for example, in abdominal, in glandular, or in bone tuberculosis.

I have never seen any bad effects from these injections, and I believe they are absolutely safe when given in the doses indicated.

One of the newer aids in diagnosis which have come to our help is the Roentgen rays. If we read some of the recent articles written on this subject, we should be led to believe that we can diagnose any case of phthisis by the fluoroscope. I have examined many cases of phthisis with the *x*-rays, and I am free to confess that I cannot see one-half the things that are claimed to be seen: but possibly my experience has not been large enough or I do not use it constantly enough. Still I do not mean to decry the *x*-rays. I consider them one of the confirmative agents we have in the diagnosis of phthisis—a disease, as you know, in which we need all the help we can get from every source. I will, however, take exception to the statement that the fluoroscope will ever replace the ear, or that one can diagnose with it lesions that cannot be appreciated by physical examinations. I should sum up the result of my experience with the Roentgen rays as follows:

1. That in the majority of cases they serve mostly as a corroborative agent of other methods of examination.

2. That the fluoroscope enables us to recognize more fully and accurately the limit of consolidated areas and to determine the presence of excavations, conditions which at times it is almost impossible for us to decide by physical examination.

Two things are requisite for the successful use of the fluoroscope—a certain amount of practice and a

Miss M.	20	Uncertain.	6 months.	18	None.	Some; R. H. always.	Ichthyol.	Good.	Yes.	Yes.	....	Both.	Much improved. Lives in Liberty.
Miss F.	22	Sister died of phthisis.	1 month.	6	None	None.	Creosote.	Good.	Yes.	....	....	Both.	Much improved. Home.
Mrs. A.	36	Two brothers and one sister died of phthisis.	2 years complaining.	17	None.	Slight.	Serum.	Fair.	Yes.	....	....	One.	Cured. Gone home to Sweden.

primary knowledge of a fluoroscopic picture of a normal chest. The thinner the subject, the more satisfactory will probably be the results. The ribs are clearly defined, and in a healthy chest an evenly clear transmission of light is visible between them. The shadow of the heart is generally black; very often the cardiac impulse is distinctly visible. The action of the diaphragm is often well defined, and during the act of expiration assumes a dome-like outline. The Edison laboratory at Orange has just introduced a large fluoroscopic screen in place of the fluoroscope which is held in the hand and which is so trying for the eyes. With this screen a dark cloth is placed over the tube and the patient's shoulders, concentrating all the light upon the screen, and the whole outline of the chest appears as a picture upon the screen in front of the patient. It is a new invention, and its advantages are that both sides of the chest are exposed simultaneously, comparisons are easily made, and the diseased condition can be demonstrated to a number of persons at once. I have obtained the most satisfactory results in defining the limit of diseased areas, and in differentiating between consolidation, softening, and cavities (which I believe can be done with absolute accuracy), by employing a metal rod, placed evenly against the chest and moved up and down until its outlines, as seen through the fluoroscope, become more distinct; this will indicate that the upper borders of the diseased areas have been reached. If pencil marks are placed along these borders and percussion is subsequently practised, the area of dulness will have been found between the lines. The areas of haziness correspond to the limit of relative dulness or infiltration. Cavities appear as bright spots among shadowy tissues; large cavities appear like a full moon behind a light cloud. Intense darkness, especially at the lower portion of the lung, indicates old pleuritic thickenings over consolidated lung tissue. In brief, we find the Roentgen rays a decided help in the diagnosis of phthisis—a help which, as it becomes more generally used and its technique more thoroughly understood, will undoubtedly go hand-in-hand with physical examination at some future time.

Treatment.—It is not of the well-known methods of treating phthisis that I would speak for a moment, but of the present status of a new line which will hold a prominent place in the next two years—namely, the serum treatment.

Every one is familiar with the fact that, long before the discovery of diphtheria antitoxin, investigators in various countries had been experimenting with the products of the growth of the tubercle bacillus, Koch's tuberculin being one outcome of this line of work. It was in the media changed by the growth, and loaded with the product thrown off by the bacillus in its metabolism, that the antitoxin for the arrest of phthisis was sought.

The discovery of a serum which had antitoxic properties in diphtheria stimulated a new line of research in reference to phthisis, and many well-known investigators throughout the world are at this moment endeavoring to obtain a serum which, when injected into man, will antagonize the growth, protect against the action of the bacilli, and finally destroy them in the body. The majority of scientists are now working, not with the media on which bacilli grow, but with the body of the bacillus itself—the protoplasm which is contained within the cell.

It is believed that this cell body of the bacillus either contains or elaborates by its cell activity three substances: a fever-producing principle, a general toxin which circulates in the blood of the phthisical patient, and a poison which acts locally and causes the well-known lesion of the tuberculous inflammation—co-

agulation necrosis. Up to the present time, the first and last properties only have been isolated; the second is still an unknown quantity, and this fact no doubt accounts for the only partial immunity which can be conferred on an animal by any of the antitoxins as now made. The investigators all seem to be working on nearly parallel lines, seeking for a substance prepared with a view to attacking the bacillus, not in itself, in germicidal fashion, but by destroying the pabulum upon which it thrives, literally starving out the enemy.

At present there are two kinds of products which have satisfied the laboratory workers as exercising a more or less complete controlling influence over the development of tuberculosis artificially induced in animals, viz., remedies which are the product of the germ itself; and serum from animals rendered immune by culture products of the bacillus.

To the first belongs Koch's new tuberculin. In the *Deutsche medicinische Wochenschrift*, April 1, 1897, Dr. Koch described a new tuberculin, TR he called it. He claimed far more for this than he ever did for his original tuberculin, and stated positively that with it he could render animals immune and could frequently cure them after they had contracted the disease. Dried tubercle bacilli were taken, finely powdered, and centrifugalized with distilled water. The opalescent solution when tested upon animals gave the tuberculin reaction. The residual germs were submitted to this treatment a number of times, until finally all were practically dissolved or broken up, the cell wall being destroyed. The latter solution in small quantities seemed to exert both an immunizing and curative action in experimental tuberculosis. This preparation is now being clinically tested all over the world. I have had no personal experience with its use. An agent of the importers brought me some bottles last June, but they had become contaminated owing to improper putting up, so I was afraid to make any clinical use of them. Clinical facts, as far as I have been able to learn from published articles, have not borne out Koch's claim for his new tuberculin.

A new antitoxin was introduced last autumn by Hirschfelder, of California. His scientific reputation was such that the product, oxytuberculin, has been extensively tried. It is made by adding peroxide of hydrogen to tuberculin, subjecting them to a steam bath for forty-eight hours, and then adding caustic soda. He then filters and neutralizes the filtrate with boric acid. The discoverer claims that as the result of this treatment the toxin of the tuberculin is converted into an antitoxin.

As far as my personal experimentation with this antitoxin on animals goes, it does nothing. Hirschfelder claims that it delays the development of tuberculosis in guinea-pigs. This I have not found to be the case. I have had an opportunity to judge of its action on the human subject in only one selected case. I saw no benefit from its use, but of course this is not a fair test. I have found that it is apt to cause some local irritation. At the present time there are three antituberculous serums being extensively used, but I understand Babes and Behring are both actively engaged in working out new products.

If the antitoxic serum treatment of tuberculosis could be freed, for the present at least, from its commercial aspect, and systematic experiments be continuously conducted in hospitals and sanatoriums, then this method might be looked to for good results.

1. The serum most extensively used at present is Maragliano's serum, or, as it is commonly called, the "Italian serum," obtained by treating horses with tuberculin and then with virulent culture of the tubercle bacilli. Maragliano says that tuberculous temperature is reduced in all cases with this serum, and modestly claims apparent improvement in the disease in very many cases. I have had no experience with this serum, but Dr. Walter James gave it with great care and for a long period of time to a patient whom I saw with him in consultation. He tells me that he "saw absolutely no benefit and no harm from its use;" the patient steadily lost ground from the beginning, and finally died.

2. A second serum is Paquin's, known as tuberculosis antitoxin. This is prepared by Paul Paquin, and is used extensively throughout the West. Its preparation and introduction are entirely along commercial lines. It certainly is not an inert substance, as I have seen a patient go into a serious collapse within a few minutes after an injection.

3. A third serum is the antistreptococcus serum. This serum is not an antituberculous serum, but is often given in cases of phthisis with mixed infection. It is claimed for it that by destroying the streptococcus which is so often present many of the annoying symptoms of phthisis are removed, such as purulent expectoration, night sweats, anorexia, and high temperature, and thus it indirectly affects the tuberculous process favorably. I tested it last spring carefully, in the New York Hospital, and had daily examination made of the sputum of the patients who were being injected. In none did the microscope show any change in the mixed infection, nor did the patients show uniform improvement. I am aware this is not the conclusion some have reached from its use.

4. United States government serum. For a long time the government has been experimenting in the biochemical laboratory of the department of agriculture with an antitoxin serum, looking primarily toward finding an immunizing agent, especially for use among domestic animals. A large experimental farm just out of Washington is connected with the laboratory and the work is very complete. Dr. de Schweinitz, the director of the laboratory, last summer wished to have this serum tested clinically at the Loomis Sanatorium, and we agreed to give it a thorough trial. The serum being provided by the government, from purely scientific motives, we were the more ready to test its efficiency. In the manufacture of this antitubercle serum, attenuated cultures, culture fluid, and tubercle bacilli were injected into horses continuously for fifteen months (4,459 c.c. of the fluid being injected in some horses). Animals were experimented upon with the serum from these horses. The following conclusion is taken from the government report: "The experimental results obtained lead undoubtedly to the conclusion that, while the treatment with antitoxin serum is still in the experimental stage and should as yet be used only under the best conditions, we are on the road to success in the treatment of this disease and nearer our goal than ever before." Some of this serum has been sent to L. [illegible]y continuously for the last seven months, and thirty-eight patients have been injected every day or every other day for varying lengths of time with ten minims of the serum, with the following results. A report of the first fifteen cases treated is here given.

Conclusions.—The average number of injections given each patient was thirty-eight. No other treatment was employed. All had the benefit of climate and good food. Four were discharged cured, six improved, and five became worse under the treatment. Eleven gained in weight, two remained stationary, and two lost weight.

I have always considered that any particular line of treatment carried on with patients who are also under the best climatic conditions may not be a very fair test of its efficacy. So I have been using this serum lately on a number of patients in my wards in Bellevue Hospital, but the treatment has not been continued

REPORT OF CASES TREATED WITH ANTITOXIC SERUM

(UNITED STATES GOVERNMENT SERUM, DEPARTMENT OF AGRICULTURE), LIBERTY SANATORIUM.

Number of Case.	Weight. Pounds.	Number of Injections.	Average Dose. Minims.	Reaction.	Gain in Weight. Pounds.	Lung Condition Beginning Injection.	Disease.			Remarks.
							Arrested.	Improved.	Not Improved.	
1	132	26	10	Once.	5	Consolidation right lung, upper portion.	....	Yes.	....	Returned to work. No relapse.
2	128	50	10	None.	11	Slight consolidation right apex. General bronchitis.	Yes.	....	....	Home; works. No relapse.
3	121	54	10	None.	15	Infiltration right apex.	Yes.	....	....	Returned to city.
4	196	48	10	Slight.	15	Consolidation and infiltration right apex.	....	Yes.	....	Returned to Sweden.
5	143	48	10	None.	40	Infiltration both apices.	Yes.	....	....	Returned to work as nurse.
6	104	36	10	Twice.	None.	Consolidation right upper lobe.	....	....	Yes.	Injection stopped at own request. No result.
7	132	30	10	Once.	6	Infiltration both apices.	Yes.	....	....	Worked in city.
8	104	38	10	Twice.	Lost 5	Cavity right apex.	....	....	Yes.	Process commenced in left lung. No result.
9	97	28	8	None.	None.	Consolidation both upper lobes.	....	....	Yes.	Obliged to return home. Still taking injections; improving.
10	109½	40	10	Once.	1	Consolidation and softening right lung.	....	Yes.	....	Improved under treatment. Stopped; returned home; now worse.
11	153	36	10	None.	12	Slight infiltration right lung.	....	Yes.	....	Lost tubercle bacilli. Returned to city.
12	131	30	10	Once.	3	Infiltration right apex.	....	Yes.	....	Physical signs improved.
13	126	36	12	None.	11	Cavity and consolidation right lung.	....	Yes.	....	Cavity smaller.
14	110	18	8	Once excessive.	Lost 6	Consolidation right upper lobe.	....	....	Yes.	No result.
15	113	40	10	Once.	3	Advanced consolidation and some softening right side.	....	....	Yes.	Apparently improved early in treatment. Result not permanent.

long enough to reach any conclusions. If it improves that class of cases, I for one shall believe in its possibilities.

Were I to formulate such conclusions as I have been able to gain of serum therapy in the treatment of tuberculosis as it stands to-day, they would be as follows: None of the serums have marked or immediate effect on the disease. The question is, Should they be expected to? If one tries all the serums, in a disinterested way, it must be recognized at once that they are certainly not inert substances.

One cannot but be impressed with the moral effect which hypodermic injections have on some patients. I have seen in neurotic patients, fever leave and weight increase under daily hypodermics of water.

Dr. Stubbert, the physician in charge of the Liberty Sanatorium, reports that comparative tables of the results of the treatment of phthisis show a balance in favor of serum, in increase in weight, decrease of expectoration, general improvement, and physical signs.

Climatic Treatment.—So far we face the fact that climatic treatment for phthisis is the one to which the profession at large turns—"Where shall we send our tuberculous patients?" being the chief and often difficult question before the doctor. A mistake is irremediable. It is important in many cases to find a suitable place near at home. I should like to call your attention to certain localities within easy access of New York, which I believe from practical experience to be especially suitable for cases of phthisis—their practical test and results being my apology for bringing this familiar matter before you.

1. Morristown, N. J. Here cases of phthisis uniformly do well, especially those patients who have been far away to well-known health resorts and have practically recovered from the disease and are so much improved that it is possible for them to return to a low altitude. A residence in Morristown or its neighborhood for one or two years seems to ward off any return of the trouble, and is expedient should the patient desire later to remain in New York. In advanced cases patients with quiescent processes in their lungs do well also in Morristown, and live there with comfort for years. Its nearness to New York enables the home of a patient to be maintained, even when the head of the family is obliged to go daily to New York for his business.

2. Litchfield County, Conn. In the northwestern portion of Connecticut there is an extensive tract, a thousand to eighteen hundred feet above the sea, where the air is dry, the soil favorable, and where cases of phthisis do exceedingly well. Washington is one of these places, Litchfield is another. I have seen a few patients in the early stages sent to Washington, Conn., and return in a short time cured. While the distance from New York is not great, the train service is so poor, except in summer, that much time (nearly four hours) is spent in getting there—a decided disadvantage.

3. Catskill Mountains. I know of no region to which people are sent for phthisis where more mistakes are made by the physician sending them than the Catskill region. The reason is that in the Catskills there are some of the best "low altitude places" in the world, and at the same time the very worst places that can be imagined for dampness and sudden changes of temperature. There are only a few places in the Catskills where cases uniformly do well, but in these places they do exceedingly well. I have been at pains to drive to almost every place in the Catskills, and know the topography of the region. I have seen the best results from cases sent to Tannersville and Cairo. Stamford, on the southern slope of the mountains, is dry and healthful, but not of high altitude. In the country about Windom and Durham there is a good climate for phthisis, but it is out of the beaten track and somewhat inaccessible.

4. Liberty, Sullivan County, is located on the main line of the New York, Ontario, and Western Railroad, one hundred and nineteen miles from New York, and has an elevation of from sixteen to twenty-two hundred feet above tide, the highest elevation between New York and the Great Lakes. Recent developments seem to indicate that the vicinity of Liberty will soon become one of the most popular resorts in the East for those suffering from pulmonary troubles. I consider, as my father did during his lifetime, that Liberty and the country contiguous to it offer for the cure of phthisis the best climatic conditions of any place within easy access of New York. The elevation of eighteen hundred feet or thereabouts is especially suited to incipient cases occurring in the young and those of middle life. The open condition of the country, with its plateau-like situation, and the constant movements of the air currents render the climate exceedingly dry. The noticeable purity of the air and the absence of all fogs and dampness are valuable elements, which in my opinion contribute most largely to the beneficial results observed after a residence in this locality. The summers are cool and marked by no sudden changes in temperature. The winters are characterized by a large number of clear, cold, exhilarating days with abundant sunshine.

5. The Adirondacks. The advantages of the Adirondack region over all those of easy access to New

York is the extent of country which is suitable to cases of phthisis. The high, rolling forest country varies in elevation from sixteen to eighteen hundred feet, and extends north and south for nearly a hundred miles, and east and west for about forty miles. There are virtually no unsuitable places for cases of phthisis in all this tract. My experience bears out the fact that cases do as well in the Fulton chain at the south as at Paul Smith's on the north, and that the western portion of the woods is even better suited to pulmonary cases than the mountain region of the east. Another reason which makes the Adirondacks so beneficial is that patients find here so much to do out of doors. The network of lakes and rivers adds diversity to the landscape, and affords easy communication throughout the interior of the country by means of light boats. The facilities for camping, hunting, and fishing add interest to the daily life of those in the early stages of the disease, so that their minds are diverted and their spirits raised—points of greatest importance and which more restricted health resorts do not offer. The distance from New York (ten to fourteen hours) necessitates severance of home ties, and often practically isolates the invalid from home connections—an unfortunate condition which is not attached to an enforced residence in more accessible localities.

CORRESPONDENCE BETWEEN A LAYMAN AND A SURGEON ON THE SUBJECT OF APPENDICITIS.

By ROBERT T. MORRIS, M.D.,
NEW YORK.

A MEMBER of the faculty of Yale University recently expressed to me the opinion that "between the ethics of physicians and the controversies on the subject of appendicitis, the laity were kept quite in the dark." This idea, coming from a man of wide learning, and alert to comprehend affairs in general, led me to write him, upon my return to New York, requesting him to ask a series of the most direct questions, including points that a layman might think about, even though he did not express them in conversation. His letter is here presented, together with my answers, given *seriatim*:

"NEW HAVEN, CONN., March 1, 1898.

"DEAR DR. MORRIS: The anxiety occasioned by the sudden suggestion on the part of a physician, called in to see my wife in a distant city, that an expert surgeon be called at once to operate for appendicitis, together with the experience following—viz., her recovery without any such operation, which I fear would have been fatal, because of her state of physical health in general, had it been attempted—lead me to ask the following questions:

"1. Is not the public needlessly suffering not only painful operations, but also death, because of the general belief that the only genuine cure for appendicitis is the removal of the offending member?

"2. Does not the very fact that successful operations require more than ordinary skill lead the family physician to call in the help of a specialist in cases of simple doubt and fear, on his part, rather than certain diagnosis that his patient has an acute case of inflammation which will yield only to surgical means?

"3. Are not the patients, thus given over to the specialists, operated upon out of professional courtesy, even when the specialist may know that the case does not require the operation for the immediate safety of the patient?

"4. Is not the expert operator tempted to take advantage of such "safe" cases, both for his own reputation and practice?

"5. Is not the temptation still greater for the inexpert beginner, to whom such a case is given, to try his hand when the chances are better for a successful operation, even when he knows that the symptoms do not warrant an operation?

"6. Is it possible for the ordinary inflammation of this part of the intestinal canal to be distinguished from inflammation of the appendix proper, except by expert physicians?

"7. Is it not entirely possible, by other than surgical means, to relieve inflammation of this part of the intestine?

"8. Are cases of appendicitis proper, when cured by other means than the removal of the appendix, any more likely to recur than inflammations (severe) of other parts of the intestines?

"9. Is it a fact that an expert surgeon can or cannot discriminate the appendicitis symptoms better than the ordinary family physician?

"10. Does the courtesy between the members of the profession permit the patient to get the benefit of mistakes made by the family physician, after the surgeon is actually called to assist?

"11. Is it possible by simple statistics, such as can be obtained, to ascertain after the operation has been performed whether it was needless or not?

"12. Is it possible to inform the public of the facts, known only to the surgeon, as to whether death, when it occurs, is due to the original disease or to faulty or unwise operation?

"13. Why is it necessary that there be controversy regarding these questions?

"14. Why are mere statistics of the number of cases recovered, the number lost, and the number of known cases of renewed attacks unsatisfactory as means of reaching the real importance of the surgical method of treatment, as compared with other modes of treatment?

"I have put down a lot of very plain questions, as you requested me to do. I think they will convey the nature of the queries in mind, in regard to the use of surgical means for allaying appendicitis symptoms.

"It is the danger of the operation in inexpert hands, the helplessness of the patient or his friends when the operation has been recommended, and, third, the feeling that the surgeon (unless a tried expert) does not appreciate, or perhaps does not assume, in all cases, the responsibility which has been handed over by the family physician, which most affect me in judging the case. I would like to know what replies can be made to these questions in public, and I think every one would like to know what the profession can reply to them.

"Unless they can be answered directly, the doubts will still remain; evasive answers are not necessary to impersonal questions. If you can, in replying to such questions, defend the use of surgical methods as the best means of treating appendicitis, my opinion is that you will score a most important point for your side of the profession.

"With sincere regards,

"——— ———."

Answers.—1. It has been determined from statistics of many hundreds of operations, at the hands of several American surgeons, that the surgical death rate in appendicitis is less than one per cent. in the class of cases in which infection is limited to the confines of the appendix proper. This includes primary-infection cases before infection has spread beyond the appendix, and it includes the so-called "interval cases," or cases in which one or more acute attacks of bacterial invasion of the appendix have subsided, leaving a more or less damaged appendix which is not being actively attacked by bacteria. It has been de-

termined from the statistics of several American surgeons that proper surgical operation in cases of widespread infection outside of the confines of the appendix proper can lower the death rate in this class of cases to about five per cent. in unselected consecutive series of cases, operation being performed upon all patients who are still living when the surgeon arrives. It has been determined that the death rate in appendicitis, treated by any sort of medical treatment, is not likely to be less than twenty-five per cent. eventually, although it is believed that the death rate in first attacks is not much above ten per cent.[1]

Your expression, "painful surgical operation," is a phrase that came into use before modern surgery occupied the field. In order to determine if appendicitis patients suffer as much under surgical treatment as they do under medical treatment, I addressed letters to ten consecutive appendicitis patients of mine who had been operated upon, beginning with the last one out of bed and going back ten. Some of these patients had been "cured" several times by medical treatment of the various approved forms, and some of them, no doubt, had been congratulated by their physicians and friends on having escaped "painful surgical operation." I wish particularly to avoid giving the impression that the answers from my patients are very different from answers that would have been given by the patients of any other surgeon who pretends to be familiar with proper methods of operating.

This was my letter:

"DEAR ——— ———: In order to get statistics for comparison, I am asking ten consecutive appendicitis patients to state which causes the most suffering—an attack of appendicitis treated medically, or an attack treated surgically. Please answer in less than twenty words, as I wish to publish the reply over your initials.

"Yours truly, etc.,

"———— ————."

The answers from each patient are here given, following a brief description of the case:

Patient No. 1.—Dr. G. L. H——. Aged twenty-five. Has lost one brother and one first cousin from appendicitis treated medically. Another first cousin was operated upon at Albany last week, and is recovering. Another first cousin has had one attack and is to be operated upon. G. L. H. has had several attacks, some serious, some mild. Appendix contained a mucous inclusion. Adhesions not troublesome. Interval operation.

Patient's answer to letter:

"I am pleased to say that I suffered much less under surgical than under medical treatment, and recovery was more rapid. G. L. H."

Patient No. 2.—Mr. J. S——. Aged twenty-nine. Has had two violent attacks. Appendix removed on seventh day of second attack. Three large abscesses in abdomen. Complicated adhesions. Appendix gangrenous. Patient in critical condition before operation.

Patient's answer to letter:

"In my case surgical treatment proved to be almost painless, while under medical treatment my sufferings were intense. J. S."

Patient No. 3.—Mrs. J. N. B——. Aged forty-three. Two attacks. First one mild, second one more severe. Removed appendix in fourth week of second attack through short incision. Appendix adherent only at tip. Slow ulceration of inner coats in progress.

Patient's answer to letter:

"I suffered severely under medical treatment for appendicitis, and felt no pain whatever under surgical treatment. MRS. J. N. B."

[1] See "Analysis of Cases," "Lectures on Appendicitis," second edition, medical libraries.

Patient No. 4.—Mrs. E. P——. Aged fifty-two. Had a "grumbling" appendix without marked symptoms, excepting local tenderness and protracted temperature elevation at various times during many years. Appendix removed through short incision. Chronic ulceration about an entrapped concretion in lumen of appendix. No adhesions.

Patient's husband answered:

"In answer to yours regarding my wife, she would prefer an operation to medical treatment.

"E. P."

Patient No. 5.—Dr. J. B. H——. Aged thirty-three. Four well-marked attacks. Appendix removed through short incision. Second week of fourth attack. Appendix structures markedly hypertrophic. Appendix sharply angulated upon itself and firmly adherent at all points. Evidence of former perforation at site of angulation.

Patient's answer to letter:

"I suffered a great deal more under medical treatment than I did under radical treatment.

"J. B. H."

Patient No. 6.—Miss L. W——. Aged twenty-four. Several short, sharp attacks. Continual discomfort and steadily failing health for past six months. Removed appendix through short incision. No adhesions. Proximal two inches of appendix converted into narrow string of connective tissue. Distal inch formed a tense distended mucous inclusion.

Patient's answer to letter:

"No comparison between medical and surgical treatment of appendicitis. The former is torture, the latter painless, with blissful results. L. W."

Patient No. 7.—Mr. J. F——. Aged thirty-six. Several attacks, some violent, some mild. Constant pain and failing health for some months since last attack. Appendix removed through short incision. Complicated adhesions. Two mucous inclusions, each containing a concretion.

Patient's answer to letter:

"By all means surgical treatment is less painful and quicker over. J. F."

Patient No. 8.—Mrs. R. M. L——. Aged forty-seven. Two well-marked attacks. Appendix removed in sixth week of second attack. Local adhesions. Inner coats of appendix nearly disappeared through chronic ulceration.

Patient's answer to letter:

"My suffering was greater under medical treatment for appendicitis than under surgical treatment.

"MRS. R. M. L."

Patient No. 9.—Mrs. L. L. C——. Aged twenty-five. One mild attack, one violent one complicated by pregnancy five months advanced. Removed appendix on third day of the violent attack. Dense general adhesions. Appendix gangrenous. Abscess forming.

Patient's answer to letter:

"My suffering was more intense for the three days prior to surgical interference than during all of the subsequent days. L. L. C."

Patient No. 10.—H. G. A——. Aged fourteen. Several mild attacks, one violent one. Appendix removed on fourth day of violent attack. Complicated dense adhesions. Abdominal abscess. Appendix perforated. Contained very large concretion.

Patient's answer to letter:

"I had no relief from suffering until morphine was administered. After the operation was free from pain and recovered rapidly. H. G. A."

We frequently have patients back at their occupations in less than two weeks after operation for appendicitis, after they have previously spent weeks or months in bed with various attacks, under the impression that they were going to save time by depending upon medical treatment. These short-confinement

cases are of course the primary or interval cases, in which infection is limited to the confines of the appendix at the time of operation.

Answering the professor's question No. 1, then, I would say that the death rate in appendicitis under proper surgical treatment, at the proper time, as compared with the death rate under any sort of medical treatment, is apparently at least twenty-five to one in favor of surgical treatment. The letters from the ten patients quoted indicate that the suffering under surgical treatment is less than the suffering under medical treatment. The loss of valuable time is less under surgical treatment than under medical treatment.

2. The typical family physician cares, first of all, for the best interests of his patient, and he cares very little for the opinion of the surgeon or of any one else, unless in his opinion the patient is likely to profit by the consultation. In cases of "simple doubt and fear on the part of the family physician," a good consultant often sets matters right, and the physician has the comfort and peace of mind that goes with actual knowledge about his case.

3. I do not know of any responsible surgeon who would operate until he felt sure of his diagnosis of appendicitis, unless he found some other condition sufficiently serious to warrant operation. It is usually an easy matter for one who is at all expert to make an accurate diagnosis of appendicitis, but sometimes a pelvic abscess or tuberculosis of the peritoneum, for instance, may make diagnosis difficult. Both of these conditions, however, require operation.

I do not know of any surgeon who would operate out of courtesy for the opinion of the family physician, and I do not know of any physician who would allow a surgeon to operate unless the surgeon had presented sufficient evidence to convince the physician that operation was advisable.

4. I regret to say that I do know surgeons who consider their reputations, and who have not the moral courage to stand up to their knowledge and give a dying patient his chance for recovery. Their argument is that it is better to let the desperate-case patients die, because the people do not know the difference between desperate cases and safe cases. Appendicitis is appendicitis to the public mind. Safe-case surgeons argue that if, in a desperate case, the patient dies after operation, the patients with safe cases who hear of it are likely to procrastinate until their cases also become desperate cases, and thus the death rate actually becomes larger than it would be if the desperate-case patients were allowed to die without help. Unfortunately their argument is quite true at the present day. There are other surgeons whose sense of moral obligation is so great that they try to help the desperate-case patient without regard for reputation, and they try to educate the laity and the profession to a higher plane. They know that more deaths result from "using bad surgical judgment" in trying to help desperate-case patients at present, but they believe that progress can be made only by sacrificing reputation and fighting for the right, instead of trimming their sails to "policy." The expert operator who is tempted to take advantage of safe cases only never becomes as expert as the operator who cannot find a case too desperate to call forth his full sympathies, resources, and powers. The most expert surgeons prefer, for their own sakes, to operate in the most desperate cases, because such cases offer limitless opportunities for application of knowledge and skill.

5. The inexpert beginner may get into trouble if he tries appendicitis work before he has had preliminary training in easier kinds of abdominal surgery first, but my faith in the actuating motives of surgeons is such that I do not believe that an inexpert beginner would be tempted to subject a patient to operation for appendicitis unless he felt sure of his diagnosis. Symptoms sufficient to establish the diagnosis of appendicitis are sufficient to warrant operation regularly in appendicitis. Personally I would allow my junior assistant on the hospital staff to operate upon me for appendicitis, rather than try the best medical treatment for one day.

Surgeons are actuated, first, by the desire to save life and to prevent suffering; then comes the desire to employ their personal skill in accomplishing the work. Last of all comes the idea of a fee. Some of us like to ask patients to pay several thousand dollars occasionally for a life-saving operation that requires the highest degree of skill and training for its successful accomplishment, but I do not know a surgeon who will not gladly operate for no fee at all in a case in which the family physician states that the patient cannot pay a fee.

6. It is hard to imagine one so inexpert as to find much difficulty in making accurate differential diagnosis between appendicitis and other inflammations of the cecal region. The diagnosis of appendicitis is usually as easily made as the diagnosis of a broken leg, yet I have known physicians, instead of making a proper diagnosis, to call their appendicitis cases by other names—as typhoid fever, or hip-joint disease, or colic, or gastritis, or bowel obstruction, or any of many diseases. A physician with an average general practice should see about four appendicitis cases annually.

7. It is possible by medical means to relieve many appendicitis cases, but it is impossible for any physician to tell in advance which cases are curable by medical means and which ones are not. That point is always determined afterward. If we try medical treatment first and wait to see which cases will respond to medical treatment, the ones which will not respond have passed into the complicated stage before operation is made, and thus precious opportunity is lost. In view of the fact that proper surgical treatment at the proper time allows less suffering, less loss of time, and fewer deaths than the best medical treatment, it seems wise to have all doubts settled by prompt operation. That leaves no room for doubt, and it makes appendicitis such a controllable disease that it becomes one of the least dreaded of all diseases. When I am in the city I have no fear of the disease personally.

8. Cases of appendicitis "cured" by medical means are almost certain to recur. The commonest reason for this is because a scar results from the first inflammation, and this scar contracts and incarcerates the contents of the appendix, entrapping many bacteria. This is known as a mucous inclusion. The bacteria in a mucous inclusion have a habit of suddenly increasing in numbers from time to time. Another common cause for recurrence is the presence of concretions in the interior of the appendix. These concretions occur in about twelve per cent. of appendicitis cases, and, like the scars of mucous inclusions, cannot be reached by any medical treatment. Another common cause for recurrence is blocking of some of the blood-vessels of the appendix by the first inflammation. An appendix with some of its blood-vessels blocked is particularly vulnerable to onslaughts of bacteria later. Some appendices giving the mildest of symptoms are infected with tubercle bacilli. Some appendices contain bowel parasites which cause repeated attacks of ulceration.

The argument that we should not remove the appendix because it may have some undiscovered use is made by people who do not know that the appendices which are removed have usually had their function already destroyed by the bacteria. Bacteria remove many more appendices than are removed by the surgeon. Appendicitis is nothing more or less than

destruction of the appendix by bacteria, and the surgeon who removes the infected appendix removes the nest of bacteria, as the gardener removes the nest of the tent caterpillar from his apple tree.

9. The question of ability to recognize the symptoms of appendicitis is one that rests with the diagnostic acumen of the individual, and there is no distinction to be made on the ground that the individual is a physician or a surgeon. On consulting my record books, I find that I have operated upon twenty-eight appendicitis cases for the physician who asked me to see your wife, and he has had a number of other cases operated upon by other surgeons—about forty cases in all I am told—and in none of these has he been mistaken in his diagnosis, although many of the cases were complicated ones. On the other hand, I have known surgeons of recognized ability to go astray on the diagnosis. The careful observer who has improved his opportunities for observation seldom makes a mistake, and when he does it is commonly for some condition which needs operation just as much as if the case were one of appendicitis.

10. The patient gets all of the benefit whenever mistakes made by the family physician are corrected by the surgeon who determines that a case is not one for operation. Professional courtesy never takes precedence over personal honor, in my circle of surgeons at least.

11. It would be a simple matter to determine on examination of the specimen whether the operation was needless or not. I am not acquainted with first-class surgeons who would be willing to remove a normal appendix. One hears a good deal of that sort of thing, but it usually originates as a joke or the attempt of some ill-natured individual to injure a successful rival. It is part of the function of a responsible surgeon to quiet the fears of timid people who come to him with imaginary cases of appendicitis.

12. Death, when it occurs after operation at the hands of a successful surgeon, is more often due to continuance of uncontrollable infection, rather than to faulty or unwise operation. The unskilful operator is apt to be a timid operator, who leaves work unfinished when he finds himself among complications, and there are unfortunately many cases of this sort in which infection continues unnecessarily.

13. There is necessity for very little controversy on appendicitis questions. Few diseases are so thoroughly understood. The origin, the symptoms, and the results of appendicitis have been clearly described and scientifically classified by authors. Controversy is mostly carried on by men who are not familiar with the works of authorities upon the subject, and a large number of physicians and surgeons are constantly on the point of discovering facts that have already become classical. A trained controversialist, who opposes the rule to operate immediately on making the diagnosis of appendicitis, can be floored by a boy who will ask these questions: (1) Can you tell in advance in which cases infection is to remain within the confines of the appendix? (2) Is not the operative death rate less than one per cent. at the hands of several American surgeons in cases operated upon before acutely progressive infection has extended beyond the confines of the appendix itself? (3) Are not the death rate and the suffering rate and the loss-of-time rate much greater under either medical or surgical treatment after infection has spread beyond the confines of the appendix itself? These questions, left to deliberation by a logical mind, lead to a logical conclusion which needs no elaboration in these pages. The death rate from appendicitis in the United States alone is estimated from safe data to amount to considerably more than fifty thousand annually.[1] This is mostly a preventable death rate. The distressing part of it is the thought that such a large preventable death rate attracts so little attention, while widespread interest would attach to the killing of fifty thousand of our citizens annually by a hostile nation in war. There is presumably no reader of these lines who has not lost friends and acquaintances unnecessarily from appendicitis. Many patients are not within reach of skilled surgical service at the time of their first attack, but such patients who recover can be sent to the nearest point for skilled services and have the appendix removed "in the interval" before the next attack comes on.

A careful examiner can usually determine by palpating the appendix, after the patient has recovered from a first attack, if the appendix contains a mucous inclusion or a concretion, or if it is otherwise disabled. There are few patients so poor in money or in friends that they cannot pay railway fares that will take them to some proper surgeon.

When a patient dies from appendicitis to-day we are to assume that somebody is culpable. Sometimes it is the physician, who allows the case to drift into desperate infection while thinking that it will improve every day. Sometimes it is the surgeon, who does an incomplete or unskilful operation: but more often it is the friends of the patient, who fearlessly take the responsibility of giving bad advice. The patient himself usually desires early operation. There is an indescribable appreciation of the gravity of the case on the patient's part, and whenever I am called in consultation to a house where one physician advises operation and another does not, where part of the family desire operation and another part does not, I customarily say, "Let us leave it to the patient." I do not remember a case in which the patient has not said, "Operate."

14. Statistics on the surgical side are satisfactory, because they have been carefully compiled. Statistics on the medical side are unsatisfactory, because they lack essential features. They should describe the number of deaths, the number of recoveries, length of time wasted in bed, the condition of the patient's general health in the interval between attacks, and the condition of the appendix as revealed by palpation. Observations should have some stated time limit, say five years, for instance. No one has ventured to give us any medical statistics of this sort. Physicians of my acquaintance who followed up their cases in this truly scientific way for a while soon became convinced that their appendicitis patients needed prompt operation, and they stopped trying to get medical statistics. Every now and then some physician publishes a slovenly compiled list of appendicitis patients cured by medical treatment. The reason why such statistics are readily determined to be absurd is because we know what a large proportion of the "cured" patients still carry incurable mucous inclusions and concretions and tuberculous foci, or chronic abscesses. Such statistics seem to be offered usually in a spirit of controversy, and they are extremely mischievous, because they are often believed in by physicians and by laymen who are not familiar with our classified data on the real pathology of appendicitis. The subject is thoroughly understood by a part of the medical profession.

Sterilization of Laryngeal Mirrors.—Dr. Körner (*Monatsschrift für Ohrenheilkunde*, No. 10, 1897) claims that laryngeal mirrors may be sterilized in a boiling soda solution without injury, provided the plating is of quicksilver, not tin amalgam, and the covering is of copper. The mirror must be immersed in water heated almost to the boiling-point, and dried immediately after removal.

REASONS WHY THE PLACARDING OF HOUSES IN WHICH ARE PERSONS SUFFERING WITH SCARLET FEVER OR OTHER CONTAGIOUS DISEASES SHOULD NOT BE CONTINUED.[1]

By ARTHUR V. MEIGS, M.D.,

PHILADELPHIA, PA.

It may be that some of those who are present have not fully informed themselves in regard to the law which governs the present practice of the Philadelphia board of health. It is an act of June 18, 1895, and section 2 reads as follows:

"Section 2. Upon receipt by the health authorities of a report of the existence of a case of cholera, small-pox (variola or varioloid), scarlet fever, typhus fever, yellow fever, relapsing fever, diphtheria, diphtheritic croup, membranous croup, or leprosy in any of said municipalities, they may at once place or cause to be placed in a conspicuous place or places upon or near the house or premises in which said case may be located, a placard or placards upon which shall be printed in large letters the name of the disease from which the person or persons in said house or premises may be suffering as aforesaid, as the case may be. Provided that variola or varioloid shall be placarded as 'small-pox,' and that diphtheritic croup and membranous croup shall be placarded as 'diphtheria,' and said placard or placards shall remain thereon until such time as the rules and regulations established by the health authorities regarding the destruction or disinfection of infected bedding, clothing, or other articles which have been exposed to infection and the disinfection of houses and premises have been fully complied with. Provided that in addition to the placarding aforesaid, or in lieu of the same, the said health authorities may place a guard or guards upon said house or premises."

The point to which I wish to direct attention is that the law distinctly provides that placards *may* be placed upon houses, but that their use is not obligatory. It is desirable that every physician in the city should know that this whole question is absolutely in the hands of our local health authorities. The board has the power, if it should see fit, by the simple passage of a resolution, to change to-morrow its procedure and cease the use of placards.

The temptation to enter upon a detailed arraignment of the board of health of our city, both of its constitution and its administrative methods, is strong, but it would not be wise to do this now. It is enough at present to call attention to a few defects. Although the board is composed of six members (including the director of public safety, who is *ex officio* its president), two only are physicians. Whatever may be said of the physicians, it is certain that the other members have never been chosen because of their knowledge of sanitary science. Such being the composition of the board, let us pause a moment to consider in what manner it has administered its important functions. It must be conceded in the first instance that its duties are of such a nature that it often incurs unpopularity because its actions cause hardship to individuals. Are there heard in our city no expressions of disapproval of the board except these unavoidable ones which have been indicated? Far from it; as well as I can learn, all classes of people who come in contact with the board—citizens who suffer from sickness, physicians, plumbers, and undertakers—all alike condemn both the rulings of the board and its administrative methods.

I will give only two instances as types of unwise actions of the board—one to show the wrong it is capable of doing physicians, and the other as an illustration of the iniquitous behavior of one of its inspectors. In the early part of last summer the board by resolution directed the health officer to prosecute a physician for not having reported a case of scarlet fever. When the case was called in court it was shown that at the time of the first visit the diagnosis was not made. A second visit was not desired by the people, and the patient was not seen again until ten days or more afterward, when, on being summoned to the house and finding the patient to be suffering with dropsy and the skin desquamating, the physician judged the disease to be scarlet fever and at once reported it as such. The magistrate decided that as the case had been reported as soon as the nature of the disease was recognized, no offence against the law had been committed, and accordingly the physician was ordered to be discharged. What are we to think of a board which is so ignorant of the law or so careless of the rights of physicians as to subject one of them to the expense, humiliation, and injury of prosecution upon such flimsy grounds?

The second case is as follows: Within a few weeks a physician was called to the house of a man belonging to the working class, where he found a child with scarlet fever. The mother did not wish her child taken to a hospital, and, therefore, after investigation to satisfy himself that the house was in good sanitary condition, the physician reported the case and certified that the patient could "be properly cared for at home," and that the premises did not "need sanitary inspection." Notwithstanding this, the medical inspector of the board of health came to the house and rudely told the mother that she would not be allowed to keep her child at home and that the ambulance would come the next day to take the patient to the hospital. The ambulance never was sent, but a few days later the inspector returned and was much more polite, not so much as alluding to any necessity for the removal of the child to the hospital. What can be thought of an official inspector, whose duties necessitate constant intercourse with people in trouble owing to sickness, who could be so wantonly cruel and brutal as to indulge in an idle threat against a poor mother nursing her sick child, when the event proved that there was neither intention nor power to execute the threat?

The board of health is responsible for all misbehavior on the part of its officials, and if it continues in its present course of folly there is danger that at last our long-suffering people will rise up in rebellion against the injuries that are done them; and then sanitary science and the march of improvement will receive a check from which they can recover only very slowly, because measures that entail great hardship upon individuals can be put in execution only if supported by public opinion.

Last summer I took occasion in London and Paris to make inquiries in regard to what is done in the management of contagious diseases occurring in those cities. In London I was referred from the embassy of the United States to the local government board for information, and in Paris the secretary of the consul-general advised me to inquire of the administration générale de l'assistance publique. I was told that no such thing as placarding is done in either city. What struck me more than anything else in my interviews was that in both cities the officials seemed greatly impressed with the necessity of avoiding running counter to the sentiment of the medical profession. In London the official smiled when I told him of yellow placards, and said, "Our people would not submit to that." In Paris it was evident that the sentiment against any intrusion upon family privacy is so strong that the

[1] Read before the College of Physicians of Philadelphia, February 2, 1898.

government dreads rousing opposition upon this point. The feeling in France in regard to the sacredness of family privacy is well known by every one who has bestowed any consideration upon French customs.

There may be some here who will say that it is nothing to us in the United States what they do in Europe. Such a sentiment is very narrow-minded. Conceit in regard to the perfection of our own methods is as unbecoming as would be a slavish imitation of European customs. Our only wise course is to acquire information wherever we can get it, and to adopt improvements regardless of their source. It is therefore very important that we should be fully informed in regard to what is doing in Europe. Sufficient attention is not paid at present in this country to the opinions of physicians in regard to questions of health. It seems as if the guidance of sanitary legislation and its management had passed into the hands of politicians, and that little or no reliance is placed upon the statements of the physicians who actually attend the sick. This is a most foolish thing, for in the end it is upon the physicians that municipal and rural officers of the law must depend for much of their information in regard to disease, and if the ill will and opposition of the former are incurred little can be accomplished. In England the law provides that every time a physician makes a report of a case of contagious disease he is paid two shillings and sixpence if the case is in his private practice, or one shilling when the report is made as officer of an institution. If our city would send a commission of two or three properly qualified persons to study and report upon the methods of sanitary procedure in Boston, New York, Washington, and Chicago, and then in London, Glasgow, Paris, and Berlin, a great deal of useful knowledge would be acquired which is very much needed. At present our health authorities are not going about the matter in the right way. The diseases which may be placarded, according to the law of 1895, are of the kind against which most can be accomplished by efforts looking to their prevention, for which little or nothing is being done. Our health authorities should direct their efforts to cleanliness and measures to improve the general hygiene of the city instead of advertising by the posting of yellow placards the existence of disease after it has come. The right method is for the physicians to notify and the health officers to prevent.

There are several reasons why houses should not be placarded and various ways in which placarding is productive of harm. The state of panic created in the public mind is certainly an evil, for it is perfectly well known how difficult it is to deal with frightened people. Probably the greatest harm which comes from the enforcement of placarding is that it greatly increases the number of cases that are concealed. The public and physicians join hands in this practice, and it is only what might be expected. Respectable physicians have told me that they never report cases of diphtheria if they can avoid it, or report them only when they think death is imminent and the risk of detection becomes very great. In a pamphlet entitled "Rules for the Management of Contagious and Infectious Diseases by the Sanitary Committee, Adopted by the Board of Health, May, 1893," there is included an extract from the "Supplement to the Reference Handbook of the Medical Sciences," by William H. Ford, M.D., president of the Philadelphia board of health. Among other things in this extract, which is incorporated as an integral portion of the "Rules," is the following: "There is a difference of opinion as to the advisability of placarding houses in which contagious or infectious diseases exist. There are benefits to be derived from warning the public of danger; but on the other hand the common aversion to the requirement may lead to the suppression of the true knowledge of the disease, which may be attended with disastrous consequences. Under a well-organized system of sanitary inspection this practice might be dispensed with." As the late president of the board of health expressed himself in this manner and his opinion received the official indorsement of the board only two years before the same board adopted the practice of placarding houses, why is it not its duty to institute the "well-organized system of sanitary inspection," which the board itself declared would enable it to dispense with the oppressive practice of placarding?

The placarding of houses for contagious disease involves trampling under foot the rights of individuals and such violent intrusion upon family privacy that we ought to pause and ask if we are not in danger of losing one of our precious heritages derived from our English origin, that "every man's house is his castle." How much immunity from disease have we obtained in return? The mortality records would seem to indicate that we are less free from typhoid fever and diphtheria in Philadelphia than they are in London, where yellow placards are never used, but where there is a good sanitary system.

THE NODES OF RANVIER.

By EDGAR J. SPRATLING, B.Sc., M.D.,

PALMER, MASS.,

FIRST ASSISTANT PHYSICIAN, MASSACHUSETTS HOSPITAL FOR EPILEPTICS.

These seem to be organs for the reception of sensory impulses, thus acting as a means of co-ordinating sensation, and not simply bands constricting a nerve fibre to equalize the white matter of Schwann, that being a secondary and purely mechanical function. In support of this let us give the following facts: There are no nodes in the tracts of the brain, in the cord, in the sympathetic system, or in the centres of the larger nerve trunks. The frequency of the nodes on a fibre is in proportion to the sensory or tactile power of that fibre. An injury of the brain parenchyma, cord, or sympathetic system cannot be localized by the injured individual. The nodes, as accessories to the terminal plaques, receive sensation through the so-called constricting band, which is in immediate contact with the axis cylinder, not being separated by the neurilemma; the neurilemma itself terminates in segments (excepting its outer layer, which covers the bands and the plaque), just as does the white insulative matter. This constricting band is identical histologically with the axis cylinder, so far as can be determined, after it is stripped of its neurilemmal covering. Silver nitrate does not easily penetrate the neurilemma between the bands; consequently the insulative matter is nearly, if not quite free from stain, while a nodal band and, continuous with it, the cylinder are intensely stained, showing their intimate contact. With aniline stains their behavior is relatively the same. How then are we to ascribe different functions to a homogeneous whole? We cannot; on the other hand, we can prove, circumstantially at least, that their uses merge into one another. For example, tease out a single fibre—the longer the better, and preferably with a terminal plaque (chemically pure glycerin will prove the best teasing-medium); have a microphone or finely adjusted telephone earpiece connected with a very weak interrupted-current battery; cut the afferent wire and solder a fine needle to each of the cut ends. Now place the nerve fibre in the microscopic field in order to gain facility in the application of the needle to the nodes, internodes, plaque, and cut end; the fibre must be still moist. Place the observer at a distance from the battery to avoid confusion of the buzz, having fixed one

needle in a position alternating with the other from node, plaque, and internode, without the observer's knowledge of the part being touched. The sound will be more than double in intensity when a node rather than an internode is touched, showing its superiority in the matter of conductivity. Substitute now a rheoscope from the earpiece and note the difference in deflection. This seems to prove that the node is capable of receiving impulse in nearly if not quite equal degree with the terminal plaque. That they are coordinators is suggested by the fact that one cannot localize the pain in the severed nerve trunk; but let the surface of the trunk be irritated and the sensation is at once assigned to the proper spot. Yet we do not deal with terminal plaques. Only those fibres nearing the part from which they are to convey sensation possess frequent nodes, and then always in direct proportion to the quality of the function that they are to fill.

Progress of Medical Science.

Hysteria in Childhood.—The *Centrablatt für Nervenheilkunde und Psychiatrie* (December 11, 1897) contains an abstract of a lecture by Dr. L. Bruns on the above subject. The author holds the same view as Möbius, and believes that the general symptoms of hysteria are of psychical origin and that such symptoms only should be regarded as hysterical as can be called forth by the will or can be simulated. Symptoms referable to organic lesions do not occur in uncomplicated hysteria. The hysteria of childhood forms about twenty per cent. of all cases, is equally frequent in both sexes, and is not influenced by social station. Hereditary taint often exists. Mimicry and careless bringing up are etiological factors. The periodical outbreaks depend upon some psychical disturbance, such as fright or fear. In development the symptoms are often monosymptomatic. Hysterical stigmata are most often absent; hystero-epileptic attacks rarely occur. The monosymptom is usually marked (hystérie maissive). Paralyses in all degrees, flaccid or with contractures, usually without involvement of the face, are common. Less often are there sensory disturbances; the writer has never observed complete hemianæsthesia. Other symptoms are astasia and abasia, mutism, stuttering, blepharospasm, wilful tremor seldom, choreic movements oftener, tic convulsif, grimace movements, chorea rhythmatica, hemiepilepsy, hystero-epileptic convulsions. Major convulsions are rare; usually the hysterical attacks are dependent upon a psychical basis; *e.g.*, somnambulism, chorea magna, and also hysterical cough, rapid breathing (tachypnœa). True neuralgias seldom occur; more often joint neuralgias. Single amblyopia or amaurosis of one eye, facial spasm, deafness, deaf-dumbness, sometimes dysphagia, anorexia, with refusal to take food. Seldom œdema. Occasionally trophic disturbances as a result of self-injury. The children are usually petulant, unruly, often wilful. The prognosis is good; the child is more easily influenced psychically than the adult. The treatment should be entirely psychical; foremost stands isolation. The child must be removed from its previous surroundings and completely separated from its parents; if possible, it should be placed in an institution. The family "doctor," being familiar to the child, impresses the child less authoritatively and has less power of suggestion than a strange physician. There are two methods of treatment—the one by moral chastisement, the other by wilful disregard of the symptoms. The first is more rapid and more certain. When possible it should be enforced at one sitting, until a cure is effected. The subjective psychical treatment, especially in the form of energetic verbal suggestion, is preferable to the objective (electricity and hydrotherapy). Hypnotism is not to be recommended. If the physician does not succeed, he is not to recommend illegitimate medicine; on the other hand, he should not necessarily prohibit its use, since a cure therefrom occasionally results.

Subcutaneous Rupture of the Spleen, Extirpation, Cure. — Dr. B. v. Beck (*Münchener medicinische Wochenschrift*, 1897, No. 47) gives the history of a case of splenectomy. A nineteen-year-old coachman fell from his coach seat and was run over by a wagon weighing about eight hundred pounds; the front and hind wheels were said to have passed transversely across his abdomen. There were temporary loss of consciousness, frequent and severe vomiting. He was brought to the hospital in a state of collapse, and the diagnosis of profuse intraperitoneal hemorrhage from rupture of the spleen was made. An intravenous salt-solution transfusion of five hundred cubic centimetres was at once given. Under chloroform, median laparotomy was performed. From the abdominal cavity seven hundred cubic centimetres of fluid blood was removed. In the splenic region about five hundred cubic centimetres of coagulated blood was removed, after which the spleen, bleeding fairly freely, could be seen. On the concave side near the hilus the spleen showed a rupture running transversely through the whole organ; on the convex side some small tears could be felt. The incision was enlarged by one running to the left hypochondriac region. The spleen could thus be isolated; the vessels at the hilus were ligated with silk, the spleen was removed, the abdominal cavity washed with salt solution, and the abdominal incision sewed up. A further intravenous transfusion of two hundred cubic centimetres of salt solution was then given. There was no fever after the operation. A slow recovery from the severe anæmia followed. The patient was up after four weeks. The indication in this case for a splenectomy was very clear. Since suture of the spleen would be too long a process and not reliable, the operator gives great weight to the transfusion in this case. The only pathological symptom noticed after the extirpation was the slow regeneration of the blood, both as regards the hæmoglobin and the number of red and white corpuscles.

Changes in the Skin in Acute Rheumatism, and Observations on the Nature of Erythema Multiforme.—Dr. S. Singer (*Wiener klinische Wochenschrift*, No. 38, 1897) writes that in the course of acute rheumatism lesions are observed in the skin, the most of which can be placed under the group erythema multiforme. This polymorphous erythema shows itself in the form of erythema gyratum, figuratum, or urticatum, on the trunk and extremities. Next to the rosy-red spots there come hemorrhagic surface eruptions; smaller or larger nodular painful infiltrations (erythema nodosum); in a few instances erythematous spots with vesicular formations. The extensor sides of the extremities are the favorite seats of the above lesions, though they are also found—but not to the same extent—on the flexor side of the limbs and upon the trunk. The writer has observed the accompanying polymorphous erythema in seven cases of rheumatism. Two of these cases were examined bacteriologically, in one of which the staphylococcus pyogenes albus was found in both the urine and the eruption. Besides studying the lesions accompanying rheumatism, Singer has made bacteriological examinations in two cases of erythema multiforme, the blood being obtained by lancing the lesions. The first case was one of septic infection, having its starting-point in a tonsillar abscess, accompanied by high fever and a polymorphous erythema of a scarlat-

inous nature, with disseminated nodules, papular efflorescences, many pustules, and acute nephritis. The urine and the pus from the tonsils and the skin pustules contained the staphylococcus pyogenes aureus. The second case occurred in a man with a papular erythema of the trunk. The cause of the erythema was an infected wound of the hand. The urine and the papules contained the staphylococcus aureus; the eruption might therefore be looked upon as a staphylococcus metastasis. The writer thus sums up his views: "Erythema multiforme is both symptomatic and idiopathic. The symptomatic form occurs most often as an accompaniment of a generalized pyæmic process; next often it accompanies articular rheumatism. The so-called idiopathic form of erythema—through its most frequent occurrence during the spring and fall; by fever, pains in the joints, relapses; its combination with angina and endocarditis—shows such a true relation to articular rheumatism that the majority of these cases we must look upon as rheumatic processes, the skin lesions overshadowing the joint symptoms. Staphylococci and streptococci are the only bacteria found in erythema multiforme. Because of the kind of bacteria present, we may look upon the erythematous eruptions accompanying septico-pyæmic processes as pyæmic skin lesions. Since erythema multiforme and acute articular rheumatism are so closely related, the latter may be discovered to be a pyæmic disease."

The Protective Power of Leucocytes.—Dr. Jacob (*Zeitschrift fur klinische Medicin*, Bd. xxxii., Hefte 5 and 6) says that if an infectious disease attacks the organism the protecting power of the leucocytes depends upon the amount of the toxin produced by the invading bacteria. If this toxin amount be very great, the white blood corpuscles are affected by a continuous negative chemotaxis; they do not leave the blood-making organs, and they do not form any bactericidal secretion. Should the amount of bacterial toxin, on the other hand, be only moderate, the negative chemotaxis is gradually changed into a positive one; the leucocytes hurry to the seat of conflict, and form bactericidal products. These latter, however, are of a generic, not of a specific nature; it is only from the two components—the toxin of the bacteria and the secretion of the leucocytes—that a resultant antitoxin is formed, which antitoxin kills or at least diminishes the power of the bacteria. It is at this time that phagocytosis sometimes occurs, the leucocytes taking upon themselves the rôle of transporters after having fulfilled that of bactericidal secretors.

Etiology and Histology of Pneumonia, both in Childhood and in General.—As a result of forty-one autopsies on children having primary and secondary pneumoniæ, Dr. H. Dürck (*Deutsches Archiv für klinische Medicin*, Band 58, Heft 4 and 5) found a more or less complicated mixture of bacteria, among which the diplococcus pneumoniæ was most often present. The composition of this bacterial mixture has, however, no effect upon the histological structures of the pneumonic exudate. A histological division between lobular or pseudo-lobular pneumonia and lobar pneumonia cannot be carried out. The term "broncho-pneumonia" is justified only when the inflammation has been proved to travel from the terminal bronchi into the peribronchial tissue. In thirteen autopsies of children who died from other causes and whose lungs were normal, the writer always found bacteria; here, too, the diplococcus pneumoniæ was most frequent. That the presence of bacteria in these normal lungs was not due to post-mortem infection, Dürck proves by his discovery of the same bacteria in the lungs of domestic animals but recently killed and dissected. The writer concludes from this that the presence alone of bacteria in the lungs—which bacteria are present in the lungs of every healthy person—is not sufficient to cause pneumonia, but the organs must in some manner first undergo harm and damage. This he proves by experimental research. The intratracheal application of pure culture of the bacteria found in pneumonia did not suffice to induce the disease; when, however, the lungs were irritated by the inhalation of dust and other similar extraneous materials, or by cold, then a pneumonia immediately developed. The effect of cold the writer explains by its producing an acute intense hyperæmia of the lungs.

The Modern Management of Diphtheria and Croup Cases.—The treatment of diptheritic inflammation consists in the early and proper administration of reliable antitoxin, supplemented by the nasopharyngeal toilet. The time for discussing the pros and cons of antitoxin treatment is past; the specific curative power of this remedial agent is an established fact. Behring's claim that if antitoxin be used early the mortality from diphtheria will not exceed five per cent. is borne out by the reports of competent clinicians the world over. Opposition to anything so radically new as Behring's discovery is one of the associating features in the evolution of scientific medicine. Vaccination and antiseptic surgery stand in evidence of this fact. Any practitioner who studies the collective investigation reports for 1896 and 1897 on antitoxin for diphtheria and croup in private practice, issued by the American Pediatric Society, and fails to use antitoxin because he "does not believe in it," should not be intrusted with the management of a case of diphtheria, and the practitioner who thinks a case is mild, and waits for severe symptoms before using antitoxin, utterly fails to grasp the situation, and will frequently be disappointed.—Dr. Augustus Caillé (at the eighty-fourth annual meeting of the Vermont State Medical Society, October, 1897).

The Present Status of Surgery of the Lungs.—During a meeting of the surgical section, Versammlung deutscher Naturforscher und Aerzte, September 20–25, 1897, Dr. Sonnenburg discussed the above subject. He divides lung surgery into pneumotomy and pneumectomy; he always makes a large flap and removes several ribs, in order to gain as large a field as possible. As to the pleura, he recommends the immediate—not mediate—suture thereof; often the pleura is already adherent. Puncture of the lung has been warned against because of fear of infection. It is certainly better to puncture after resection of the ribs; puncture, too, is very often uncertain, even though the abscess be near by, and repeated puncture with a short needle is often necessary if the abscess be a deep-seated one. On the other hand, the longer the needle the greater the danger to the large vessels in puncturing. Palpation gives better and quicker results. This is best carried out by separating the parietal pleura from the ribs, and then introducing the hand between the pleura and ribs; the field for operation being thus discovered, the ribs are removed directly opposite the diseased lung. Regarding the question of knife or cautery in attacking the lung tissue, Dr. Sonnenburg prefers the knife when the tissues are hard and sclerosed; there is no danger of hemorrhage. When the tissues are soft, inflamed, succulent, cautery is the proper method. The abscesses are to be opened wide and tamponed, particularly when a communication of the abscess with bronchi exists; else the patients cannot breathe. The operation for ecchinococcus of the lung gives very good results; the treatment of these tumors by aspiration and injection of medication the speaker considers dangerous. Among inflammatory conditions of the lung, abscess, gangrene, and bronchiectasis have been attacked surgically. Acute abscesses offer a good prognosis, particularly

when early operated on; they occur most frequently after true pneumonia and after influenza. Chronic abscesses, on the other hand, do not offer a good prognosis: most often leaving a fistula after the operation, because of the more or less indurated condition of the tissue. In eighty per cent. of the cases the abscesses were found in the lower lobes. Metastatic abscesses offer very little chance for the surgeon; such cases almost invariably are fatal. There is more hope in those cases produced by an abscess in the neighborhood, *e.g.*, diaphragmatic abscess, abscess of the liver. Abscesses caused by foreign bodies are generally putrid and accompanied by a purulent pleuritis; often the foreign body is situated quite distant from the seat of the abscess. Only when single and sacculated ought bronchiectases to be operated on; when small and multiple they most rarely heal—they leave fistulæ. Operations for gangrene have resulted in thirty-five cures out of forty-seven cases; Sonnenburg's cases all ended fatally. Finally, actinomycosis may be operable, particularly when the abscesses formed are superficial.—*Wiener medizinische Blätter*, No. 40, 1897.

Researches on the Injection of Lecithin.—Dr. Cesar Serono, *La Tribune Médicale*, December 1, 1897, says that Gobley has given the name of lecithin to the neutral phosphatic fatty material that Chevreul has noted in fibrin, and which, according to Berzelius, would be formed with fatty acids. We find this substance in the yolk of an egg, in the nervous system, in the blood, in the bile, etc. The author has made numerous experiments by injecting different kinds of lecithin under the skin of animals. Danilewski preceded him in these researches and observed that, after these injections in dogs and chickens, the weight of these animals increased rapidly and that there was an extraordinary modification of red blood corpuscles. Dr. Serono has noted the same results in frogs; he has called attention to the energetic action of this substance on dogs and also on patients of different ages in whom he has used lecithin as a reconstituent, which compares favorably with arsenic but is more rapid in its action. There are always an increase in weight and an improvement in the general condition. A series of eight, ten, or fifteen injections of from fifteen to twenty centigrams of lecithin daily suffices completely to transform the patient's condition. This substance increases the red globules and the hæmoglobin slowly, organic changes are accelerated, the amount of urea is even more than doubled, and there is a great increase in weight. The author has never injected lecithin in large doses, and it would be interesting to follow the effects that would be produced in certain morbid conditions.

Culture Media for the Bacillus of Smegma.—Dr. H. Laser (*Munchener medicinische Wochenschrift*, October, 1897, No. 43, page 1,191) states that the bacilli of smegma that one finds on the surface of indurated chancres and of condylomata, and which do not develop in ordinary culture media, do so very well when a sowing has been made on agar to which blood has been added. On these plates or in tubes of mushroom, at the end of twenty-four hours, colonies analogous to those of streptococci or of the bacillus of diphtheria are found. Stained by the process used by Koch for the tubercle bacillus, the bacilli of smegma present a rose color under the microscope. A pure culture of the smegma bacilli transplanted to gelatin does not grow. It increases but slightly on agar, in an aqueous solution of peptone, in beef bouillon, and but little better in bouillon to which glucose has been added and on mushroom to which glycerin has been added. On potato there is scarcely any development. The results of inoculation with pure cultures made under the skin or into the peritoneum of guinea-pigs and white mice show that, at least with these animals, smegma bacilli are not pathogenic. According to the author, the culture of the bacilli of smegma in a state of purity may have a practical interest, especially in cases in which the microscopical examination of the sediment of the urine shows the presence of rose-colored bacilli having all the appearance of the bacilli of tuberculosis. If there is any doubt, it suffices to make a culture of the sediment; the smegma bacilli give a culture at about the end of twenty-four hours, while the bacilli of tuberculosis develop only at the end of from ten to fourteen days, or even later.

Uropoiesis and Faradization of the Liver.—Dr. Gino Gini, *La Tribune Médicale*, December 1, 1897, says that it is well known that the salts of ammonium in the human organism and in that of the higher animals are transformed into urea by a process of synthesis with the carbonic acid and with the elimination of water. Salomon and Schröder have proved that this transformation takes place in the liver. According to other scientists the formation of urea takes place in other organs, and especially in the muscles. The conditions which favor uropoietic activity are but incompletely understood; we know only that the presence of acids greatly retards the synthesis of urea, and also that febrile processes do not modify the production of this substance to any appreciable extent. We do not know that the destructive processes or slow inflammations of the liver have any influences; nevertheless it has been ascertained experimentally that extirpation of a part of the liver diminishes proportionately the excretion of urea. We may or may not ignore the intervention of the nervous system in uropoietic activity; certain works of Cavazzani seem to prove that any innervation of the liver does not influence directly the production of urea. A communication of Chassevant and Richet to the Society of Biology demonstrated the existence of a special ferment in the process of uropoiesis. The importance of the activity of the hepatic cells in the act has not been sufficiently studied or recognized; it is not known whether the liver transforms all the ammoniacal compounds which the blood brings to it into urea; or whether the synthetic activity of the liver is able, at certain times or in certain pathological conditions, to perform the work of transforming all the ammoniacal compounds in the blood into urea; or if the liver is able to form urea otherwise than by synthesis from the products of "regression of metabolism." The author has sought to find out if a stimulus applied directly to the liver could modify the uropoietic activity. Other scientists have also worked along this line by using faradic currents applied to the liver through the abdominal wall, but the result has not been definite. Dr. Gini offers the following conclusions founded on his researches: 1. Faradization of the liver does not cause any immediate modification in the elimination of urea (experiments were made on rabbits). 2. After the second or the third day of faradization there will be an increase in the quantity of urea lasting for two or three days. 3. This increase is the direct result of the force and of the extension of muscular contractions provoked by the electric current. It is the effect of the increase of the organic construction of the muscles. 4. Uropoietic action of the liver is subordinate to the quantity of the products of "regression" of the organic exchange, and since stimulation of the nerves of the liver does not increase the uropoiesis of this viscus, one cannot by stimulation directly increase the uropoietic function of its cells. It remains to determine the effect of direct or indirect stimulation; this has not yet been done.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 21, 1898.

ACCLIMATIZATION IN THE TROPICS.

THE question of the white man's ability to conquer the tropics and to make for himself a permanent home in those delightful regions is one that has hitherto possessed a purely academic interest for physicians in this country, but the fortunes of war and projects of annexation are making it probable that this will soon be changed. Porto Rico, the Sandwich Islands, and the Philippines are all tropical islands, and if they, one or all, come under our flag, doubtless many of our citizens will go thither to seek their fortunes, and the question of acclimatization will at once become a most practical one.

We find, in the *British Medical Journal* of April 30th, an interesting account of what is therefore for us a most timely discussion on this topic. The discussion took place in the rooms of the Royal Geographical Society, in the presence of many of the best-known authorities on tropical pathology. Most of those taking part in the debate held that there is no reason whatever why the white man should not be able to adapt himself to the new conditions of life in the tropics and protect himself against the diseases that prevail in those regions. The popular belief that the white man cannot successfully colonize the tropics is disproved by the fact that he has done so. It is undoubtedly true that many Northerners who go to equatorial regions contract disease there and die, but in the majority of such cases the man is the victim of his obstinate unwillingness to change his habits in respect to eating, drinking, and clothing, and to conform his mode of life to the new conditions.

The chief diseases, both acute and chronic, of tropical countries—those which formerly caused such ravages among the white settlers and gave rise to the prevalent theory that Europeans could live only in the temperate zone—are all microbic in origin and consequently preventable in great measure. We cannot, of course, expect to see them absolutely wiped out of existence, at least this side of the sanitary millennium; but their sting, like that of small-pox, can be extracted by means of an improved public and private hygiene and other prophylactic measures. A comparison of the healthfulness of the West India Islands under enlightened British rule with that of the two until recently under Spanish misrule shows what can be done by sanitation to convert a pest hole into a paradise. Indeed, as Dr. L. Sambon, in opening the discussion above referred to, well said, sanitation has within the last few decades wrought wonderful changes in all tropical countries, as regards health conditions, and the changes have been so great in some places that regions which were once considered most deadly are now even recommended as health resorts.

Dr. Patrick Manson, than whom there is no greater authority on the pathology of equatorial regions, began his remarks with the confession that in former years, under the influence of early teaching, he shared in the pessimistic opinions then current about tropical colonization by the white races. In recent years, however, his views on this subject had undergone a complete revolution—a revolution that began with the establishment of the germ theory of disease. He now firmly believed in the possibility of tropical colonization by the white races. Heat and moisture, he contended, were not in themselves the direct cause of any important tropical disease. The direct causes of ninety-nine per cent. of these diseases are germs. When these germs and their habits are known fully, victory will be within man's grasp. Most microparasites, when they are once within the body, are fairly safe. But these same parasites, in order that their respective species may keep in existence by spreading from one host to another, must at some time or another leave the human body, and during this necessary extra-corporeal state they are eminently vulnerable. To kill them then is simply a matter of knowledge and the application of this knowledge—that is to say, sanitary science and sanitation.

One earnest contention of those who argue against the possibility of successful colonization of the tropics by the white races is that, even if the original colonist lives out his natural term of years, his children will bear in themselves evidences of the degenerative influences of a hot climate. It is true, indeed, as was admitted by Sir Harry Johnston, that in many parts of the tropics the climate does cause a deterioration of European races. As an example of this is cited the offspring of British parents in India, who, if brought up in that country, do not reach the standard of stamina seen in the home-bred Briton. This is no doubt true of other places than India and also of other than tropical regions, but it is not true of all tropical countries. It is a question whether it is the heat alone that works this change, or whether there are certain as yet unappreciated telluric influences which are responsible for the loss in stamina. In India, Ceylon, tropical America, and Australia, the problem of colonization may be regarded, to quote Sir Harry Johnston again, as solved. In other regions certain definite diseases still stand in the way—namely, malaria, dysentery, and yellow fever in the West Indies, and blackwater fever or hæmoglobinuria in Central Africa. Even for malaria quinine is by many regarded as a not absolutely sure prophylactic; and for the other diseases there is none as yet. The real question of colonization of the tropics lies in the finding of means of protecting Europeans against the diseases named. That this means will some day, if not very speedily, be found, can hardly be doubted by any but the most confirmed sanitary and therapeutic pessimist.

THE MICROBE OF BALDNESS.

ANOTHER important discovery in the field of bacteriology has recently been announced. Nowadays the discovery of the germ of a disease is an event of so frequent occurrence that the finding of a new one does not possess the surpassing interest of a few years ago; in fact, it appears that it might not be rash to predict that ere long men of science may find themselves in the position of Alexander the Great, who is said to have wept because there were no more worlds for him to conquer. The researches which have just been crowned by success, and which have, it is stated, solved the mystery connected for years without number with the cause of baldness, is naturally a matter of surpassing concern to people in all parts of the world. Baldness has ever been regarded as one of those bodily changes to which all flesh is heir, and esteemed an ordinary incident in the course of nature; but we are now told that we have given too much credit to nature —that in this instance at least she is not responsible, and that the cause of baldness must be laid to the charge of the ubiquitous microbe. M. Sebouraud, an ex-pupil of M. Pasteur, a well-known authority on the nature and cause of ringworm, has by his investigations exposed the secret of baldness and thrown new light on that well-worn subject. He declares that common baldness is a perfectly definite malady of microbial origin. In a leading English review an instructive account is given of the elusive microbe, which runs as follows: It is a minute colorless body, pointed at both ends, and increasing in number by constant division into two, and, since the divisions do not immediately break off, long chains frequently form, each link in the chain being a distinct microbe. It congregates in colonies of enormous numbers in the hair follicle below the epidermis and just where the sweat gland joins the follicle. At this point there is somewhat of an enlargement, and in this little cavity it finds a convenient habitat. But, further, each colony is wrapped up in a kind of cocoon, by fatty matter from the sebaceous gland; the cocoons vary in size, and are easy to obtain by squeezing the skin at the mouth of the gland. For instance, the coil of fatty matter which is ejected when a "blackhead" is forced out of the skin by pressure, is simply an enormous cocoon holding within it myriads of this bacterium; indeed, it is appalling to think of the bacteriological flora for which our skins are the happy hunting-ground. Sometimes the cocoons have an opening—a kind of road to their interior; at other times they are completely closed; but always they contain a vast collection of this particular microbe. M. Sebouraud explains that the manner in which the microbe acts to cause baldness is by slowly poisoning the hair at the roots. For some time, although M. Sebouraud was satisfied in his own mind that he had discovered the cause of baldness, he was unable clearly to demonstrate the fact. To give convincing proof of his theory, he must show himself able to produce baldness by introducing the microbe into a head of hair. As no human subject came forward to offer his head and hair in the interests of science, M. Sebouraud was compelled to fall back on a rabbit. He accordingly procured and inoculated a rabbit with a liquid in which he had cultivated isolated microbes. The result exceeded his most sanguine expectations, as, after undergoing the inoculation treatment for six weeks, the animal was entirely bald. Unfortunately for the immense army of bald persons, M. Sebouraud holds out no hope of a radical cure; in fact, he regards it as an impossibility. Nevertheless, the discovery of the cause is a decided advance, and will assuredly incite the bald to hope that by further investigations a reliable antitoxin may be evolved.

News of the Week.

Medical Practice in the Klondike.—A correspondent of the *Medical Sentinel* utters a warning to physicians from this country who may be contemplating a journey to the Klondike. Before any such are permitted to practise medicine in that region it will be absolutely necessary, he writes, to pass examinations before the board of examiners of the Northwest Territory (not British Columbia), whose headquarters is Calgary, and of whom Dr. Britt, Banff, N. W. T., is registrar. The provincial authorities have announced that the medical law will be strictly enforced.

Sterilized Milk for the Children on Randall's Island.—The department of charities of New York has accepted the sterilized-milk plant on Randall's Island which Nathan Straus, formerly president of the health board, presented to the city. The plant has a capacity for sterilizing enough milk for one thousand children per day. There are six hundred children in the institutions on the island.

The Doorkeeper at the Pasteur Institute.— The new *concierge* of the Pasteur Institute in Paris was the first patient who was treated by Pasteur for hydrophobia. While a shepherd, he had been badly bitten by a mad dog, and was persuaded to offer himself for trial of the injection treatment. Pasteur presented him with a silver medal and employed him in his laboratories, and now he has just been appointed *concierge* of the institute.

Obituary Notes.—DR. ISAAC N. QUIMBY, of Jersey City, died of pneumonia at his home in that city. He was born in Bernardsville, N. J., sixty-eight years ago, and was graduated from the medical department of the University of New York in the class of 1859. He served as a surgeon in the army of the Potomac during the civil war. He was an active and prominent member of the American Medical Association.— DR. DAVID WENDELL YANDELL, of Louisville, Ky., died at his home in that city on May 2d, after a long illness. He was born in Murfreesboro, Tenn., in 1826, and was the son of Dr. Lunsford Pitts Yandell, who had just began practice in that year. He was a graduate of the medical department of the University of Louisville in 1846. He served as surgeon in the Confederate army during the civil war. He was president of the American Medical Association in 1871.

—Dr. Lott Southard, of Newark, N. J., died at his home in that city on May 14th, after a long illness. He was a graduate of the Geneva Medical College in 1852. He was born in Baskingridge, N. J., seventy-one years ago.

The Late Dr. I. N. Quimby.—At a special meeting of the Jersey City Hospital staff, held May 7, 1898, the following resolutions were unanimously adopted:

"*Whereas*, Dr. Isaac N. Quimby, for many years a member of the Jersey City Hospital staff, has been removed by death, therefore be it

"*Resolved*, That we, members of the staff, fully realize how great is our loss in being deprived of the kindly counsel and companionship of our late associate, Dr. Isaac N. Quimby.

"That we feel that by his death, not only among ourselves but in the community at large, a vacancy has been created which cannot easily be filled.

"That we tender our most sincere sympathy to his family in their sad bereavement.

"That a copy of these resolutions be published in the daily papers of the city and in the prominent medical journals of the country."

Extension of Relief of the United States Marine Hospital Service.—In a circular dated May 2, 1898, Dr. Walter Wyman, supervising surgeon-general of the Marine Hospital service, writes that the United States marine hospitals are to be made available for the reception of the sick and wounded of either the United States army or the United States navy. All medical officers of the service are directed, upon a written request of the proper military or naval authority, to receive and care for such patients.

Reduced Fare to Denver.—The various trunk lines have reduced their fares to one and one-third for all delegates from Greater New York to the meeting of the American Medical Association in Denver, making the round trip $65. To all who join the association party the transportation committee of the County Medical Association will give a full sleeping-car berth to Denver free of charge, thus saving each delegate $11. The train leaves West Forty-second Street ferry, June 2d, at 6:15 P.M., *via* New York, Ontario, and Western Railroad. Each person desiring to avail himself of this privilege is requested to forward $10 to Dr. J. J. E. Maher, 34 West Twenty-fifth Street, the chairman of the committee, the balance, $55, to be paid before June 1st. The committee will be in attendance for half an hour before the departure of the train, and will issue tickets on presentation of receipts for money paid. Excursion tickets are not available before June 1st.

The New York State Medical Association.—The fourteenth annual meeting of the third district branch of the New York State Medical Association will be held at Syracuse, on Thursday, June 2d, under the presidency of Dr. H. W. Carpenter. The secretary is Dr. F. W. Higgins, of Cortland. The fourteenth annual meeting of the fifth district branch will be held in Wurzler's Building, 315 Washington Street (near City Hall Square), Brooklyn, on Tuesday, May 24, 1898. The president is Dr. N. W. Leighton, and the secretary Dr. E. H. Squibb, of Brooklyn.

The Indian Territory Medical Association.—The semiannual meeting of this society will be held at Wagoner, I. T., on June 1 and 2, 1898. The president of the association is Dr. E. N. Allen, of South McAlester, and the secretary Dr. Le Roy Long, of Caddo.

The American Medical Editors' Association.—The annual meeting of this society will be held at Denver, on Monday, June 6th, the day preceding the opening session of the meeting of the American Medical Association. The association will be entertained at a banquet on the evening of that day by the local committee on medical journals. Dr. Thomas H. Hawkins is the chairman of this committee.

A Legacy for the Advancement of Medical Science.—Mrs. Caroline Croft is reported to have left $100,000 to Drs. Henry K. Oliver and John Collins Warren, of Boston, for the purpose of making investigations to ascertain some method of curing cancer, consumption, and other diseases which are now regarded as incurable.

Female Nurses for the Army.—Four trained nurses were recently sent to the army hospital at Key West, they having been regularly enrolled in the army. They belong to the hospital corps of the Daughters of the American Revolution, and were selected by Dr. Anita Newcomb McGee, director of the corps, for this duty.

The Pharmacists and the Manufacturers.—A writer in *The Evening Post* says that a discussion between the physicians and druggists of Philadelphia, carried on by the druggists ostensibly in advocacy of a national formulary, which would give a standard method of preparing the many prescriptions which have become popular with the physicians and the public, assumed later the appearance of a war by the pharmacists on the manufacturing chemists. The latter have been in the field for a long time with pellets prepared according to standard formulas, and there is less profit in the sale by the druggists of these standard tablets than in the compounding of prescriptions. Some of the Philadelphia doctors told the druggists that in their opinion the manufacturing chemists, with their facilities for getting drugs in large quantities, and accomplished chemists to assay them and supervise the manufacture, could accomplish results more cheaply and more certainly than the druggists. In answering this the druggists asserted that many manufacturing chemists employ children in the weighing and mixing of drugs, and that they are not covered by the law which requires a drug store to employ a registered pharmacist.

Turkish Losses in the Greek War.—It is stated that Turkey lost less than one thousand men in battle in the Greek war, but nineteen thousand died in Thessaly of disease, and twenty-two thousand were

sent home invalided, and of the latter eight thousand subsequently died. Among the dead were seventeen army surgeons.

New London (Conn.) County Medical Association.—The one hundred and seventh annual meeting of this society was held at New London, on April 7th, under the presidency of Dr. A. W. Nelson, of New London. The following officers were elected: *President*, William Witter, of Norwich; *Vice-President*, E. P. Douglass, of Groton; *Clerk*, Carlisle F. Ferrin, of New London.

Dr. Carlos Finlay, of Havana, is reported missing from that city, and fears are entertained for his safety, as it is known that his name is in the blacklist of the Spanish volunteers, who have been in full control since the city was placed under martial law. His many friends in this country are hopeful, however, that he has succeeded in escaping among one of the several bands of refugees who have come away or have fled to the interior since the blockade of Havana was established. Dr. Finlay is well known for his studies in yellow fever, and was, we believe, the first to promulgate the theory that this disease is spread through the agency of insects, and especially of mosquitoes. He also employed mosquitoes as a means of inducing a mild attack of the fever, and so effecting immunity with a minimum of risk to the unacclimated.

The American Gastro-Enterological Association.—The annual session of this association was held at Washington, D. C., on May 3, 1898. The following papers were read: "A Case of Atrophy of the Stomach, with Exhibition of Specimen," Dr. Julius Friedenwald, Baltimore, Md.; "A Case of Acute Pancreatitis, Carcinoma of the Cardia," Dr. Morris Manges, New York; "Nervous Dyspepsia, with Report of Cases," Dr. Frank H. Murdoch, Pittsburg, Pa.; "The Effect of Auto-Intoxication on the Liver and Kidneys. Exhibition of New Instruments for Intubating the Duodenum and Outlining the Greater Curvature and Colon," Dr. John C. Hemmeter, Baltimore, Md.; "Precision of Terms in Diseases of the Stomach," Dr. Charles D. Aaron, Detroit, Mich. The election of officers resulted in the choice of the following: *President*, D. D. Stewart, Philadelphia; *First Vice-President*, Max Einhorn, New York; *Second Vice-President*, John C. Hemmeter, Baltimore; *Secretary and Treasurer*, Charles D. Aaron, Detroit; *Councillors*, Henry L. Elsner, Syracuse, A. P. Buchman, Fort Wayne, Frank P. Murdoch, Pittsburg.

The American Association of Genito-Urinary Surgeons.—The twelfth annual meeting of this association will be held at Cranston's Hotel, West Point, N. Y., June 7 and 8, 1898.

Cremation in Germany and Austria.—The *British Medical Journal* say that the Vienna Medical Society at a recent meeting considered two reports presented by Professors v. Hoffman and Gruber on the advantages and drawbacks of cremation in regard to public health. The society passed the following resolution: "Cremation by means of modern combustion ovens is unexceptionable from the hygienic point of view; but earth burial does not involve such drawbacks and dangers that cremation should be considered as a necessary sanitary reform. Compulsory cremation presents insurmountable difficulties and is open to objections of great importance from a medico-legal point of view. Optional cremation, on the other hand, is not open to the slightest objection provided that the burning of bodies is carried out only after careful post-mortem examination." The same paper states that cremation appears to be making headway in Germany. In addition to the crematoria at Gotha, Heidelberg, and Hamburg, one has recently been established at Jena. The last has been erected by private subscription, and is reserved for private use. There is a likelihood of another being erected before long at Mannheim. Germany now stands third among the nations in respect of the number of its crematoria. Italy comes first with twenty-four, America next with twenty-two, Germany is a bad third with four; then come England with three, France with two, Sweden with two, Denmark with one, and Switzerland with one.

The Working of the Wisconsin State Medical Law.—Dr. Gilbert E. Seaman, of Milwaukee, writes that the statement of the *Chippewa Falls Herald*, recently referred to in these columns, that the Wisconsin medical law is not enforced with great rigor, is incorrect. "The fact is," he writes, "that the Wisconsin medical law has worked admirably. We have a very efficient board of examiners, and I believe that every man who has begun practice in this State since the law went into effect has the certificate of the State board." The *Milwaukee Sentinel* says that the law has had the effect of keeping many undesirable physicians out of the State. As an evidence of this, it is cited that during the first quarter of the board, from July 12th to October 12th, ninety-six applicants for licenses did not put in an appearance when the board met, and after notice of the qualifications required by the board had been sent to the applicants. During the second quarter about fifty applicants failed to respond, and this last quarter some sixty failed to appear. The qualifications are not only a diploma but affidavits from two reputable physicians testifying to the good character and morality of the applicant.

New York Mycological Club.—At the annual meeting of this society, held Monday, April 4th, the following officers were elected for the ensuing year: *President*, Henry G. Piffard, M.D.; *First Vice-President*, W. C. Deming, M.D.; *Second Vice-President*, W. B. Garside, M.D.: *Third Vice-President*, Miss C. C. Bedford; *Secretary*, Mrs. A. R. Witte; *Treasurer*, Thomas J. Keenan.

The Black Hills Medical Society.—At the second annual meeting of this society, held in Lead, S. D., on April 14th, the following officers were elected: *President*, A. H. Bowman, Deadwood; *First Vice-President*, C. W. Hargens, Hot Springs; *Second Vice-President*, C. E. Zerfing, Lead; *Secretary and Treasurer*, A. G. Allen, Deadwood; *Board of Censors*, Drs. Dickenson, Hargens, and Torrence.

Society Reports.

MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND.

One Hundredth Annual Session, Held at the Hall of the Faculty at Baltimore, April 26 to 29, 1898.

Tuesday, April 26—First Day.

The one hundredth annual session of the Medical and Chirurgical Faculty of the State of Maryland was called to order at the hall of the faculty, 847 North Eutaw Street, April 26th, at twelve o'clock noon, Dr. Charles M. Ellis, of Elkton, president, in the chair; Dr. J. Williams Lord and Dr. Robert T. Wilson, secretaries.

The president, Dr. Charles M. Ellis, spoke of the improved financial condition of the faculty, and referred to the fact that in one year it would celebrate the completion of one hundred years of existence as a medical society, and hoped to have at that time all debts paid and a sum of money laid by as a surplus. Up to the present time fifty-one members had applied for admission.

A paper, entitled "School Desk, Eyesight, Etc.; Cases in Practice," was then read by Dr. J. B. R. Purnell, of Snow Hill, in which he spoke of the size of the school desks in proportion to that of the children using them, and the effects it had on the eyesight, and referred also to the adjustable school desk.

The Antiseptic or Germicidal Treatment of Disease.—Dr. Edward Anderson, of Rockville, read a paper with this title. He referred to the great scope of the subject, and said that we should not rely too much on text-books, but use our own experience. We do not remember in using germicides that the blood has marked germicidal properties, and we should also bear in mind that such substances as common salt have a certain amount of antiseptic and germicidal power. In many cases of infant diarrhœa he had found great benefit from antiseptics, and he thought that the sooner physicians ceased to consider these as local troubles, the better it would be for the patients themselves. In making these remarks he was speaking, he said, not only for himself, but for the large number of country physicians whom he represented.

A report of "Thirty-five Cases of Hip-Joint Disease, Treated at the Robert Garrett Hospital for Children," was then made by Dr. W. B. Platt. He said that hip-joint trouble was one of the most tractable of diseases when treated early, but when treated late was one of the most intractable of diseases. There was always a serious question as to when to operate and when not to operate. Sometimes it was better to do so early, and sometimes late. It depended on the condition of the patient, his surroundings, etc. Some patients could not be kept in the hospital long and did not recuperate properly after the operation. The results after resection of the hip-joint were often very good, even when done late. He had two or three cases of his own in mind. Two were doing well and one was not. One patient was wearing a brace and high shoe. The third patient died of shock soon after the operation, but out of the hospital. Some would recover after careful curetting of the sinuses and cleaning them out. Hip-joint cases were extremely susceptible to eruptive diseases. He noticed that in the Robert Garrett Hospital those with hip-joint trouble had been especially affected by such diseases as measles and scarlet fever. Joint diseases were usually attributed to injury, but there were so many children falling and hurting themselves and being knocked about without having hip disease, that this cause could not always be relied upon. In nine out of his thirty-five cases there was a clear history of injury. In eleven the right side, and in twenty the left side was affected, and of these thirty-five patients seventeen were boys and eighteen were girls. Twenty-three had, and twelve did not have sinus. He showed two very interesting cases of double hip-joint disease which were making a very good recovery.

Dr. Anderson said that he had often noticed that there was a great amount of counter-irritation, and when one hip became diseased the other grew better. He had noticed also that in cases of consumption when sinus was established the lung trouble often grew better.

Dr. Platt stated that it had been said that heredity played a great part in these hip-joint diseases, some asserting that the complaint was often hereditary for two generations back. Tuberculosis was so common that it was a little uncertain if that had the influence it was said to have. It was known that many of these patients died of tuberculosis, but he did not think that the joint trouble was necessarily the cause of the tuberculosis. There was no reason why these hip-joint cases should be fatal, and, in fact, many were not.

Dr. J. C. Harris spoke of the extreme tenacity of life exhibited in some cases of cured hip disease, and mentioned cases in his own practice.

The Country Doctor was the title of an address delivered by the president, Dr. Charles M. Ellis. He said that he wished to submit to the faculty such observations of the country doctor's habits of life and thought and of the influence of environment as an intimate participation and personal experience for a third of a century might give him. He showed how the country doctor differed from the town doctor; what his needs were and the difficulties in overcoming them, and finally made some suggestions for helping him. He made no attempt to throw around him the glamour of romance and poetry, but exhibited the man only as he knew him, with all his virtues and his vices. Often he was without the proper equipment and he had no help at hand as did the city physician. The speaker then gave a very minute description of the life, habits, and characteristics of the country doctor.

Many a physician in the country grew to be a very important man and took the lead in his community; such a man might have many faults, but they were known more to himself than to his neighbors. Such a man gained the respect of all around him, and soon grew into the perfect family doctor. He made no attempt at specialism, but was ready in all emergencies. In surgery, in obstetrics, in skin diseases—in fact, in any department he must be ready to act without consultation; and while he must succeed in all branches of surgery, he was also successful, as a rule, in internal medicine. There were few such men who could fill all these requirements, but the type served to show the difference between the city and the country physician. But men who were thus successful rarely stayed in the country. Like Sims, Agnew, Goodell, and others, they soon found their way to the large cities, where they made their marks.

The greatest objection to the country doctor was that, as a rule, he took the short course in medicine and then he was launched on his labor without any further experience. The city doctor had the advantages of medical societies, intercourse with colleagues, and post-graduate experience, while the country doctor had to exercise his own ingenuity, and it was in the constant exercise of his own natural resources that his education was completed. It was this habit of self-reliance that made him such a capable man, but he also might become too conceited and have too much self-esteem and self-possession. Then, in a

small place, there were the effects of social surroundings and professional jealousies, which were more keenly felt than in the large cities. The city doctor and country doctor were supposed to be alike at the start, but the city doctor soon left the other one far behind. There was one way in which the facilities of the country doctor might be improved, and that was by the establishment of cottage hospitals throughout every community. Then, again, the country doctor should take a post-graduate course at the end of his fifth and of his tenth year, and nothing could ever prevent his doing this. The county medical societies should also be cultivated and the meetings should never be missed. The speaker said he had learned this by his own personal experience. The country doctor should also belong to the State society, and this he should consider second only to his own county society.

The lack of books and the absence of hospitals were a great drawback to the country doctor. This could be in part prevented in Maryland by the State faculty library. The country physician hesitated to read a paper before a city society, on account of the critical audience. Educational clubs in the country districts could help to enlighten and instruct the country physician, and books could be distributed by means of the cottage hospitals, and if there were no such hospitals then the drug store might be used as a centre. There were nearly four hundred cottage hospitals in Great Britain, a few in New England, and none in Maryland or the South. In the cottage hospital the country doctor could gain a certain amount of experience in exhibiting and in studying the various cases. He could perform a certain number of autopsies and have the advantage of using the microscope. The first hospital in England was established in 1853. There were no trained nurses at that time, but they had become very important now. There was very poor nursing in the country districts. The trained nurse acted as a subsidiary physician, and paid visits when the doctor could not come. She should be an adaptable woman, of good moral tone.

Some would say that it was very difficult to establish such hospitals, but in Maryland, with the aid of the faculty, it would not be at all difficult. Assistance could be had from the State treasury, from the county treasury, from private subscriptions, and from various organizations. The county medical officer could also act as bacteriologist and pathologist. Thus could be formed a kind of medical society. It would be a sort of university-extension teaching, as it were. It would cause a great addition to the membership of the faculty, and would be a power to command respect to any demands.

After the reading of this paper, the thanks of the society were extended to Dr. Ellis and the paper was referred to the publication committee.

The Vaginal Operation for Extra-Uterine Pregnancy.—Dr. William S. Gardner related a series of cases and showed that while these operations were not at all easy, and that the number of cases reported was very small, still the success had been considerable, and it was evident that this was a very practical method of treating extra-uterine pregnancy.

Dr. Howard A. Kelly said that this matter was extremely important, and that it was one of the more serious and dangerous operations, but when properly done it saved some unnecessary mutilation. The operation, as formerly done, was to tie up the vessels and thus ward off the danger from hemorrhage. Another way was to open the cavity through the posterior vaginal vault, clean out the clots, and thus save the patient. But there should be one word of caution to surgeons who were doing this operation: they must be prepared to open the abdominal cavity and take out all the structures necessary. All of his patients got well but one.

Pathology of Endometritis.—Dr. Thomas S. Cullen read a paper with this title. The histological appearance of the epithelium covering the mucous surface was composed chiefly of large nucleated leucocytes; it was swollen and somewhat distorted. The uterine glands might be normal in part, but the mouths of the glands were very much swollen and there were many pus cells present. In chronic endometritis the mucous membrane was highly granular and had an appearance like that of polypi. Between the acute and the chronic stages were all transitions. The term granular endometritis was highly improper, and it should be abandoned. Endometritis was supposed to be very frequent, but the speaker had found only forty-nine cases in eighteen hundred gynæcological cases at the Johns Hopkins Hospital. The treatment there consisted in dilating and curetting the uterus. Dr. Cullen exhibited several beautifully executed drawings.

Dr. H. A. Kelly said that endometritis was exceedingly rare; only about one case in fifty that came to the clinics was really endometritis.

Dr. William H. Welch said that some considered chronic endometritis as being very common, and some as being rare. It was not uncommon to have variations in the number, shape, and size of the uterine glands, and it was not right to call this endometritis even if it was clinically so. The scrapings were not normal, but they were irregular in shape and size, and there was a sort of hyperplasia. There were cases which showed actual change in the stroma, with hyperplasia of the stroma cells. As to microscopical diagnosis of the scrapings, this was particularly of value in cancer. Many physicians were careful in risking a diagnosis after examining these scrapings. The negative results did not necessarily convince, but experience had shown that cancer cells would usually reveal themselves in the scrapings.

Dr. B. B. Browne said that many patients with so-called endometritis got well after curettage, and it was not known what the disease was until the scrapings had been made; *i.e.*, the diagnosis was not made until the patients had been treated by scraping, so that the diagnosis does not make much difference.

In conclusion, Dr. Cullen said that he agreed with what Dr. Welch had stated about his cases, and that upon a study of the specimen he had found that the scrapings and specimens were hardened in different fluids.

The Treatment of Tuberculosis of the Uterus and Fallopian Tubes.—Dr. W. W. Russell said that the principal work in this field had been done by Dr. J. Whitridge Williams, of Baltimore. There were two forms of tuberculous salpingitis—one in which the disease was found in the abdominal cavity and in the tubes; the other in which it was found in the tubes and the abdominal cavity was not necessarily affected. He had had no cases of the first sort and twelve of the second. The uterus was found to be tuberculous in every case of endosalpingitis. If the disease was limited to these organs, then the affected tissues should be removed and the patient's general condition should be looked after, but if tuberculosis was in other parts of the body, then it was useless to operate; when there were dropsy and other symptoms operation was not necessary. He then spoke of the various methods of removing the ovaries, and of the choice of routes, whether abdominal or vaginal. If the latter route was chosen, the dissection should be made carefully. The speaker then described the operation in detail. He said that few cases were recognized soon enough to be operated on, and this was true in many of Williams' cases. Diagnosis was made in about one-half of one per cent.

Treatment of Fibroid Tumors of the Uterus.—Dr. H. A. Kelly said that rapid strides had been made in this field, and it was but a little while ago that surgeons hesitated to take out these tumors. This operation had gone through several stages in the last fifteen years, and had been performed in a very haphazard way. The abdomen was opened; the uterus was pulled out; the peritoneum was sewed down around the uterus and pinned to it, and the stump was left to mummify and slough off. Schröder, of Berlin, urged the treatment of this by creating a pedicle and dropping it back into the cavity, and the result was a large mortality from sepsis. Fritsch, of Breslau, and Kelly, of Baltimore, were the first to do the operation in the more modern way and thus avoid sepsis and hemorrhage. They stitched the peritoneum around the uterus. About this time Stimson, of New York, suggested ligating the four sources of blood supply, and after these vessels were tied the stump could be dropped back and there was no sepsis. The technique was important and so was the time. It used to take from one-half to one hour to complete this operation, and then often the patient died. It was necessary to break up the adhesions and tie the vessels, but now the operation could be done in three minutes and the mortality should not be more than three or four per cent. He referred to two young women who had fibroid tumors, who were both engaged to be married, and on whom he had operated with success. He based his remarks on an experience of ninety-one cases. He took out the tumors in these cases and left the uterus, and undoubtedly this could be done in nearly all cases, especially with women in the child-bearing period. He had four deaths in these ninety-one cases, but none in his experience became pregnant afterward. He said he wore gloves, used gauze, and looked out for hemorrhage. He urged conservatism in the treatment of these cases, and also as to any operation.

Dr. Thomas S. Cullen said that in one of these cases the fatal result was through his fault and not Dr. Kelly's. One woman upon whom Dr. Kelly had operated had had four miscarriages. The speaker said that he never did a myomectomy if he found any evidence of sepsis in the tubes.

Wednesday, April 27th—Second Day.

Interstitial Pneumonia.—Dr. Jackson Piper read a paper in which he described three cases tending to show that (1) interstitial pneumonia, the result of acute pneumonia, was amenable to treatment, even after some months' duration; (2) that a consolidation under the second day would terminate either in gangrene or in consumption. His conclusions were that it was never well to leave a patient with unresolved pneumonia until all remedies had been tried.

State Sanatoria for Tuberculosis.—Dr. J. E. Gichner said that tuberculosis in all its various manifestations was caused by one and the same organism; that the cause of disease was distributed by consumptives; that there was no place in Maryland where patients could be exclusively treated and taught how to live; that many tuberculous persons got well without suspecting infection; and that the patient tended to recover when given the opportunity to create resisting tissues, which fact went to explain the many cases of recovery; and, lastly, he thought that the best results of our labors to ameliorate the disease were in prevention. Physicians should be sanitarians. There should be a State sanatorium, where patients could be treated properly.

Dr. William B. Canfield said he thought that one point which Dr. Gichner had made was especially good—it was that patients tended to get well when given the opportunity to create resisting tissues. He had been connected with a small hospital for the treatment of consumptives in the city of Baltimore, and had noticed the marked improvement in patients who had received no medicine, but only food. This hospital was supported entirely by private contributions and received no city or State aid. There had been treated in the last two years forty-two patients, and of these probably twelve had so far recovered that they were able to return to their former occupations. This hospital was for the treatment of incipient cases only, and he would be glad to have physicians throughout the city and State who had cases of early tuberculosis notify him and they would receive free treatment.

Dr. Gichner said in reply that he purposely had not mentioned this institution, because of its being a private one and being situated on a dusty street where cars passed, which was not in accordance with his ideas.

The Preventive Treatment of Rabies.—Dr. John Ruhräh said that in the year past, at the Pasteur Institute of the College of Physicians and Surgeons in Baltimore, thirty-five cases of rabies had been treated, with no deaths. He was glad to say that the Germans had taken up the Pasteur treatment. Statistics of this institution would be issued yearly. He had divided his patients into (1) those bitten by animals which were undoubtedly rabid and proven so by inoculation experiments; (2) those bitten by animals whose condition had been verified by a competent veterinarian; and (3) those bitten by animals which were said to be rabid by others than veterinarians. His cases were principally from the first and third classes. It was necessary also to classify the cases with regard to the position of the bite, according as the animal had bitten through the clothing or into the skin directly. If cauterization was of any use, it had to be done within the first half-hour, as when done an hour or more later it was perfectly useless. The actual cautery or hot iron would suffice. Nitric acid was the best chemical agent; nitrate of silver was perfectly useless, yet many physicians used this. There seemed to be a great prevalence of rabies in Baltimore and surrounding counties. It seemed to occur periodically among animals. Of the thirty-five patients treated, twenty-five were bitten by animals that were proved to be rabid afterward, and ten by animals so suspected. He then compared his statistics with those of other institutions.

Facial Paralysis.—Dr. Henry M. Thomas read a paper based on a study of eighty cases. He said this was peripheral facial paralysis or Bell's paralysis, and all of his cases were from the medical ward of the dispensary of the Johns Hopkins Hospital. He had had eighty-five cases, of which forty-nine were in women and thirty-six were in men—the usual proportion. One woman had two attacks on the right side. Of his patients, forty-three were paralyzed on the right side, and thirty-three on the left side, and two on both sides. As to the ages, in one it was congenital: five were between one and ten; seventeen between eleven and twenty; seventeen between twenty-one and thirty; twenty-one between thirty and forty; thirteen between forty-one and fifty; seven between fifty-one and sixty; and four over sixty. As to cause, in forty-seven of his cases none could be given; in seventeen cases exposure was given as the cause, but in many cases the history was indefinite: injury was said to be the cause in twenty-eight cases; twenty-five were from some surgical cause, and three were accidental. One seemed to be caused by removal of an ear; another was from a foreign body in the middle ear; a third was from an injury of the lower jaw; and a fourth was from the removal of a tumor from the front of the ear. Another case was caused by the injection into the jaw of an iodoform-oil emulsion for an injury. The speaker thought that injury was not so prominent a

cause of paralysis as text-books would have people believe. Great stress was laid on the neuropathic tendency. One case was due to injury by forceps. The symptoms were not very marked; sometimes there was a slight pain; sometimes the sight was affected, sometimes the hearing.

Dr. John Bloodgood spoke of a surgical operation in connection with some of his cases, and the difficulties of avoiding the nerves in some operations.

Cancer of the Stomach. — Dr. Thomas McRae reported one hundred and fifty cases of gastric cancer treated in the Johns Hopkins Hospital. All of these were cases of primary cancer except three, which were secondary. Generally the diagnosis was made post mortem. He referred to the age of these patients: six were between twenty and thirty; one was twenty-two and one twenty-four; two were twenty-six and two twenty-eight; seventeen were between thirty and forty, thirty-eight between forty and fifty, forty-nine between fifty and sixty, thirty-six between sixty and seventy, and four over seventy. Of the thirty-six twelve were male and twenty-four female. Of the whole number, one hundred and thirty-one were white and nineteen were colored, the proportion in the Johns Hopkins Hospital being seven white to one colored. In eleven cases there was a family history. Thirty-eight had tuberculous involvement, but there seemed to be no connection between the tuberculosis and the onset of the disease. As to habits, seventy-seven used alcohol—eight excessively, sixty-six moderately, and three very sparingly. Thirty-three complained of dyspepsia, seventeen had had attacks of acute gastritis, eleven had chronic stomach trouble, while five came to the hospital complaining of troubles dating one or two years back. Ten had no complaint of stomach trouble at all. Others complained of pain and vomiting, and showed the presence of a tumor. The method of onset was also marked. In thirty-nine cases the onset was rather sudden. Twenty-six had notice of disease in three months, eight between three and six months, and eight over six months. He then gave statistics of the time, place, and manner of diagnosis.

Latent Cancer of the Stomach. — Dr. Julius Friedenwald read the paper. There were two varieties of latent cancer: (1) those cases in which the gastric symptoms were absent or masked by other general symptoms and the gastric disease was not suspected; and (2) those cases in which there were no symptoms. The pathological conditions leading to latency were the position of the growth (at neither orifice) and a surface not ulcerated. He reported an interesting case with the autopsy history.

Dr. Osler said that he had seen so many cases of cancer of the stomach since he had been in Baltimore, he was almost inclined to think that it was a peculiarity of this region.

Dr. McRae also discussed this paper.

The Necessity of Postoperative Treatment of Congenital Clubfoot.—Dr. Tunstall Taylor emphasized especially the fact that after a child's clubfoot had been operated on, the proper instruments should be used and the child should be looked after until the muscles and other parts should regain their normal condition. Many surgeons operated and then expected results at once. He also showed several very ingenious instruments for holding the muscles in place.

Thursday, April 28th—Third Day.

Excision of the Ossicles for Chronic Purulent Otitis Media.—Dr. Harry Friedenwald read a paper with this title, showing a patient. The serious nature of these cases, he said, had been recognized, and the rule now was to give the flow of pus every opportunity to escape. The cavity of the middle ear, being very small and irregular and containing small bones and bands and membranes, was difficult to drain. In his case, the walls of the middle ear or the attic had become carious, and the patient, who was sixteen years of age, came to this condition as the result of diphtheria. He had pain in the ear, and on examination a large polypus was found reaching beyond the outer opening of the auditory canal. This was removed, and afterward the ossicles were removed on account of caries and the polypus was curetted. After this the case went on to recovery, and the patient was doing well except that he was very slightly deaf.

Suppurative Appendicitis; Operation Followed by Fæcal Fistula.—Dr. Thomas H. Emory, of Taylot, Md., reported the case. The patient was a colored man, twenty-four years old, upon whom he had operated for appendicitis under most unfavorable circumstances and with most unhygienic surroundings. The case went on to recovery, there being only a small fistula remaining. The interesting features of this case were (1) absence of chills at any time; (2) a moderate range of temperature and the character of the pulse; (3) the symptoms, which two or three days before the operation seemed to be subsiding; (4) the fact that at the time of the operation the abscess was apparently ready to break, the walls being extremely pliable; and (5) the absence of any tumor or fluctuation.

A Case of Stab Wound of the Abdomen.—Dr. J. W. Chambers reported a case of this nature. The patient was a man who, on January 28th, had been stabbed with a case or table knife at the penitentiary by one of the convicts. There were two abdominal wounds, one to the left of the median line and extending through the abdominal muscles and through the omentum, cutting the transverse colon for a distance of three inches. There was also a transverse incision through the small intestines. After he received these injuries the man walked one hundred yards, the intestines protruding, and one hour later he was brought to the hospital, and twenty minutes after that he was operated on. The intestines were washed, put back, and sewed up with Lembert's interrupted sutures; the other wound was treated as an open wound and was more in the region of the liver. There was prompt recovery. The fact that the intestines protruded probably kept the peritoneal cavity free from any contamination. The case was interesting as showing how much injury could be done to a man in this way without bad results, and then it was also well to know the importance of a rapid operation. Within an hour after the injury this man was operated on. He was now apparently well, was able to attend to his work, and had not suffered very much from the shock.

Dr. John Morris, who was on the lunacy board of Maryland, spoke of the man who did the stabbing. He said that over many of the men who were confined in institutions where there was no work there came a wave of insanity once or twice a year. This man was detained in an insane asylum, and seemed so much better that he was brought to the penitentiary, where he stabbed one of the keepers.

The Transplantation of the Rectus Muscle in Operation for the Cure of Certain Cases of Hernia.—Dr. John C. Bloodgood read a paper with this title. The important points to be recognized at the operation were that the conjoined tendon was obliterated, or was very narrow, or was very attenuated; that the lower angle of the inguinal canal had lost its support, and therefore something must be substituted for it. He divided his cases into two large groups: those in which the conjoined tendon was wide and firm, and those in which practically it was completely obliterated. Dr. Bloodgood had advised and in eight

cases had performed a plastic operation in the rectus muscle, bringing the muscle down and so suturing it as to form a support. The procedure was a very simple one. The method of operation was about the same as that followed by Halsted. On insertion of the deep sutures, the sheath of the rectus was divided in the direction of the muscle bundles from its insertion through the symphysis pubis upward for a distance of five centimetres. After the division of the sheath the outer border of the muscle bulged out, but it could be held back with sutures. The deep silver wire sutures were then inserted, as Halsted described. During the last few months the operation had been performed several times in the Johns Hopkins Hospital.

Rectal Medication.—Dr. Samuel T. Earle, Jr., said that there had always been great difficulty in applying ointments and suppositories in diseases of the rectum. Allingham had devised hard-rubber tubes, which were well enough in chronic cases, but which were rather expensive for short use in acute cases. A well-known firm had devised compressible, collapsible tubes, such as painters used, with a long nozzle, and he had found that these tubes, being made in definite sizes, could be filled with ointments according to the prescription desired, and applied with great certainty and exactness. He used them now entirely in his practice.

Bacteriological Study of Cystitis and Urinary Infections.—Dr. Hugh H. Young said that this work had been begun about two years ago at the Johns Hopkins Hospital, and was extremely interesting, though very hard to carry out. The object was to see, in cases of cystitis, what organisms could be found in the bladder, and his method of making examination was by suprapubic puncture of the bladder, so as to get out the cultures. This was done with every antiseptic caution. The bladder was always easy to be reached above the pubes, even when nearly empty, by compression of the abdominal walls. He spoke of the bladder walls in posterior urethritis. It was strange that the bladder was not affected by specific urethritis, but this was rarely the case. It was only when there was a wound of the bladder walls that infection took place. Of eighteen cases of acute cystitis which he had had, the staphylococcus pyogenes albus was obtained in eight, and in several it was found after the use of instruments. A young man, eighteen years old, had specific urethritis, and was treated in the proper way at the hospital, with apparent cure. He was sent home with instructions to continue his treatment, and owing to some faulty technique returned with cystitis. On examining the contents of the bladder as above stated, the speaker found the same organisms as in another case. This continued for two weeks, but the man recovered finally. The other case was that of a German, fifty years old, who was rather fond of beer; one night he drank an unusually large quantity, and the next day showed symptoms of cystitis with some hæmaturia. Here the staphylococcus pyogenes albus was again found. The man had never had urethritis and no instrument had been used on him. In five of these cases nothing was found. Melchor held that the bacillus coli communis was the most common cause of inflammation in the bladder, but it was not the cause of acute cystitis. Some organisms seemed to produce a mild attack and some a severe attack of cystitis, and in the long-continued cases the colon bacillus seemed to drive all the others away. These conditions had not been explained. He had also found cultures of gonococcus in gonorrhœal rheumatism, and Dr. Thayer, in one case, had even found organisms in the blood.

Dr. William B. Canfield said that the work which Dr. Young had described was most elaborate and was greatly to be admired, and he thought that the physicians ought to be very grateful to him for bringing out the details so clearly. In the case of the German above mentioned, he thought it was rather strange that the organisms should be found simply from the beer and from no external cause. He also thought that five sterile cases among so few was a very large proportion.

Dr. Young replied that these organisms might find their way in the body through the blood, as they did in other internal disorders. He was also surprised that five cases were sterile, but he had done his work with great care and was satisfied that he was correct.

Epidemic Cerebro-Spinal Meningitis.—Dr. William T. Councilman delivered the annual address on this subject. He said it was only within recent years that physicians had been able to distinguish in epidemic cerebro-spinal meningitis a definite disease of definite etiology. An organism which might be distinguished by certain characteristics of its own had been found in the inflammatory exudation in certain cases of meningitis. This organism could be grown in suitable cultures, and the pure culture when inoculated into susceptible animals produced the disease and this disease followed a regular recognized course. There was a great deal of confusion at first by mistaking this disease and its organism for other diseases and other organisms. What was needed now was a series of a sufficient number of cases in which the meninges had been examined during life, so that the different types of the disease could be more sharply defined. The first description of what was now known as this disease was made by Vieusseaux in 1805. An epidemic of cerebro-spinal meningitis occurred in Medfield, Mass., in 1806, and later other epidemics occurred in various parts of this country. This disease, he said, affected principally the young. It might be carried by infected clothing and in various ways. It was commonly called brain fever. There was little in the literature on immunity from this disease. The organism which was now recognized as the specific cause of this disease was first described by Weichselbaum in 1887, and the description was confirmed later by Jager in 1895. It was a micrococcus of about the same size as the ordinary pathogenic micrococci, and appeared in diplococcus form as two hemispheres separated by an unstained interval. It stained with any of the ordinary stains for bacteria and was decolorized by the Gram method. The speaker then described at some length its manner of growth on various media and its effect on animals. In the post-mortem examinations made it was generally found, and its situation varied according to the stage of the disease. Besides the meninges of the brain and the coverings of the spinal cord, the organism was found in few places in the body. The spleen was often enlarged. There were described three forms of the disease—the acute, the chronic, and the intermittent. Pneumonia was often a complication, but it must not be supposed, as was once thought, that the pneumococcus was a cause of meningitis. The surest way of making a certain diagnosis was by lumbar puncture, and this should always be carried out when possible. The method was easy and experience had shown that it was devoid of danger.

At the conclusion of this admirable address, which was listened to with attention by many hundred physicians, a vote of thanks was tendered the orator and a copy of the address was requested for publication.

Friday, April 29th—Fourth Day.

The Importance of the Early Recognition of Enlargements of the Pharyngeal Tonsil.—This was the subject of a paper by Dr. Frank D. Sawyer, in

which he dealt especially with this trouble as manifested in young children, spoke of the symptoms and bad effects if it was allowed to continue, and showed how easy the treatment was and how often it was neglected.

Dr. Edward M. Schaeffer said that this subject was an important one and he was glad it had been brought forward. He spoke of the utter ignorance of the laity on such things, and insisted that they should be instructed on the dangers of allowing a child to go unoperated on when it gave every evidence of a large growth of adenoids filling the posterior pharynx.

Dr. William Osler said that the profession was also to blame, and he thought that the profession at large needed education on this subject just as much as the laity. He saw every year eight or ten cases of serious trouble resulting from negligence on the part of the physician, who should have compelled the parents to have the child submit to an operation at the hands of a specialist. Diagnosis was a very easy matter. A child that breathed with open mouth and snorted in its sleep should be at once put in the hands of a specialist. It was not every specialist in nose and throat complaints who could treat properly such cases. This was an important subject and the profession needed enlightenment as well as the public.

Free Leucocytic Granules in the Blood and their Reaction to Various Stains. — Dr. William R. Stokes and Dr. Arthur Wegefarth demonstrated these. In the white blood corpuscles of normal human blood the small granules could be seen in motion like the Brownian movement, and in other specimens the granules were shown free and stained. This was a preliminary report only.

Officers.—The following officers were then elected for the ensuing year, which will mark the completion of the one hundredth continuous year of the existence of the faculty, it having been founded in 1798: *President*, Samuel C. Chew; *Vice-Presidents*, Mary Sherwood and J. McP. Scott; *Secretaries*, J. Williams Lord, Robert T. Wilson, W. Guy Townsend, and H. O. Reik; *Treasurer*, T. A. Ashby.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, May 9, 1898.

W. W. Van Arsdale, M.D., Chairman.

Resection of the Rectum for Carcinoma of Three Years' Duration.—Dr. James P. Tuttle presented a man, fifty-four years of age who, when first coming under observation, had complained of pain in the sacrum and rectum, and had had bloody stools. Examination showed carcinoma of the rectum, and as the growth could be moved on the bladder and prostate, and could be dragged down, Dr. Tuttle had inferred that the case was operable. At the operation he found not only the upper part of the rectum but also an inch of sigmoid flexure was involved. This required the removal of about ten inches of the gut. After the removal of the meso-rectum it was found easy to take away the remainder. An end-to-end anastomosis of the bowel was made, and the man recovered without any complications beyond the occurrence of a fæcal fistula in the wound. This lasted four or five months, a complication which, the speaker said, was exceedingly common in such cases. In a recent case he had used the Murphy button, reinforced by the Lembert suture, and in this instance there had been no fæcal fistula. The patient presented was in excellent condition, was able to work, and was entirely free from pain. By direct examination of the rectum with the Kelly tube and the electric light, it was demonstrated that no stricture was present.

Cancer of the Breast in the Male.—Dr. Ramon Guiteras presented an Italian, who had been admitted to the Columbus Hospital on February 17th, with a tumor of the right breast, said to have existed for fifteen years. The fact that the man spoke in a peculiar dialect prevented a thorough understanding of the details of his previous history. There was a tumor on the outer side of the right breast, along the border of the pectoralis major muscle. It was three inches in length and one and one-half inches in width, was markedly indurated, and presented an ulcerating surface. Palpation showed the axillary glands to be enlarged. The man was well nourished, and was well developed except that the upper extremity on the right side was several inches larger in circumference than that on the other side. Three days after his admission the tumor was removed by the ordinary incision, which was continued along the border of the pectoralis muscle and into the axilla. This muscle being much infiltrated, it was also removed. The pectoralis minor was cut in two, and the glands were removed, after which the divided muscle was reunited with sutures. The case was reported because of the great rarity of carcinoma of the breast in the male.

Dr. L. Bolton Bangs said that he had seen at one time the patient presented by Dr. Tuttle, and the examination had impressed him with the fact that there was a new growth of the rectum so extensive as to make the case unfit for operation. Consequently when he had learned subsequently of the successful issue of the operation he had fully appreciated the great diagnostic skill of Dr. Tuttle.

Dr. Rogers said that his experience in operating on the rectum was limited to three cases. Two of them had been operated upon by the Kraske method, both with disastrous results. In the third he had operated through the abdomen, and the result had been exceedingly satisfactory.

Dr. Tuttle said that the portion of the rectum taken out extended down within an inch and one-half of the anus. The disease practically did not involve either of the sphincters.

The Surgical Treatment of External Deformities of the Nose.—Dr. D. H. Goodwillie read a paper on this subject. He said that some of the more important causes of external deformities of the nose were: (1) congenital, from imperfect intrauterine development; (2) traumatisms directly, or indirectly by the pathological changes set up; (3) hypertrophies and tumors of the hard and soft tissues, both intranasal and extranasal; and (4) malignant, specific, and other constitutional diseases. The first patient presented, a lady of twenty-one years, showed the good result obtained in a case in which there had been an opening in the bridge of the nose produced by sloughing away and the removal of a metallic bridge that had been inserted by another surgeon. Six cases were reported in detail, representing a variety of external nasal deformities, and these, as well as a number of other curious conditions, were illustrated by wax casts, showing the appearance both before and after treatment.

Arthropathy Consequent on Trauma.— This is often relieved by the hot-air treatment, especially when combined with massage and passive motion. Frazier found its physiological effect to be as follows: a temporary increase of circulation, respiration, and temperature; moderate fugacious anæsthesia; loss of weight, probably due to the loss of water from the skin and lungs; and a decided nitrogen output. These effects are purely local in origin.—*Annals of Surgery*, October, 1897.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 13, 1898.

T. Mitchell Prudden, M.D., President.

Aneurism of the Ascending Arch of the Aorta.—Dr. Harlow Brooks presented three cases. The first one was that of a man, seventy-five years of age, who had been brought into the hospital in a moribund condition. The body exhibited the usual senile changes, and the arteries were atheromatous throughout. In the ascending arch of the aorta, at the point of origin of one of the coronary arteries, was a sacculated dilatation. The general condition of the heart was fairly good for one so old. The kidneys showed chronic diffuse nephritis.

The second case was that of a woman who had been admitted to Bellevue Hospital with a history of alcoholism and of acute articular rheumatism five years before. Three months before admission she began to have shortness of breath on going up and down stairs. Swelling of the feet and shortness of breath were her chief complaints on admission. She died very shortly after entering the hospital, so that no physical examination was made. The pericardium was injected and greatly distended. The heart was enormously enlarged, weighing twenty-eight ounces. Its walls were flaccid and relatively thin, showing recent dilatation. The cavities contained post-mortem clot. The general arterial trunks showed very little disease. In the arch of the aorta, just above the sinuses of Valsalva, was found a foramen, about 1.2 cm. in diameter, bifurcated by a column of tissue, about 1 mm. thick. This led into a cavity, measuring 3 cm. in diameter. The sacculation so produced was completely enclosed in the thin walls of the right auricle.

The third case was that of a man, forty-four years of age, who entered the hospital complaining of shortness of breath and cough. Fourteen years ago he had rheumatism, and had had numerous attacks since that time. During all the subsequent years he had had more or less shortness of breath. For the last six months there had been constant cough without expectoration, and at the time of his entrance into the hospital there were slight œdema of the lower extremities and pain in the upper part of the back. The physical examination revealed an extreme degree of pulmonary emphysema and a diffuse systolic and diastolic murmur over the lower portion of the manubrium of the sternum. The pulse was small, equal, regular, rapid, and of considerable volume. The liver was apparently increased in size. At the autopsy the heart was found to be enlarged, weighing sixteen ounces. In the right cavity was some fluid blood, and there was considerable interstitial change, especially in the papillary muscle. There was considerable thickening of the aortic and mitral valves. In the ascending arch of the aorta, just below the innominate artery, was still another sac, which had ruptured through the walls of the aorta and had made a wall for itself, consisting of the external wall of the trachea and of the adhesions existing between the trachea and the transverse arch of the aorta. This sac was lined by recent granulations. The sac was not occluded by clot, and did not contain even post-mortem clot.

A New Method of Obtaining Blood during Life for Bacteriological Examinations.—Dr. Walter B. James exhibited a small instrument which he had been using at the Presbyterian Hospital during the past year for this purpose. He said that previous attempts to obtain cultures from the blood had been more or less disappointing, because of the varying results of different observers. Thus, one observer had examined nine cases of typhoid fever, and claimed to have obtained the specific organism in all of them, while another investigator examined fourteen cases and obtained it in none. These differences in results were apparently largely due to the method employed. One method was to use sterilized glass bulbs, having tapering points, which when the ends were broken off were thrust forcibly into the vein. The results were accurate enough, but this method was so uncomfortable and dangerous that it had not been much used in this country. A sterilized hypodermic syringe had been used by many, but it was difficult for the physician to keep it properly sterilized. The method which he was about to describe, and which had been used with satisfaction at the Presbyterian Hospital, had three objects in view, viz.: (1) to render the procedure as nearly as possible absolutely sterile; (2) to make it absolutely safe and not too uncomfortable for the patient; and (3) to have it sufficiently simple to be available for the house staff of a hospital or for general practitioners. Some small glass tubes were drawn to a taper, and each one was fitted with a hypodermic needle. The end of the tube was stopped with cotton. A number of these tubes could be sterilized by dry heat, and kept in stock ready for use at a moment's notice. Experience seemed to show that no elaborate preparations for disinfecting the skin were necessary. The practice had been to thrust the needle into the vein at the bend of the elbow. The tube would ordinarily be almost filled by the venous blood pressure, but if necessary gentle suction might be made with the mouth. The tube was then withdrawn and the blood forced out by the breath on to suitable culture media. From examinations made in one hundred and sixty cases, representing many different diseases, and from a study of the literature of the subject, the conclusion had been reached that blood culture experiments, as ordinarily made, from puncture of the tip of the finger, were absolutely worthless. In a fair proportion of the cases of typhoid fever at the Presbyterian Hospital the specific bacillus had been found, and in a fair proportion of cases of sepsis, showing general pyæmia, a culture of the streptococcus had been obtained from the blood. In two out of three cases of endocarditis in which cultures were made from the blood, in a case due to infection with the pneumococcus lanceolatus, this bacterium was repeatedly obtained.

Dr. R. H. Sayre asked if any experiments had been made, following out those of Dane, of Boston, regarding blood in cases of tuberculosis associated with abscesses, with a view to determining if possible when the case became a mixed infection and when it was simply tuberculous.

Dr. James replied that they had examined a dozen or more cases of tuberculosis in which there was thought to be mixed infection, but the streptococcus was not found in any of them.

Dr. W. H. Park said that for the past year the workers in the laboratory of the health department had been endeavoring to get results from streptococcus serum, and the chief difficulty had been to get blood free from contamination. The literature of the subject showed that streptococcus serum had been not infrequently employed when the blood examination showed only the staphylococcus present.

Dr. James Ewing thought that some such simple apparatus as that just described would greatly facilitate the more general examination of the blood. The apparatus was certainly very simple and easily sterilized, and hence was in that respect superior to any aspirating syringe. But on the end of the glass tube were connections for a hypodermic needle, necessitating the same sterilization as for the aspirating syringe. On the other end was a cotton pledget, through which he supposed the blood was aspirated by the mouth. Unless the cotton pledget was left in, he

thought there would be great liability to contamination. Another objection to the instrument was that it did not have sufficient capacity; one cubic centimetre was hardly enough—at least five cubic centimetres should be obtained and planted on different media. The larger the quantity of blood, the greater the chance, in cases of mild infection, of securing the particular germ which was in the circulation. He had found a hypodermic syringe a satisfactory instrument, except that it was somewhat difficult to sterilize. With it, five cubic centimetres could be obtained without trouble. He had not found great difficulty in sterilizing the syringe with a ten-per-cent. formalin solution, the syringe being kept filled with it. Just before being used, the syringe should be washed out thoroughly with boiled water. He had not experienced any great difficulty in getting into the vein, except in moribund patients, and in these by the application of a tourniquet for a few moments sufficient blood could be obtained. A vertical puncture was better than a longitudinal thrust. The advantage of using a large quantity of blood had been well shown in a series of observations on diphtheria made by Wright. By using a larger quantity of blood he had obtained the diphtheria bacillus in a considerable percentage of severe cases. Personally he had failed to get the streptococcus in fatal cases of malignant endocarditis, even when five cubic centimetres of blood had been subjected to examination.

Dr. James said that, of course, the instrument could be made larger, but he had thought it better not to use too much blood, for fear that there might be some bactericidal action set up. The method of cleansing the hypodermic syringe described by Dr. Ewing was of course satisfactory, but these details would not be carried out by many in general practice. His tubes could be kept in stock absolutely sterile. In not one of the cases examined was there any local reaction whatever, and none of the patients complained any more than they would of an ordinary hypodermic injection.

A Case of Hemorrhagic Disease of the Newborn, with a Bacteriological Examination.—Dr. Elizabeth Mercelis reported a case of this kind. She said that at the New York Infirmary for Women and Children, from February 25 to April 20, 1897, there had been nine cases in which hemorrhage had occurred in the newborn. In three it had been multiple and severe, and all had been fatal. In three others it had been multiple and slight, and of these one had been fatal. In two of the infants, who were small and frail, there had been hemorrhage from the nose only. One of these children died. Some of these cases were slight, and occurring independently would have been disregarded. Six of the nine cases were in male children. The mortality in the whole series was fifty-five per cent. Two of the more marked cases were made the subject of special study. The first of these cases developed hemorrhagic swellings, which ruptured spontaneously. Cultures were taken from the finger before death, which occurred on the thirteenth day. The cultures remained sterile. The autopsy showed extensive cutaneous and subcutaneous hemorrhages, extending from ear to ear and from the maxilla to the clavicle. On the left side was a sloughing area, with an opening, three centimetres in diameter, which exposed the external jugular vein. No point of rupture of the vessel could be detected. The skin of the hands and feet was tough, leathery, and almost black. The umbilicus was normal. The thoracic and abdominal organs were congested, but there were no hemorrhages. The heart showed slight vegetations. Cultures taken from the liver and kidney were planted on agar plates and on broth, but no growth resulted.

In the second case there were hemorrhages from the bowel, stomach, and uterus, and death occurred on the sixth day. The autopsy showed petechial spots on the right arm and chest. The umbilicus was normal, and the cord was still adherent. The lungs were congested posteriorly. The tricuspid and mitral valves of the heart exhibited vegetations along their edges; the foramen ovale was almost closed. The liver was fatty. The spleen was very much congested. The kidneys showed no special congestion and no hemorrhages. The pancreas, adrenals, and thymus were negative. The stomach was pale, and there were no hemorrhages or ulcerations. The intestine throughout was filled with dark reddish, tarry material showing blood. There was slight enlargement of the isolated follicles of the colon, but there were no other changes in the mucosa. About the ureteral openings in the bladder were elevated hemorrhagic areas. The uterus was filled with fluid blood; the adnexa were negative. The brain showed moderate congestion of the meninges; there were no hemorrhages into the ventricles or basic ganglia.

Cover-slip preparations from the different organs in the second case showed several large and small cocci, without a definite capsule, which stained more or less, and were scattered in groups, pairs, or short chains. The cocci were often oval, and here and there a distinct bacillus form was seen. Agar plates from the liver, spleen, and inferior vena cava showed no growth after twenty-four hours. The broth tube from the heart's blood was uniformly cloudy. The agar-agar tube from the uterus showed a continuous delicate whitish growth along the line of puncture, but no surface growth. That from the kidney had a slight growth below the surface. Preparations from these gave an organism varying much in size, shape, and intensity of staining, as described; bipolar staining was common. It was examined on various culture media, but whatever the medium the growth was always delicate and did not increase after twenty-four or forty-eight hours. There was no growth in gelatin. When broth was inoculated directly from an animal, a growth occasionally occurred — rarely otherwise. When one-fourth to one-eighth centimetre of hæmoglobin was added to the broth, or a decinormal solution of KOH, until the media were quite alkaline, a growth in aerobic and anaerobic cultures took place. In glycerin-agar the development was more noticeable along the puncture, but there was none on the surface. In blood serum there was a colorless surface growth. Ascitic fluid seemed to be the most favorable medium; here the clouding was general. Milk, after twenty-four hours, became slightly acid, and after forty-eight hours coagulated. The normal limit of viability of the organism was from two to four days. When one and one-half cubic centimetres of an ascitic fluid culture was introduced into the peritoneal cavity of a pig, death resulted in twenty-one hours. There were marked subcutaneous œdema and an accumulation of a moderate amount of turbid fluid in the peritoneal cavity. The heart, liver, and kidneys were negative. The intestine, spleen, and uterus were congested, but contained no hemorrhages. There were no hemorrhages in the lungs. Cover-slip preparations gave the same pictures as already described. In the cultures from the liver and heart the growth took place below the surface.

The microscopical appearances found in rabbits and other animals inoculated with this organism were as follows: The liver showed engorgement of the vessels, degeneration of the liver cells, and fragmentation of the nuclei. In the rabbit, small hemorrhagic areas were found. The spleen was much congested. The pancreas showed an area of free blood in the tissue. A cross-section of the ventricle of the heart of the pig showed an absence of the endothelium over one-fifth of the wall and a few diplococci in short chains.

Certain areas in the lung of the rabbit showed the alveoli to be filled with blood and epithelium. Except in the lungs, the effused blood was not to be distinguished from congestion by the naked eye.

Morphologically, the organism at times suggested the pneumococcus lanceolatus or the bacillus of Friedlander, but was distinguished from them by culture peculiarities, some of which had been already mentioned.

In conclusion, Dr. Mercelis expressed her indebtedness to Dr. W. H. Park for the privilege of working in the laboratory of the board of health, and to Dr. Anna Williams for verifying the results.

Carcinoma of the Œsophagus with Involvement of the Trachea and Subclavian Vein.—Dr. John H. Larkin presented a specimen of this kind, removed from a man, fifty-four years of age, who had always been well up to two months ago. About that time he began to grow pale and weak. At the time of his admission to hospital, two weeks before death, there were some cough and considerable dyspnœa. Physical examination gave the typical signs of bronchitis and emphysema. With the exception that the heart action was irregular and the sounds were muffled, the other viscera were normal. The urine contained no albumin, and no tubercle bacilli were found in the sputum. The case was treated for chronic bronchitis and emphysema and anæmia. The dyspnœa became very distressing, but there was no noteworthy change in the man's condition up to just before his death, which occurred very suddenly. The autopsy was performed four hours after death. The body was well nourished, but exceedingly pale. There were no evidences of peritonitis. The lungs were extremely emphysematous. The liver was exceedingly pale. Behind the manubrium of the sternum was a large firm mass, about the size of a small orange, in front of and to the left of the trachea, and behind and above the arch of the aorta. In the œsophagus was a small papilliferous tumor, about 15 cm. above the cardiac end of the stomach. It measured 2 cm. longitudinally, 1.5 cm. transversely, and 1 cm. from base to apex. About 4 cm. above this tumor were two small, irregular ulcers, probably the result of pressure. The lumen of the trachea was narrowed to a mere slit. The mass lay chiefly to the left of the trachea, extending from the arch of the aorta to the suprasternal notch. The great vessels lay in front, and the tumor mass was rather firmly wedged between the manubrium and the spinal column. The cross-section of the tumor measured 6 cm. antero-posteriorly, and 5 cm. laterally. About 2 cm. above the bifurcation of the trachea the mass protruded into the lumen. The left subclavian vein was adherent to the top portion of the tumor, and two small nodular masses were found projecting into its lumen.

Microscopical examination showed the tumor to be an epithelioma, which was undoubtedly primary in the œsophagus, and extended directly around the trachea and subclavian vein.

The points especially emphasized were: (1) The smallness of the primary growth and the extent of the growth around the trachea; (2) the penetration of the subclavian vein by direct extension and the possible mode of dissemination of metastases by the blood; (3) the mildness of the symptoms compared with the grave post-mortem findings; and (4) the fact that the sudden death was due to mechanical asphyxia.

Dr. Prudden remarked that examination of the sections was interesting, because over the epithelioma growing into the vein was a thin pellicle of fibrin which had bound the loose epithelial cells in place against the wall. Certainly the loose cells would have been in contact with the flowing blood except for this protection.

A Sarcoma of the Leg of Slow Growth.—Dr. R. H. Sayre presented the skiagraph of the leg of a boy of seven years, who when eighteen months old fell, striking the crest of the tibia and producing a slight abrasion. A little nodule appeared shortly afterward, and some months later it was incised and scraped out. The wound healed, but the leg was somewhat crooked. He then had another fall. Subsequently another surgeon made a long incision, and removed a large quantity of soft material and packed the wound. The boy was kept off his feet for about a year, yet the leg began to bend. Finally he broke the leg. The case came under Dr. Sayre's observation last fall, and an operation was advised but not consented to. When seen again quite recently the boy had a temperature of 99.2° F. The skiagraph showed a peculiar soft condition of the bone. On operation for the purpose of removing a wedge-shaped piece of bone, the bone was found to be soft like sponge. It bled quite profusely, and the appearance suggested syphilis or malignant disease. The operation was extended until fairly healthy-looking bone was encountered. On decalcification of the removed bone, it was found to be a spindle cell sarcoma, and amputation was performed. The bone had made no effort at repair. It was remarkable that the disease should have lasted for six years without giving rise to metastasis.

A Method of Recording Anatomical Data and the Results of Special Observations and Research in Laboratories, Colleges, and Hospitals by the Application of the Card-Catalogue System.—Dr. Henderson B. Deady read a paper on this subject, and gave a demonstration of the method as used in the Pathological Institute of the New York State Hospitals. He said that the record of a case could be considered in three divisions, viz.: (1) The autopsy notes, history, and date of accession; (2) the data relating to preservation; (3) the subsequent work relating to the slide and its technique. The old form of case book, he said, was discarded, and the data of accession were entered in the "accession book"—an adaptation from the library accession book which was considered the keystone to all the systematized laboratory work. In this book were entered: (1) The accession number; (2) the date on which the case was received; (3) the name of the patient or specimen; (4) its source, *e.g.*, hospital; (5) the clinical diagnosis; (6) the date of death; (7) the date and hour of autopsy; (8) a reference as to the receipt of autopsy notes and history. The history and autopsy notes were kept in a separate book, typewritten on paper of uniform size bearing the accession or case number, which the case got from the accession book. The slide labels were small squares divided by two horizontal lines into three spaces. On the first line was placed the accession number, followed by a decimal point. The number which immediately followed the decimal point was any unit from 1 to 9, and represented an arbitrary but convenient anatomical classification of the material. The pieces from the material as it was divided for preservation were all numbered, and these numbers followed the classification number in regular order. Thus, 871.13 meant case No. 871, and the third piece of brain, the figure "1" immediately following the decimal point meaning in the anatomical classification "brain and its membranes." Pieces taken from a specimen after preservation were numbered consecutively. The number was written on the second line (this the speaker called the block or distribution number). The slides made from this piece were also numbered consecutively and the number was written on the third line. All the notes of preservation were kept on cards, one card for each specimen. In this card catalogue was also kept a memorandum of the pieces "distributed." Each worker had one card for

the piece assigned to him, called a block card. On this were written the complete number describing the piece and the notes of technique referring to the piece from the time he received it. In the same way he filled out a card for each slide made from this piece, the card bearing the full number and notes of technique. The same system was applied to drawings made from material in any of these three phases. The drawing bore the number of the specimen, and a colored card bore the number, drawing, technique, and delineator. By this system each piece of material, the notes referring to it, and drawings were indexed, quickly put away or referred to, and were made permanent records of the laboratory, accessible and intelligible to any one for all time—the material in all stages bearing the number only, the data being on cards bearing the same number.

Dr. D. H. McAlpin inquired as to the relative expense per thousand cases, the number of clerks required to maintain the system, and also whether a fireproof safe was provided for these important records. The system, he said, would not be found to be at all complex as soon as one had become thoroughly acquainted with it. In different laboratories there were somewhat similar systems, though smaller and less pretentious. At the Carnegie Laboratory the cost was less than two cents each for a complete record of cases.

Dr. Frederick S. Ward spoke of the system employed at the Pathological Laboratory of the College of Physicians and Surgeons. The record of a case, he said, made use of an accession book, a book of complete records, a card index to anatomical material, and a cross-reference card index to material and slides. In the accession book were recorded the number of the specimen, date of receipt, name of patient or specimen, source, clinical diagnosis, date of autopsy or operation, by whom the autopsy or operation was performed, anatomical diagnosis, collection number, references, and remarks. The first eight of these items were made when the specimen came to the laboratory and the last three when the necessary data had been obtained. In the book of notes were recorded the foregoing items, together with the full clinical history, macroscopic and microscopic examinations, and references to slides and literature. The card index of material presented the accession number, source, diagnosis, preservation of material, reference to slides, etc. The cross-reference catalogue was one of organs and lesions, referring both to material in the collection and to slides in the cabinet. The slides were filed away and indexed according to systems and subdivisions of these systems. For instance, there were the alimentary and genito-urinary systems, tumors, etc., as the main division, with subdivisions of organs and varieties of tumors. The initial letter of the system to which the slide belonged was printed in red; and others, when required, of the subdivision in which it fell were printed in black, together with the number of the slide, the latter being the reference to the slide. Every specimen coming to the laboratory was recorded in the accession book, receiving thereform the accession number, examined, and then met one of three destinations: 1. It was thrown away; 2, saved for gross demonstration before the class; 3, placed in the laboratory collection. In the latter case it carried its accession number to the card index and to the book of notes. A specimen having received a collection number, this was borne on jar label, record, all reference cards, and slides.

Dr. Francis C. Wood exhibited the cards used to index the histories in St. Luke's Hospital. Cards of different colors, he said, were provided for male and female patients. The large cards with little tags on the top were indexed according to diseases and the tags referred to the attendant treating the case, so that each could, with very little expenditure of time, pick out the patients who had been under his care. The small cards were used to index the patients by name. Pathological reports were indexed on a card of a special color. On all these cards were given the volume and page of the history book in which the record of the particular case could be found in full.

The following "card" specimens were also exhibited.

Advanced Cirrhosis of the Liver with Marked Atrophy of the Right Lobe and Compensatory Hypertrophy of the Left Lobe.—Dr. Eugene Hodenpyl presented this specimen, which had been removed from a man who had died of pulmonary œdema, and had suffered for a number of years from frequent and profuse epistaxis. No other symptoms referable to the liver were observed until a few days before death, when slight jaundice and anasarca developed.

Sacculated Aneurism of the Arch of the Aorta, Showing Perforation and Frequent Hemorrhages.—Dr. Hodenpyl also presented this specimen which had been taken from a man, fifty-five years of age, formerly a truck driver, and accustomed to lift heavy weights. There was no evidence of syphilis. He had been well up to three months ago, when he had a rather profuse hemorrhage from the mouth, which was followed after several days by a second and a third. On his admission to the hospital, a pulsating tumor was detected in the thorax at the root of the neck. Bleeding from the mouth took place several times while he was in the hospital, the last occurring just before death. At this time he lost thirty-five ounces of blood. The autopsy revealed a sacculated aneurism of the arch of the aorta, measuring ten by ten centimetres and extending upward, backward, and to the left. There was a large opening on the posterior aspect firmly adherent to the bodies of the vertebræ, which were not eroded. There was a second circular opening into the œsophagus, five millimetres in diameter, at a point three centimetres above the bifurcation of the trachea. The left lower lobe of the lung was distended with aspired blood.

Gummata of Brain with Widespread Syphilitic Infiltration.—Dr. John H. Larkin presented this specimen, which came from a prostitute, twenty-six years of age, who had had the primary lesion four years before, and little or no treatment at the time. For three months before her death she complained of severe nocturnal headache, vomiting, and diminution of vision in the right eye. On her admission to the hospital, one week before death, she had headache, double right-sided hemianopsia, and confusion of ideas. There was also a large elevated mass over the left parietal protuberance. She grew rapidly worse and died in coma. At the autopsy the bone over the left parietal eminence was found to be soft and necrotic; the dura mater was adherent to the brain and necrosed bone; the periosteum was greatly thickened over the whole left parietal bone, but especially at the site of the necrosis. There were no other manifestations of syphilis in other viscera, which were, including the heart and liver, in a state of advanced fatty degeneration.

Chronic Nephritis and Cardiac Hypertrophy; Extensive Hemorrhages.—Dr. G. A. Tuttle presented the heart and kidneys from an Italian, twenty-five years of age. For a month and a half the man had had hemorrhages from the nose and mouth, but no cough. Later there had been some bleeding from the lobe and canal of the ear, from the lip and tongue, and a clot had been passed by the rectum. He had a general convulsion on the day of his death. The urine contained albumin, but no casts. There was marked anæmia. The autopsy revealed no cause for the hemorrhages beyond chronic nephritis and cardiac hypertrophy.

Heart Clot; Granular Nephritis.—Dr. Tuttle also exhibited the heart from a woman who had complained for a few days of feeling vaguely ill. A few hours before her death she became deeply cyanosed. There was a double murmur at the apex and at the base; the urine contained albumin and casts. Microscopical examination of the mass in the left auricle showed it to consist largely of clotted blood, apparently fresh, and in other parts of organized clot. The kidneys showed a granular nephritis.

Simple Ulcer of the Stomach Involving the Splenic Vessels and the Pancreas.—Dr. Tuttle also exhibited a specimen showing simple ulcer of the stomach, with the pancreas for its base at each end, the central portion of the pancreas having sloughed away. In the floor of this ulcer were seen the openings of the splenic vein, the intervening portion of the vein having entirely disappeared. There was also a single opening into the splenic artery, which caused the death of the patient. In addition there was a small abscess in the tail of the pancreas. Microscopical examination of the pancreas and edges of the ulcer showed no new growth. The specimen was taken from a woman, fifty-one years of age, who died August 24, 1897.

The society then went into executive session.

Correspondence.

LONDON LETTER.

(From our Special Correspondent.)

PARLIAMENT—TUBERCULOSIS COMMISSION'S REPORT—RENAL CALCULUS—BLOCKING OF MESENTERIC VESSELS CAUSING INTESTINAL OBSTRUCTION—MILITARY EXPEDITION WITHOUT A SURGEON—SMALL-POX—DEATH OF DR. MARSHALL, OF CLIFTON.

London, April 29, 1898.

The habitual-drunkards bill was read in the House of Commons for the first time on Monday. Its object is to substitute reformatory treatment in special institutions for penal treatment in prisons. It is thus practically confined to criminals, and some disappointment will be felt that it is not more comprehensive.

The bill for permitting prisoners to give evidence on their own behalf has passed a second reading.

The report of the royal commission on tuberculosis has been presented to Parliament. Some of its conclusions were inevitable, but it is well for the public that they have been put on record after exhaustive inquiry. The commissioners find that that milk plays the most important part of any article of food in infecting man, and they regard the inspection of this article as at present amounting to nothing. The inspection of meat, they say, varies in value with the class of men employed as inspectors. They recommend that in urban districts public slaughter houses should be obligatory, and that all carcasses should be inspected and if found sound stamped. Tuberculin they pronounce an infallible test in the hands of a competent veterinary surgeon. They further recommend that meat inspectors should be required to pass an examination; that notification of all diseases of the udder should be compulsory and that milk venders should be compelled to give information to the sanitary authorities as to the sources of their supplies; that all cowsheds should be registered, properly drained, ventilated, lighted, and distant at least one hundred feet from any dwelling-house. It will thus be seen that examinations, notification, and registration—three methods of dealing with questions which are continually being urged as cures for all evils—are advised to be tried and trusted against the infection of man by animals.

In order to eliminate bovine tuberculosis, it is recommended that stock owners should be encouraged to test their herds, by the gratuitous provision of the services of a veterinary surgeon to carry out the treatment with tuberculin, also supplied gratis. Owners availing themselves of this provision must undertake to isolate reacting animals from healthy ones.

Renal calculus has just occupied the attention of two of the societies, though from different points of view. To the Medical Society Mr. Battle related three unusual cases. In one there was continual hæmaturia, even when the patient was lying in bed, without the characteristic pain. In another there had been more or less pain for some ten years, but no attack of renal colic. In the third acute pyonephrosis was caused by obstruction of the ureter. Nephrotomy was performed and a calculus removed. Subsequently exploration of the ureter was performed and later a pultaceous mass passed through the urethra, after which the lumbar wound healed.

Dr. Holman asked whether myxœdema as a complication would make hemorrhage more likely, as he had a case of this disease in which renal colic supervened; the ureters became blocked and an abscess formed. This was evacuated, but the urine continues to pass through the wound, as the stone has not been removed.

Mr. Bruce Clarke said he had sometimes detected impacted stones by passing a rubber bougie down the ureter, and so was able to remove the calculus.

To the Clinical Society Dr. Taylor and Mr. Fripp related a case in which the calculus was detected by the Roentgen rays. There seems to be great difficulty in detecting calculi by this method, for some of the most skilful operators fail. Dr. Blacker said that though he had examined dozens of cases of supposed renal calculus he had been able to suggest the presence of the stone in only three. The case brought forward had the classical symptoms, except that there was no hæmaturia. The chief points of interest in the case are: the indication of the position of a calculus by the skiagraph after failure of an exploratory operation; the unusually high position of the stone, above the twelfth rib, although it was on the right side; the fact that the twelfth rib had its deep surface covered to a large extent by pleura; the completely atrophied condition of the kidney. Having failed to detect the stone through the usual lumbar incision, Mr. Fripp reopened the wound a week later, and, guided by the skiagram, removed part of the twelfth rib, and so was able to extract the stone from its abnormally high position. It weighed half an ounce, was of the shape and about the size of the end of a small pencil; it was surrounded by a cyst, consisting partly of atropied kidney substance, which was also removed. The patient did well.

Another subject was before the Clinical Society at the last meeting. This was the blocking of the mesenteric vessels as a cause of intestinal obstruction. This rather unusual circumstance had occurred in a case related by Dr. Bradford. A young man, aged twenty years, was admitted with abdominal pain and vomiting which became stercoraceous, and a mass was felt in the left iliac region. Abdominal section was performed, but no band or volvulus found. At the post-mortem the mesentery was thickened and its veins were thrombosed. The superior mesenteric vein was wholly blocked with firm decolorized clot. The trunk was thickened and its disease extended into the tributaries. The mesenteric glands were enlarged and congested, and one had suppurated; the abscess cavity communicated with one of the thrombosed veins. Dr. Taylor said that some years ago he had brought forward a

somewhat similar case, which had occurred in a child, aged seven years, but in that it was the artery and not the vein which was obstructed. It was pressed on by a calcareous substance, probably of tuberculous origin. Dr. Toogood referred to a similar case in which the artery was obstructed; the symptoms came on suddenly and closely simulated intestinal obstruction. On section blood was found both in the peritoneal cavity and in the mesentery. In reply to questions, Dr. Bradford said that the pancreas was healthy in his case, and it was obvious that the veins had been affected before the intestine.

The next subject down for this meeting was closely allied. It was a case reported by Mr. Raymond Johnson, of tuberculous peritonitis in a woman, aged thirty-three years, who was suddenly attacked with symptoms of intestinal obstruction. The abdomen being opened, yellow tubercles were found scattered over the intestines and there was a solid mass felt, which proved to be thickened and congested mesentery. The whole length of the small intestine was examined but no cause for the symptoms discovered, and the abdomen was closed. The patient left the hospital in three weeks. It was conjectured that the condition of the mesentery and bowel might be due to thrombosis of some branches of the mesenteric vein, caused by the deposit of tubercle around them, and that the symptoms resulted from temporary paralysis of that part of the intestine, the circulation of which was interfered with.

The *Army and Navy Gazette* has published the statement that an expedition was sent forward in Uganda without any provision for wounded or sick, although fighting was expected. A captain was seriously wounded and died without surgical aid. Surely this will rouse indignation against the war office and disgrace "my military advisers." This is what the obstinacy of the authorities has reduced the army service to. What a comment on Lord Wolsley's boast, that he could embark two army corps, completed in every respect, as soon as the ships could receive them!

Dr. Collins, whose name was removed from the "Register," is being tried for criminal abortion.

A student has committed suicide through failing to pass his final examination.

The deaths from small-pox at Middlesborough have reached one hundred and eighty-eight out of thirteen hundred and thirty-one cases. The epidemic seems to be declining.

Dr. Marshall, of Clifton, died on Sunday, aged sixty-five years, of pneumonia. He was M.D. and F.R.C.S. Edin., and consulting surgeon to the Bristol General Hospital and lectured in the school for about ten years. He was a skilled operator and a great admirer and follower of his former teacher, Syme.

THE LIMITATIONS OF THE ELECTROLYTIC METHOD OF TREATMENT.

To the Editor of the Medical Record.

Sir: A paper by my friend, Dr. Rockwell, in the Medical Record of April 16th last, "On the Value and Limitations of the Electrolytic Method of Treatment," etc., contains several statements so distinctly at variance with the experience of modern electro-therapeutists that I am impelled to draw attention to them. I have, indeed, received several letters from physicians in different parts of the country, urging me to correct these statements, as they were totally opposed to the experience of the writers.

Probably the most inadmissible statement of Dr. Rockwell is that "the limitations of electrolysis are distinct and positive." No one is entitled to make such a statement at the present time, for the possibilities of an electrolytic alteration of the tissues of the body are coterminous with the powers of chemical action itself, when enforced by adequate power. It is the idea that "electricity"—a name hateful to many physicians who ignorantly associate it with the old quackery—accomplishes these physical alterations that is distasteful to many, and this mental attitude influences even timid operators. Those who encourage this foolish prejudice may turn their minds entirely away from the mere conveying-agency for power, which electricity really is, and, like the trolley-car motorman, speak only of the power that is conveyed by the electric agency. Converted within the body into mechanico-chemical energy, its effect is limited only by the supply of organized flesh to be changed into inorganic elements when the power itself is adequate. With an adequate supply of power the whole of the doctor's person could be reduced to hydrogen, carbon, etc. It is evident, therefore, that the true limitations of electrolysis are not to be gauged by the effect of old-fashioned toy batteries, but rather by actual experiment under as favorable conditions of power supply as modern equipments give, and controlled only by expediency, vital resistance of the organism, and clinical results.

This conception of the almost limitless chemical energy available by means of electricity renders Dr. Rockwell's reminiscences of his old-time experiments in cancer of only historical value. These experiments must have been made in the dark ages of electricity ("twenty and more years ago"), in total ignorance of the actual current employed, and are therefore on a par with our ancestors' inability to run cars, light streets, etc., with electricity; in other words, the technique was defective. My own recently devised cataphoric method of treating cancer owes something of its success to all such experiments.

Dr. Rockwell says a good word for the Apostoli treatment of fibroids, but doubts whether they are ever dissipated. I can introduce him to several persons whose fibroids, which had been measured accurately by previous medical attendants, have disappeared under the Apostoli treatment. One of these ladies is a resident of New York City, having come to Philadelphia for this method of treatment.

As to the value of negative-pole electrolysis in stricture of the urethra, as demonstrated by Dr. Newman, I can also bear full and favorable testimony, in spite of the possibility of its misuse in the hands of electrically ignorant persons. In this procedure the cataphoric action of the current attracts water to the electrode, which, with the slight electrolytic softening of the stricture, results in a marked assistance to dilatation as well as a stimulus to absorption. That this method requires time, skill, and patience is true; but in spite of these drawbacks I cannot conceive of a well-informed patient preferring any other form of treatment, except in the rare instances when this has been intelligently tried and failed.

I have been an agnostic myself at times in passing judgment on new electro-therapeutic procedures and claims, but the more I deal with currents approaching in character and force those most successful in the industrial arts, the more I feel that judgment should be withheld in such matters until the technical details of new procedures have been scrupulously reproduced.

G. Betton Massey, M.D.

1636 Walnut Street, Philadelphia.

Diagnosis of Hip Disease.—Puncture the joint with the needle of a syringe and make microscopical examination of the fluid. This puncture is made in the line of Barker's incision, over the anterior part of the joint below, and in a line with the anterior superior spinous process of the ilium.—Young.

THE SURGEON'S GLOVES.

To the Editor of the Medical Record.

Sir: The report in the Medical Record of the recent discussion on aseptic surgery in the Academy of Medicine has no doubt been read by many of the profession with a certain amount of surprise. The letter in last week's issue of the Medical Record from the pen of Dr. R. T. Morris echoes the sentiment of every intelligent and common-sense operator in the land.

How much could the gynæcologist do with his fingers covered with gloves, thus masking all his sense of touch? The student in the dissecting-room commits a grave error by working with gloves, thus making his first lesson in the cultivation of the flesh-and-tendon sensation, so essential to the surgeon, a complete failure. To use "boxing gloves" in an ovariotomy is, indeed, hard on the ovaries.

E. C. Chamberlin, M.D.

57 West Eighty-Third Street, New York City.

AN INGENIOUS SWINDLER.

To the Editor of the Medical Record.

Sir: You will be doing the profession of the country a service if you will put them on their guard against a swindler who has recently been "working" the profession in Chicago. The fellow's method is to call upon a physician and introduce himself as a doctor who is in trouble of a peculiar nature. When he called upon me he stated that he formerly practised in Owasso, Mich. He said that he committed a criminal abortion on a woman, who soon after died of septic poisoning. The woman, as he told his story, made an ante-mortem statement, incriminating him. On being told by a friend, who met him as he was driving on a country road, that the sheriff had a warrant for his arrest, on the charge of manslaughter, he turned about and fled, never returning to Owasso. He added that he left $2,900 in bank in town, and owned a valuable business block, left him by his father. This, in brief, was his story. He then anxiously inquired if I could give him any assistance in getting his money out of the bank. I at once asked him to give me his real name, which he readily consented to do. In his presence I at once opened my copy of Polk's "Medical and Surgical Register of the United States," and informed him that he had made a mistake in the middle initial of his own name. He disputed the accuracy of the "Register," but I didn't wish to have anything to do with him, and so dismissed him. I saw nothing more of him, but I have just been informed by a friend, of Cleveland Avenue, this city, that this man has since been industriously "touching" physicians on the north side, by telling his tale of woe and getting them to cash checks on that money in the bank, always at enormous discounts. The doctor caused the fellow's arrest, and after spending two weeks in the North Chicago Avenue station he has left the city. But he will doubtless try to "work" the profession in other cities. Hence you will be doing a service by publishing this in your widely circulated journal.

Charles Gatchell, M.D.

Eczema.—In acute cases, when we have heat and swelling, employ soothing remedies; in subacute cases, when the swelling has subsided and when the papulation, vesication, pustulation, or exudation is more or less active, use astringents and slightly stimulating remedies; in chronic cases, when we have thickening with scaling, stimulate; in all cases protect the skin from external irritation.—Dr. George Thomas Jackson, "Handbook of Diseases of the Skin," p. 175.

New Instruments.

THE URINO-GLUCOSOMETER.

By Heinrich Stern, Ph.D., M.D.,

New York.

Robert's fermentation method for the determination of dextrose in urine is a most trustworthy one. The present writer has devised a little apparatus for the more practical and convenient application of this quantitative test.

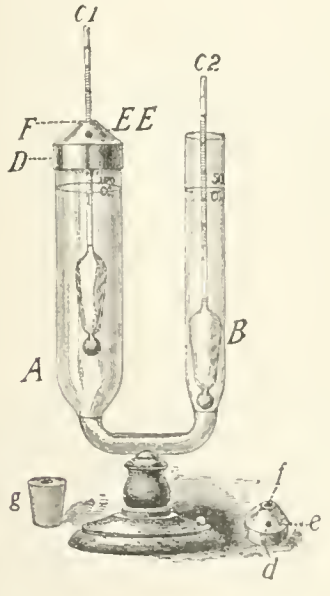
Description of Apparatus.—The apparatus consists of one wide (*A*) and one narrow (*B*) glass tube, which are united together in the form of a "U," and mounted on a wooden foot.

The wider tube is made to contain one hundred cubic centimetres, the narrow one to hold fifty cubic centimetres of urine. The tubes are carefully gauged and marked.

Both tubes are fitted with aluminium caps (*Dd*). These caps possess a flat top, the centre of which is perforated (*Ff*), through which the hydrometer is passed.

There are still other perforations in the cap (*EEe*) for the escape of the developing CO_2.

A rubber stopper (*g*), fitting the narrow tube, accompanies the apparatus.



To assure greater accuracy and a more distinct reading, the urinometer is made in two parts (C_1, C_2), one for the specific gravity from 0.990 to 1.030, the other for that from 1.030 to 1.070.

The scale of these hydrometers is so plainly visible that even a quarter of a degree may be readily estimated. The older urinometers and hydrometers in general present this drawback—that the reading is a direct one, the level of the fluid being the indicator of the specific gravity on the scale. Inaccuracies arising from this fact are quite numerous. The reading on my urinometer is an indirect one, the fixed, flat top of the cap serving as an indicator.

The cap also keeps the hydrometer in position, without causing any friction and giving the instrument ample play.

To ascertain the specific gravity of urine both tubes may be utilized; the urinometers are made to work in either of them.

I do not think that there is a more accurate urinometer in the market than this instrument, which is manufactured by Messrs. Eimer & Amend, New York, under the name of "Stern's urino-glucosometer."

Utilization of the Apparatus for the Determination of Glucose.—In the narrow tube place fifty cubic centimetres of the urine to be examined, and close tightly with the rubber stopper; in the larger tube place three or four grams—that is, one-quarter or one-third of a cake—of Fleischmann's yeast. Pour the urine into the tube to the mark one hundred cubic centimetres. Insert the desired urinometer and place the aluminium cap in its proper position. The urinometer, however, need not be inserted at once; this can be done after fermentation is completed. Still it is better to place it in position when starting, as it thus will indicate, step by step, the progress of the fermentation. The yeast cell will become active at a temperature of from 27° to 28° C.—that is, from 80° to 82° F. The apparatus should therefore be placed in a room in which there is a constant temperature of that degree. Fermentation in this moderate temperature will be completed in from twelve to fifteen hours. The CO_2 which is evolved during the process will escape through the perforations in the metal cap. After completion of the fermentation the cap should be lifted for a short time, the urine stirred or whipped, or the apparatus shaken, to effect a more complete elimination of the CO_2. Next the cap should be put in position again, the yeast particles should be allowed to settle, which takes place rapidly, and the specific gravity may be read off at the flat top of the cap. Following this the specific gravity of the urine contained in the narrow tube should be taken. Next ascertain the degrees of density lost during fermentation. Each degree of specific gravity lost will correspond to 0.2196 gram of glucose in every 100 c.c. of urine. Thus, if the density of the unfermented urine is 1.036, and of the fermented portion 1.020, the sixteen lost degrees must be multiplied by 0.2196. Therefore 3.1536 grams of glucose were contained in the one 100 c.c. of the urine examined. The amount of dextrose voided per diem may be easily calculated, if the quantity of urine passed for that time be known and if the examined part of the same was a specimen of the twenty-four hours' secretion. If it is desired to ascertain the quantity of glucose in grains to the fluid ounce of urine no calculation is necessary, as each degree of density lost corresponds exactly to one grain of dextrose per fluid ounce. For instance, if the specific gravity of urine be 1.036 before fermentation and 1.020 after this process, sixteen grains of dextrose were contained in each ounce of the tested urine.

Remarks.—The mother yeast cells will flow in the urine and on its surface. They are protoplasmic elements, and will slightly alter the specific gravity, but only slightly. The test as described will suffice for all practical clinical purposes, and will readily and with a great degree of trustworthiness point out dextrose in quantities of 0.5 per cent. and above. If greater accuracy is looked for, the urine should be boiled and filtered to effect a complete removal of the absorbed CO_2 and the yeast albumins before the final reading of the specific gravity is made. The yeast cell will bring about complete fermentation much sooner if the saccharine urine is subjected to a somewhat higher and steady temperature. To effect complete fermentation in six hours, the author has devised special fermentation tubes to be used with a sand bath. The sand should have a temperature of 33.5° C. The fermentation test, as above described, is to be recommended not so much for the detection of glucose, but as an easy means for ascertaining the fluctuations in the quantity of urinary dextrose during the time of observation.

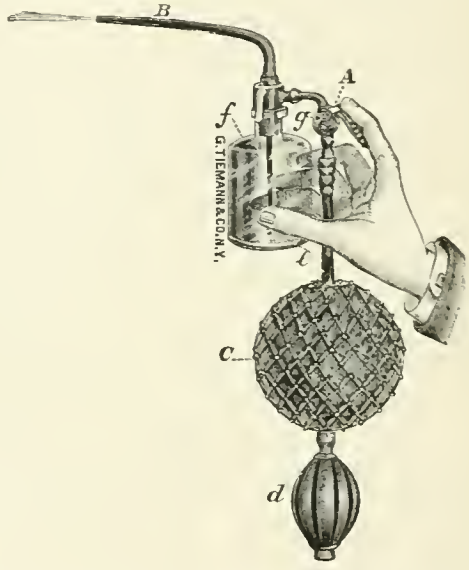
Vomiting of Pregnancy.—Oxygen water (ten volume gas strength) ℥ ss.–℥ i. Dilute at time of giving about sixteen times.

NEW CONSTANT-CURRENT EAR SYRINGE OR INJECTOR.

By HENRY W. WANDLESS, M.D.

DALLAS, TEXAS.

During my practice I have been greatly annoyed with the inefficiency of the ordinary ear syringes. They are seldom in order and are bunglesome; besides, the valves or pistons afford a very convenient place for storing bacteria and other sepic matter. The current thrown with them cannot be accurately landed or its force guarded. If the piston is hard to start, it often goes with a sudden jerk and with considerable force, sometimes causing the patient great pain. The fluid used must be kept in an open vessel and the syringe reloaded for each injection. The fluid gradually cools, often below the desired temperature, without the knowledge of the operator, unless advised by the patient, which does not always happen. The quantity of fluid used is necessarily large. The nozzle of the syringe must rest in the external meatus, and if there is much swelling this is very inconvenient and sometimes impossible. The temperature of the fluid is usually determined by putting the end of the finger into it, which is neither clean nor accurate. I remember that when I first saw this operation the same bowl was used as a drip cup and for holding the fluid



injected, the same fluid being syringed over and over again, which seems to me a dangerous practice (the danger being to the next patient).

Some of the advantages of this new constant-current syringe, or injector, are as follows: 1. It has no piston to get out of order; 2, it may be operated with a rubber receiver and hand inflation bag or from a compressed-air tank; 3, the quantity of fluid it uses is small; 4, the force of the current may be regulated precisely; 5, the jet may be landed on any particular part of the membrana tympani or in the external canal; 6, the current thrown is small and the outflow does not interfere materially with the inflow; 7, the temperature of the fluid can always be known, as the bottle containing it is held in the hand; 8, the flow is continuous until the solution or the compressed air is exhausted, or is cut off by the operator; 9, the instrument is clean and practically aseptic; 10, it is convenient and always in order; 11, the current may be started or discontinued suddenly or gradually; 12, the air pressure is completely under the control of the operator by means of the author's new instantaneous cutoff; 13, it is not necessary to place the tip in the external meatus in order to insure accurate landing of

the stream; in fact, it is used more satisfactorily when held an inch or so from the ear; 14, the solution retains its temperature longer, being in a tightly corked vessel.

The apparatus is composed of a bottle (*f*) for holding the fluid, a hard-rubber stem (*e*) for conveying the fluid out of the bottle, a tip (*B*), a soft-rubber receiver (*C*), an inflation bag (*d*), the author's new instantaneous cutoff (*A*), and (*g*) an opening for instantaneous escape of air from the bottle when it is cut off.

The bottle is made to withstand about thirty pounds' pressure to the square inch and the rubber receiver about fifteen pounds to the square inch; the latter is about all one can overcome by hand. The instantaneous cutoff need not be described here; suffice it to say that the current is instantaneously cut off and at the same time the air pressure in the bottle is released, stopping the entire operation instantly.

The apparatus is operated upon the plan of an ordinary spray or atomizer. Persons who have an air tank may dispense with the soft-rubber receiver and inflation bag, and attach the instrument directly to the air tank.

To operate the instrument, the receiver is first filled with air to the desired pressure, which requires a few compressions of the hand inflation bag, and is stored to be used as occasion requires. The cutoff is then attached to the thimble and the bottle is held in the right hand between the thumb, second, third, and fourth fingers, while the index finger operates the lever or trigger of the cutoff. The current is turned on by depressing the lever and is cut off by releasing it, the left hand being free to manipulate the external ear.

In operating the instrument attached to an air tank, the *modus operandi* is the same as stated above, except as to the source of the air pressure. The air being turned on by means of the cutoff, it passes directly into the bottle, forcing the fluid up through the stem (*e*) and finally through (*B*). No air can escape until all the fluid is driven before it.

I was particularly pleased when I observed the small volume of air necessary to operate the syringe. To use a bottle full of solution requires a like volume of compressed air, uninterrupted; an interrupted current requires somewhat more.

The full force should not be turned on at first, as it startles the patient and sometimes gives him considerable pain; besides, the danger of injury and shock to the tympanum is considerable.

Pulling the external ear up and out generally throws the drumhead in plain view of the operator. After the stream is discontinued the drum is hidden by some of the solution remaining in the canal, which is released by lowering the ear. A speculum may be used and the stream thrown through it, which often is quite an advantage. The patient unconsciously assumes with his head the position suggested to him by the manipulations of his ear. The interruptions in the current may be as frequent as desired, being entirely under the control of the operator.

In removing impacted cerumen from any part of the external canal, the instrument is exceedingly efficient. One may play upon the impaction with the stream with the greatest accuracy, and it may be undermined and dislodged easily. For removing purulent and other discharges from the ear, it has given me the greatest satisfaction.

The satisfaction and pleasure which I have experienced in the use of this syringe are not, I am sure, due to the interest I would naturally have in my own device, for I have used it sufficiently to have abandoned it were it not a superior instrument, in my judgment.

The tube should always be cleared of any of the solution before it is put away; especially is this necessary after using a solution of salts. These solutions sometimes dry in the end of the tube and block it; a wire passed through the end tip is sufficient to remove this. A solution for this purpose, and one which I have found generally satisfactory, is that made from an alkaline antiseptic tablet, the formula for which I recently published in the *Journal of the American Medical Association*. The strength of the solution is one tablet to from one to four ounces of boiling water. A convenient way is to keep this solution made up full strength, one tablet to the ounce of water, and dilute when necessary with water or a solution of boric acid.

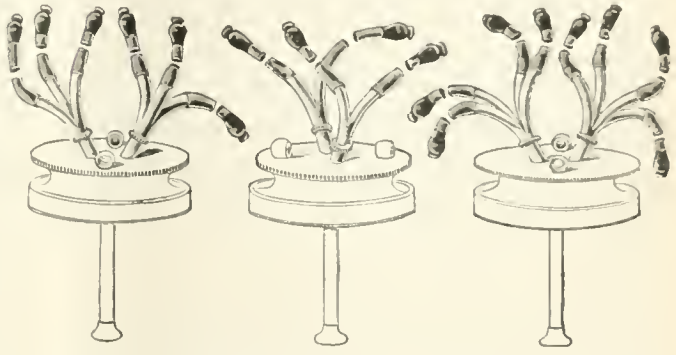
The apparatus is made by George Tiemann & Co., of New York.

NEW ATTACHMENTS FOR THE PHONENDOSCOPE.

By A. S. WALSH, M.D.,

NEW YORK.

The occasions on which the phonendoscope may simultaneously be used by a number of physicians are too numerous to mention. It very often happens that physicians may, when in consultation, want to examine the same patient at the same time. If only one ear of the physician is used, the regular tubes that come with the phonendoscope will answer, but if both



ears of each examiner are to be used of course four tubes are necessary. For this purpose we have the set of tubes shown in the centre of the illustration, to which it will be noticed four tubes are attached. This is simply a Y-shaped fork. Thereby two or four physicians can examine with the same phonendoscope. The figure on the left shows a tri-fork, by the use of which either three or six physicians may examine with the same phonendoscope. The other illustration shows a four-fork, enabling four or eight physicians to examine with the same phonendoscope. I understand that these attachments are very extensively used in the European universities, especially in lectures and for private instruction. These instruments have been made by George P. Pilling & Son, Philadelphia, from samples obtained from Europe.

For the Coughing-Attacks of Influenza.—For the coughing that comes on in attacks accompanying influenza Dr. Capitan (*Medecine Moderne*, No. 5) recommends the following:

℞ Tinct. droseræ,
Tinct. grindeliæ ..... āā 2 gm.
Tinct. aconiti..... ..... 1 gm.
Bromoformi ..... 60 gtt.
Glycerini puri ..... 2 c.c.

M. S. Six to fifteen drops in sweetened white wine, three or four times daily.

—*Klinisch-therapeutische Wochenschrift*, No. 4.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending May 14, 1898:

	Cases.	Deaths.
Tuberculosis	189	168
Typhoid fever	10	4
Scarlet fever	244	26
Measles	500	17
Diphtheria	202	37
Laryngeal diphtheria (croup)	14	8
Chicken-pox	19	0
Cerebro-spinal meningitis	0	4

The Passing of the Reflex.—Dr. Patrick (*Intercollegiate Medical Journal*, February, 1898) writes as follows: "And this leads me to mention what has already begun and what, God grant, may soon be consummated—the passing of the reflex. When to the nerve specialist comes a case of epilepsy, with a note from the family physician saying that the ovaries have been removed without effect, and so perhaps the trouble is in the brain; or a case of convulsive tic, with the message that the spasm has continued in spite of cauterization of the turbinates; or, as occurred to me a few days ago, he sees a born neuropath with typical traumatic neurosis who has undergone five pelvic operations for relief of her nervous symptoms—he groans in spirit and looks longingly forward to the millennium, when the man who operates shall have or procure an adequate understanding of that for which he cuts. In the mean time, under the keen scrutiny and rigid requirements of neurology, the so-called reflex as a cause of great nervous disorder is gradually being pushed into its rightful place—that is, among the relatively unimportant curiosities of etiology."

Prohibition in Norway.—*The Times* of April 13th published a valuable account of the working of prohibitory liquor laws in Norway. The people there are genuinely alarmed at the spread of liquor drinking, and, after trying the Gothenburg system, which purified the pothouses, eighteen towns resolved to prohibit the sale of liquors altogether. They did prohibit it, closing every spiritshop, with the result that drunkenness immediately and decidedly increased. Not only was a strong kind of port wine drunk in quantities, but illicit stills were set up in most back kitchens, and the people drank the raw spirits with lamentable results. Even the children were found intoxicated, and the arrests for drunkenness increased by from thirty to eighty per cent. Prohibition, in fact, totally failed, as it always will fail where it is not supported by a popular conviction that it is criminal to drink alcohol. There it succeeds, and then it is also totally unnecessary. It is always forgotten that the population of any town or village can prohibit the sale of liquors at once and finally by the simplest of expedients, viz., not buying them. The dramshops will not give away one drop. Drink is not sold because it is seen, but because it is wished for.—*London Spectator.*

Improved Practice in Surgery.—A report by M. Reclus in one of the French journals, of several cases of severe injuries of limbs treated by a novel conservative method, has attracted much attention. Instead of removing a crushed limb, M. Reclus would embalm the injured structures in antiseptic applications and wait for a natural separation of the dead from the living parts, not interfering except to saw through bone. After careful disinfection of the skin and removal of detached fragments of bone and of loose tendons and torn muscle, the whole wound is forcibly injected with water heated to 140° F. Hot water acts as an antiseptic and increases the activity of other antiseptic agents, and, moreover, when injected into a large and deep wound, it arrests hemorrhage and warms the chilled and collapsed patient. The interior of the wound is next thoroughly disinfected with a solution of permanganate of potassium applied on pieces of wool, and finally embalmed with what is called a polyantiseptic pomade containing a very large proportion of active agents, some of which, being absorbable—such as corrosive sublimate, carbolic acid, and iodoform—are in small quantities; while others which are not so absorbable—as boric acid, salol, and antipyrin—are distributed more abundantly. This pomade is spread quickly on bands of tarlatan, which are thrust into all the crevices of the wound. The injured part is covered with a layer of cotton wool, which is firmly bound down to the surface of the limb with bandages. By the end of the third week, it is stated, the dead have become detached from the living structures and the sloughs are quite loose.—*Scientific American.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

YELLOW FEVER IN THE WEST INDIES. By Dr. I. Anderson. 8vo, 106 pages. H. K. Lewis, London. Price, 3s. 6d.

REPORT OF THE THIRD ANNUAL MEETING OF THE AMERICAN ACADEMY OF RAILWAY SURGEONS, 1896. Edited by Dr. R. H. Reed. 8vo, 282 pages. American Medical Association Press, Chicago.

Summer Health Resorts.

The Virginia Springs, both on account of the celebrity of the waters and the healthfulness of the region in which they are situated, appropriately take precedence of the summer health resorts of the United States. They are located in a branch of the great valley between the Alleghany and the Blue Ridge mountains, at an elevation of from sixteen to twenty-five hundred feet above sea level, replete with magnificent scenery; in a relatively dry atmosphere, with a summer temperature of about 66° F.; in a clean soil thoroughly drained by means of living streams, and consequently wholly devoid of the conditions that give rise to malarial diseases. Altogether their situation is one of the most salubrious in America.

The region is mountainous throughout, and in some parts rough. These are no less attractive to the tourist mountain climber who is well and wishes to be better, than are other parts to the invalid who would repose in some secluded nook and obtain the utmost benefit of the joint influence of the climate and of the renowned mineral waters.

The accessibility of the region may be so easily traced from every direction that it is deemed unnecessary to particularize the routes.

Springs of widely different chemical and therapeutic properties are in the same vicinity. The Hot, Warm, Sulphur, and Healing springs are all located in a narrow valley, about fifteen miles long between two lofty mountain ranges, east and west, parallel with the main Alleghany divide, in Bath County. From the crests of the towering mountains, four thousand feet above sea level, settlements and intervening stretches of country over fifteen hundred feet below are spread out before the beholder in a magnificently beautiful and animating panorama.

The Warm Springs occupy a shaded valley five miles distant from the **Hot,** reached by stage over an easy boulevard, and are under the same management.

The gentlemen's bath is an octagon, forty feet in diameter, and holds forty thousand gallons of water; and the ladies' bath, circular in shape, half as large again, has a capacity of sixty thousand gallons.

These pools are supplied from separate springs, each discharging upward of one thousand gallons a minute, at a temperature of 96° F., and the water constantly boils with myriads of bubbles of sulphuretted hydrogen gas which greatly contributes to the luxurious and invigorating pleasure of the bath.

The Warm Sulphur Spring—temperature, 96°–98° F.—No. 1 (sulphuretted) contains:

	Grains Per Gallon.
Calcium carbonate	4.20
Calcium sulphate	5.47
Magnesium sulphate	3.38
Calcium chloride	1.47
Soda	trace.
Total	23.11

	Cubic Inches.
Sulphuretted hydrogen	.13
Nitrogen	1.02
Carbon dioxide	2.04

No. 2 (acidulated calcic) contains:

	Grains Per Gallon.
Calcium carbonate	5.22
Calcium sulphate	14.53
Potassium sulphate	1.38
Ammonium sulphate	0.36
Sodium silicate	1.72
Magnesium silicate	
Iron crenate	2.50
Total	25.71

Gases:

	Cubic Inches.
Carbonic acid	7.94
Sulphuretted hydrogen	0.25
Nitrogen	3.25

At the Hot Springs a new and elegant bathhouse has been finished recently, adapted to every convenience. A great variety of baths is provided, and at any desired temperature, from a cold plunge to 108° F. The spout and boiler baths, which have long been the favorites, are continued, but to these are now added needle, spray, and shower douches in variety, electric, plunge, hot vapor, and mud baths, in suites of apartments especially arranged for their use. The house is also provided with rooms and appliances for inhalations, nasal douches, etc.

There are large and well-furnished separate resting-rooms for ladies and gentlemen on each floor; and a large solarium, where sun baths may be enjoyed by day; and, in the same elaborate apartment, theatrical and other amusements, for which it is adequately equipped, are given in the evening.

Sulphur (bath and drinking) Spring—temperature, 102° F.—(alkaline calcic) contains:

	Grains Per Gallon.
Magnesium sulphate	7.991
Magnesium carbonate	2.727
Calcium sulphate	4.184
Calcium carbonate	21.15[illegible]
Sodium sulphate	2.542
Potassium sulphate	1.183
Potassium chloride	0.417
Silica	1.328
Total	41.812

Boiler (bath) Spring—temperature, 108° F.—(alkaline calcic) contains:

	Grains Per Gallon.
Magnesium sulphate	8.47[illegible]
Magnesium carbonate	3.41[illegible]
Calcium sulphate	1.[illegible]5
Calcium carbonate	23.[illegible]0
Sodium sulphate	3.184
Potassium chloride	520
Silica	1.[illegible]40
Total	42.[illegible]34

Carbonic acid gas given off freely. Not measured.

The Healing Springs, three miles south of the Hot, under the same management, are amid singularly peaceful surroundings. Here the water is also abun-

dantly supplied by four springs, essentially of the same character, beautifully bright and sparkling, at a uniform temperature of 87° F. It is extensively used for drinking, and some marvellous cures have been attributed to its use. And here, too, there are extensive and elegant bathing facilities.

No. 1 (alkaline) contains:

	Grains Per Gallon.
Sodium carbonate	0.02
Calcium carbonate	9.93
Magnesium carbonate	1.36
Iron carbonate	0.56
Calcium sulphate	1.38
Potassium sulphate	0.23
Aluminium sulphate	0.03
Calcium phosphate	0.01
Sodium chloride	0.15
Potassium chloride	0.04
Silica	1.00
Carbonic anhydride	5.39
Lithium carbonate, manganese carbonate, calcium fluoride	traces.
Total	20.10

	Cubic Inches.
Sulphuretted hydrogen	1.64
Oxygen	3.05
Carbon dioxide	4.64

Thirty-five miles south of the Warm Springs are the famous

White Sulphur Springs—the "Old White," in Green Brier County, W. Va., but in the same spring region, near Howard's Creek. They are situated in a beautifully picturesque valley, about six miles from Alleghany Ridge, which separates the waters that flow into Chesapeake Bay from those that flow into the tributaries of the Mississippi River.

Here during recent years there is renewed life with increasing attractions. The natural beauty and grandeur of the scenery have never waned; indeed, during the three decades since this ceased to be the unrivalled summer resort for statesmen as well as for health and pleasure seekers, the natural attractions seem to have taken a new growth. Of this the enterprise of the "New South" has been quick to take advantage. The fashionable spirit of the "old South" has been quickened, and again, as of yore, the gallantry and beauty of Southern society—legitimately descended and perpetuated through many generations—comes to the fore. That the fame of the "Old White" is again in the ascendant is well attested by the annually increasing number of the society leaders from the more northerly cities.

The outlook of the White Sulphur Springs is that of a well-kept, magnificent park, with extensive drives, bicycle paths, and walks through splendid groves of trees. The surrounding mountains are the grandest peaks of the Alleghanies, and the lower ranges picturesque and inviting to tourists.

The principal spring of this group (of three springs) is situated twenty-two hundred feet above sea level. For more than a hundred years its waters have been famed for their efficiency in treatment of rheumatism and gout. A remarkable characteristic of this spring is the uniform temperature of the water as it flows from it—62° F. at all seasons; and equally remarkable is the regularity of the flow, thirty gallons a minute. "While other springs of the country have failed during long droughts of summer, this has invariably preserved the even tenor of its way." The outflow is clear and transparent, but deposits copiously as it flows over the surface a white and sometimes a red-and-black precipitate. Its taste and smell, fresh at the spring, are that of all waters strongly impregnated with sulphuretted hydrogen gas.

Chemical properties, No. 1 (sulphuretted):

	Grains Per Gallon.
Calcium carbonate	7.07
Calcium sulphate	78.35
Magnesium sulphate	35.42
Silicates	3.46
Magnesium chloride	1.00
Organic matter	4.36
Total	129.66

	Cubic Inches.
Carbonic acid	11.28
Sulphuretted hydrogen	0.24
Oxygen	0.48
Nitrogen	4.64

The bath facilities are adequate and excellent, with water at any temperature required in the treatment of the various diseases for which it may be recommended.

There are grand hotel accommodations and cottages with homelike surroundings, and visitors are enabled to live in the whirl of gayety or in privacy, as their taste or state of health may dictate.

There are nightly amusements of one kind or another—grand, fancy, and masquerade balls—and other entertainments throughout the season.

Roanoke Red Sulphur Springs, near Salem, Roanoke County, have been much extolled in years gone by for consumptives—probably more due to the purity of the atmosphere than to the use of the waters, though some of these are of old and well-merited repute in many disorders. The springs are situated in a particularly romantic region, twenty-two hundred feet above sea level, with many marvellous objects round about well calculated to divert the attention of the invalid as well as of the tourist simply bent on sightseeing.

"Murder Hole," an enormous hole in the ground, one hundred and thirty-six feet deep and three hundred by sixty feet in length and breadth, laid up naturally in solid rock, is the entrance to a cold cavern of supposably great magnitude, that has not yet been explored. Descent has been made into it by means of ropes, and it has been penetrated to the extent of about twelve hundred and fifty feet, revealing apparently several large chambers, inviting entrance but offering a very cool reception, 44° F., during the hottest days of summer. Near by is the twice daily Flowing Spring. The water gushes forth for about an hour each time, and then it subsides. The cause of this action has been the subject of as much speculation as that of the geysers of Montana. But the most conspicuous object in the neighborhood is the McAfee Knob—one of the grandest overhanging landscapes on the continent—an enormous projecting mountain table, four thousand feet above sea level.

Hence the tourist may make railroad connection by branch with the Shenandoah route northward, and take in the *Natural Bridge*, "one of the great natural wonders of the world," where there are a fine summer hotel, well equipped with carriages, and splendid drives round about. Thence, a few hours farther on, are the *Luray Caverns*, but a mile distant from the railroad station, where there are excellent hotel accommodations, carriages, and guides. These now famous caverns were discovered only twenty years ago, and new wonders within them are still being disclosed. Already, however, there are opened up some of the most marvellous stalagmite and stalactite formations that have ever been described. The visitor here should be provided with overshoes and rubber wrap, for the floors are damp and there is some dripping from above; nor will he be any too warm for this, the temperature of the air within being about 56° F. As described by a visitor on first entering: "The darkness was only faintly illuminated by our few candles, and I was about to remonstrate, when the click and flash of an electric arc flooded the whole place with the light. Our candles were intended merely for

peering into dark corners and helping our footsteps." The general illumination is accomplished by dozens of electric lamps hung in all parts of the wide winding vaults and passages. Despite all descriptions and photographic views of this wonderful cavern that have been published, the general verdict of persons who have visited it is that the wonderful display of colors reflected by the crystal formation illuminated by electric light is altogether indescribable—to be appreciated it must be seen. Hence the tourist may skip to

New York City, the byway of all summer tourists northward bound, on health and pleasure bent. No other place in the country has so many attractions round about within one day's sightseeing, severally accessible by elevated or surface railway or by excursion steamboats. In geographical extent, as in population, New York City is now the second city in the world. Its area is a square mile for every day in the year—three hundred and sixty-five. Its length from Mount St. Vincent to Tottenville is thirty-five miles, and its width from the Hudson River at West Fourteenth Street to the inlet of Far Rockaway Beach nineteen miles. Yet it can be traversed from one end to the other, or across, for *fifteen cents*.' There are routes in the borough of Brooklyn, fifteen miles long, which may be covered for five cents. Indeed, like the Empire State, of which it is now in population (3,438,900) the greater part, it enjoys the cheapest rates of travel in the world. If the surface and elevated roads within the city limits were extended in a single line, they would reach to Kansas City. Yet it has been estimated that by their fullest use, a thorough exploration of the great city—of all its objects and points of interest—would occupy sixty days of ten hours each, and involve an expenditure of not less than $100—fares of railroad lines and steamboat ferries. Nevertheless, *en passant*, the tourist need not despair of seeing much of abiding interest in a shorter period of time and at less expense. Of the places of amusement, of which New York is the American paradise, nothing need be said; nor of its hotels—the finest in the world.

The public parks and squares in New York are much greater in area than those of any other American city, and none are so well adorned with fine monuments, statues, portrait busts, and sculpture by eminent artists.

The Grant Mausoleum, Riverside Park, overlooks the Hudson from a height of three hundred and fifty feet; and from this viewpoint the eye takes in Barnard College, the Woman's Annex to Columbia, now erecting on One Hundred and Twentieth Street, on the Riverside Drive. Immediately below, in the square bounded by the Boulevard and Amsterdam Avenue and One Hundred and Sixteenth and One Hundred and Twentieth Streets, is the group of *Columbia University Buildings*, seventeen in number, now going up, and upon which, ere they are finished, $5,000,000 or more will be spent. In the same neighborhood is the *Cathedral of St. John the Divine*, to cost as much or more, designed by Lafarge. The cornerstone of this structure was laid December 27, 1892, but it will yet be several years before it is completed. For stateliness and beauty it will rank among the greatest ecclesiastical buildings of the world. *The Metropolitan Museum of Art*, in Central Park, near Fifth Avenue and Eighty-second Street, possesses an unparalleled collection of stone sculptures, sarcophagi, bronzes, glass, jewelry, etc.; also an important and valuable collection of paintings by the most celebrated masters, ancient and modern; and other rare objects of art too numerous to mention. The museum is open to the public five days in the week, including Sunday, without charge for admission. *The American Museum of Natural History*, also in Central Park, at Seventy-seventh Street and Eighth Avenue contains an extensive collection of birds, animals, shells, fossils, insects, minerals, and implements of the aborigines of our own and foreign lands. *The Public Aquarium*, the whilom Castle Garden, in the southwest corner of Battery Park—for many years used on great occasions—is now an object of interest to all who would see life as it is below the ocean wave—fishes, beautiful, curious, and useful.

Steamboat and railroad excursions: to *West Point* and back, comprehending the most magnificent single-day's view of river-bank scenery in the world; across the upper bay to *Staten Island*, the borough of Richmond, with a ride among or around its beautiful hills and villas, overlooking the Narrows and the lower bay, and a view seaward, limited only by the extent of vision. Another is *via* the borough of Brooklyn, thence by elevated or surface railroad—or by steamboat from Manhattan direct—to *Coney Island*, where may be seen the most enchanting exhibition of surf bathing imaginable—the outpouring of New York's circumscribed excursionists on the beach and the rush into the surf. It is indeed one of the most animating as well as most captivating views of the summer tourist; for no one can look upon this bath-needing multitude, just let loose from the narrowest confines of the great city, now rollicking in the clean white surf and filling their lungs with the needful pure air from the face of the ocean, without being animated and invigorated by the sight. And it is the more enjoyable by reason of the delightful music in the foreground, while the observer sits on the balcony of any one of the three magnificent hotels, with abundant and excellent accommodations for the hour or for the whole season if required.

Farther along the beach, but for another day's excursion, *via* the Long Island Railroad, wholly apart from the conditions of the multitude common to Coney Island, is

Long Beach, with its grand hotel and a long row of cottages, where there is delightful surf bathing in conjunction with the best of hotel refreshments and accommodations for the hour or the whole summer.

Long Branch, too, is within the regular daily excursion trips, by steamboat or railway, and if by the former, with views of the harbor and the Statue of Liberty to the best advantage, the fortifications along the Narrows, Sandy Hook, and the Highlands. No spirited tourist can afford to miss seeing Long Branch, at so little inconvenience and on such a pleasure trip too, though it be for one day only—the sublimity of the surf bathing, excellence of the life-saving police, magnificence of the hotels and stylish cottages, and the wonderful display of wealth and fashion.

Atlantic City and **Cape May,** beyond the single day's excursion trips, are nevertheless so accessible that they may be easily taken in during the ten days or two weeks devoted to sight seeing in and round about New York. They have like attractions with Long Branch, only a little warmer weather; and for those who would enjoy, or for special reasons avail themselves of a soft warm air on a clean ocean shore, with excellent surf-bathing facilities, there are no better resorts. Ten days' or two weeks' time thus spent in and about New York, besides the immediate pleasure which it affords, is well calculated to enhance the pleasures of social fellowship in subsequent travel.

Northward from New York City, one may at least hesitate for a time among

The Catskill Mountains, for a few weeks' diversion, if not indeed for all summer, provided he would get the most for his money; for there is no region of similar magnitude, charm of scenery, and healthfulness of climate in the country that is equally well equipped with excellent hotels and boarding-houses at such economical rates as the region of the Catskills.

Two and one-half hours by the New York Central or the North Shore Railway, or twice that length of time by steamboat, with a view of the magnificent scenery of the Hudson, lands one at the foothills, Rhinecliff or Catskill, one hundred and ten miles from New York. The new Otis elevating railway, recently completed, connects with the Catskill Mountain Railway at Otis Junction, and is now the popular route for Catskill Mountain House, Hotel Kaaterskill, Laurel House, Haines Falls, Twilight Park, and Tannersville. The ascent of the mountains from this point is made in ten minutes.

Of particular places more or less enjoyable in the Catskills it is not necessary to speak; for to spend the summer there to the best advantage, the tourist should ramble; and he can hardly go amiss for interesting passes, climbs, and views. It is a much better region for such tourists than it is for invalids; not that the mean summer temperature at about 70°, and the relative dryness of the air at an altitude of sixteen hundred to two thousand feet above sea level, are not agreeable and salubrious, but in default of diversion.

The Adirondack Wilderness has acquired a world-wide reputation as a sanitary resort for consumptives. Inferentially, any region or climate found to be particularly beneficial to persons afflicted with or predisposed to a disease so intractable as pulmonary consumption is, can scarcely be otherwise than beneficial to persons afflicted with or predisposed to other diseases; indeed, salutary generally. Such, at any rate, the Adirondack Wilderness appears to be. The region is accessible *via* the New York Central Railway connecting with the Adirondack division at Utica. Or *via* the Delaware and Hudson Railway to Lake George, Lake Champlain, and the northern portion of the Adirondack Mountains; as also from all points of departure in northern New England and Canada. The area comprehends 3,588,800 acres, of which nearly one-half consists of forest. It has a general elevation of about two thousand feet above sea level, and is traversed by five distinct mountain ranges, with well-defined intervening valleys, with numerous subdivisions. Over thirteen hundred lakes and mountain lakelets are scattered throughout the area, while from its central watershed twenty rivers diverge in every direction, and with these a hundred or more rivulets, famous for their trout, coalesce.

The scenery is wonderfully varied, grand, and picturesque. There are over five hundred designated mountains and mountain peaks. Five of them reach altitudes of from 4,871 to, 5,344 feet above sea level. The average altitude of the lakes above sea level is about fifteen hundred feet, and of a few of them twice that elevation. Some of these cover only a few acres, while others are twenty miles or more in length; and the shores are generally approachable, there being but little mud and no stagnant water, the affluence of the mountain streams and the porosity of the subsoil being such as to maintain the constant purity of the water.

Amid the pine and spruce growth, two thousand feet and upward above sea level, there are many delightfully sunny areas and slopes with well-drained sandy soil, and the summer temperature is of remarkable equableness, of about 68° F.

Fulton Chain Station, fifty-two miles from Utica, New York Central Railway, is the gateway to several new hotels, cottages, and summer camps, in and along the plains and slopes, with short stage or boat connections with places where comfortable accommodation can always be secured. One of the particularly notable places of this region is Childwold Park, a picturesque track of fifteen thousand acres, through which the beautiful Raquette River winds northward, after leaving Tupper Lake; it is reached by way of Childwold Station. Its principal lake is the Massawepic, upon the eastern shore of which are located the Hotel Childwold and cottages. The tallyho drive, five miles from the station to the hotel, is a delightful feature of the trip. Tupper Lake village is one mile by stage from Tupper Lake Junction. Here there are excellent hotel accommodations, and good fishing in the big and little Tupper Lakes. Saranac Inn, at the head of Upper Saranac Lake, is one of the most charming and fashionable resorts in the wilderness. It is reached by stage ride of two miles from Saranac Inn station. It presents one of the most beautiful views of lake and island scenery in the mountains. A small steamer plies between Saranac Inn and the foot of the lake, where are located Hotel Wawbeek, Rustic Lodge, Saranac Club, and Hiawatha House. The Wawbeek is one of the most commodious and best-known hotels in the region. Its architecture partakes of the picturesque scenery by which it is surrounded, and with its shapely towers and admirable proportions it forms an imposing feature in a landscape that claims the admiration of every beholder. "Paul Smith's," three and one-half miles from Paul Smith Station—one hundred and thirty miles north of Utica—is one of the oldest and most justly noted hotels in the Adirondacks. It is located on Lower St. Regis Lake. The beautiful scenery hereabout has allured many wealthy sojourners, whose costly and elegant camps have greatly contributed to the attractions of the place. But the limitation of space forbids the further attempt to describe this—all things considered—queen of summer health resorts. At its southeast corner, on what may be considered the terminal spot of the Adirondack Mountains, descending eastward to an elevation of about four hundred feet above sea level, is the beautiful village of

Saratoga Springs, the most popular and the most fashionable summer health resort in America. Saratoga Springs is accessible by the ordinary routes of transit from all directions, so that there is no need of specification. Primarily famous on account of the mineral spring discovered and first used here in 1774, Saratoga's attractions otherwise and chiefly have been and continue to be the successful results of enterprise in turning its only natural advantage to the best possible account; for there is really nothing sufficiently remarkable about the topography or natural scenery of Saratoga to attract the attention of any lover of nature, art, science, or sport. Nevertheless there has been created round about a panorama of grand hotels and ornamentation so superbly attractive to the highest social requirements as to place it in the foreground of summer resorts of the most varied types of the leisurely and affluent citizens, not only of our own country but of many foreign lands.

The hotels and springs are abundantly equipped with every requisite for health, comfort, and social enjoyment. The city is beautifully laid out, and has broad and well-shaded streets with good pavements, and good drainage.

A highly interesting object to visitors is "The Pompeia," an exact reproduction of the house of Pansa, buried by Vesuvius in the year 79. The building is an artistic monument that well ranks with the most impressive of American contributions to the art of this century.

The environments are in admirable keeping with the beautiful and cleanly streets, broad and smooth roads, and interesting drives. The most popular of the latter is that to the lake, three and one-half miles distant; and this, the lake, is a frequent attraction during the season for boat racing. Moreover, a little steamer plies it, between the Lake House and White Sulphur Spring Park Hotel, seven miles apart, and to other points. The Race Course is also an entertaining feature.

The Saratoga Mineral Springs have been among the most thoroughly studied and are consequently among the most widely known of any mineral waters in the country.

Of the other mineral-spring resorts in the State of New York, the most noted are the following:

Richfield Springs, in Otsego County, fourteen miles from Coopertown, six miles from Otsego Lake, accessible by the New York Central route, connecting with the Delaware, Lackawanna, and Western Railroad, at Utica, thence fifteen miles to the springs, near the shore of Canandarago Lake, one of the most picturesquely surrounded sheets of water in America. It is a particularly attractive feature of the springs for healthful outing.

The waters are of high reputation in the treatment of rheumatic and cutaneous affections.

The bathhouse occupies a space one hundred and eighty feet in length by one hundred and twenty feet in width, and is said to be one of the best designed and most elegantly finished bathhouses in the country. It comprehends rooms specially fitted for the use of spray, douche, steam, and electricity; and Turkish baths complete. There is a large swimming pool, constructed with special reference to instruction in swimming. The hotels are commodious and well equipped in all particulars.

The springs are saline, saline sulphuretted, sulphuretted, saline chalybeate, and calcic. "Sulphur Spring" (chiefly used), contains:

	Grains Per Gallon.
Calcium bicarbonate	4.47
Magnesium bicarbonate	6.01
Iron bicarbonate	0.24
Sodium sulphate	22.29
Calcium sulphate	67.39
Magnesium sulphate	32.82
Sodium chloride	21.73
Potassium chloride	8.23
Sodium and calcium sulphides	6.22
Alumina	0.10
Silica	1.35
Total	170.85

	Cubic Inches.
Sulphuretted hydrogen	3.63
Carbonic-acid	2.94

"Iron Spring" (chalybeate carbonated) contains:

	Grains Per Gallon.
Calcium bicarbonate	11.71
Magnesium bicarbonate	12.52
Iron bicarbonate	4.92
Sodium sulphate	0.30
Calcium sulphate	5.00
Sodium chloride	0.43
Silica	0.81
Total	35.69

	Cubic Inches.
Carbonic-acid	15.9236

Sharon Springs, sometimes called the Baden-Baden of America, are situated in Schoharie County, N. Y., in a romantic valley, eleven hundred feet above sea level, accessible by the New York Central, in connection with the Delaware and Hudson Railroad, or by a delightful drive of nine miles from Palatine Bridge, a station on the New York Central, a few miles beyond Fonda.

The springs are calcareous, calcareous sulphuretted, and one (calcareous) called "Eye Water Spring." The chiefly used are:

"White Sulphur Spring" (calcareous sulphuretted) contains:

	Grains Per Gallon.
Magnesium bicarbonate	24.00
Calcium sulphate	85.40
Magnesium sulphate	34.00
Sodium chloride	2.70
Magnesium chloride	2.70
Calcium sulphide	3.00
Magnesium sulphide	3.00
Total	154.80

	Cubic Inches.
Sulphuretted hydrogen	20.50

"Eye Water Spring" (calcareous) contains:

	Grains Per Gallon.
Magnesium bicarbonate	32.00
Calcium sulphate	77.50
Magnesium sulphate	7.50
Sodium chloride	2.50
Magnesium chloride	2.50
Total	122.00

Mud baths are used here to a considerable extent, and some extraordinary cures of syphilides and other cutaneous eruptions have been atributed to their use.

Clifton Springs, a delightfully situated village, midway between Seneca and Canandaigua lakes, twelve miles from Utica (via New York Central), is noted for its sulphur springs, which were taken advantage of fifty years ago, by Dr. Henry Foster, by the erection of the "Clifton Springs Sanatorium," which is still worthily maintained by a generous patronage.

There are three springs. The one most used, according to the most recent authentic analysis, contains:

	Grains Per Gallon.
Calcium carbonate	9.68
Magnesium carbonate	13.12
Sodium sulphate	7.76
Calcium sulphate	69.20
Magnesium sulphate	16.48
Sodium chloride	9.28
Calcium chloride	4.08
Magnesium chloride	4.08
Organic matter	trace.
Total	133.68

Sulphuretted hydrogen and carbonic-acid gases present.

Many other mineral springs are scattered—so to speak—throughout the middle and northern sections of the State, and for the most part in the midst of, or in easy communication with, delightful lake and mountain scenery, and well equipped for the entertainment of tourists or sojourners.

Lake George, two hundred and ten miles from New York, and but seventy miles from Albany, is the most famous and the most frequented of American lakes; chiefly on account of the natural beauty and grandeur of the scenery by which it is surrounded, but no less on account of the historic and legendary associations with which the vicinity is invested. For hereabout it was where Ethan Allen and the Green Mountain boys earned a nation's gratitude, and the sombre ruins of Fort Ticonderoga, still standing, memorize the victory. And here, too, it was, where the gallant French General Montcalm with ten thousand men besieged Fort William Henry; where General Abercrombie with an army of fifteen thousand men made an unsuccessful attack upon Fort Ticonderoga; and where, during the early days preceding our country's independence, engagements between the French and English with Indian allies were of such frequent occurrence as forever to render Lake George a place of historical interest to every American, of which no tourist can afford to be ignorant.

The lake is situated at an altitude of three hundred and fifty feet above sea level, is thirty-five miles long, and from three-quarters of a mile to four miles wide. It is surrounded by high hills and precipitous cliffs on all sides, and its surface is dotted with numerous little islets of remarkable beauty. Fort William Henry, Lake House, Sagamore, Fort George, Crosbyside, Lake View, Marion House, Fernwood, Pearl, Prospect House—on the summit of Prospect Mountain—and many excellent boarding-houses besides, afford ample hotel accommodation and unlimited facilities for enjoying the scenery, and there are delightful drives and boating.

Within a hundred miles of Lake George, in the adjoining counties of Essex and Hamilton (extending to Warren, in which Lake George is mostly situated), there are about two hundred smaller lakes interspersed amid a landscape of great beauty and healthfulness. They are easily accessible, and there is no lack of hotel or boarding-house accommodations. Farther west there is a chain of larger lakes, and in the southwest are still others. A striking feature of the river and lake scenery of the State of New York is the number, beauty, and grandeur of the *waterfalls*. Trenton, Taughannock, Minnehaha, and Rainbow Falls, near Watkins Glen, and several others in relation with the group of lakes in Cayuga, Seneca, Yates, and Ontario counties, are notable for the charming scenery in the neighborhood and the healthfulness of the region.

Watkins Glen is justly celebrated for the marvellous beauty of the scenery roundabout, and, above all, for the beauty of Seneca Lake Falls close by—a region, indeed, possessed of an individuality as distinctly characteristic as that of Niagara, though insignificant in comparative grandeur. All of these delightful resorts and the lines of travel to reach them are so thoroughly designated on travellers' maps as to render description in this regard wholly unnecessary; and so, too, with regard to accommodation—they are almost unexceptionally adequate and suited to the varied tastes and requirements of tourists or sojourners.

Niagara Falls is now brought within a single day's journey from New York, *via* the New York Central Railway, by which all daylight tourists, in passing, are given a few minutes' delay for a glance at the cataract. But no adequate appreciation of Niagara can thus be gained, nor can there be by any description. For, as Anthony Trollope wrote:

"Of all the sights on this earth of ours which tourists travel to see, I am inclined to give the palm to Niagara. In the catalogue of such sights I intend to include all buildings, pictures, statues, and wonders of art made by men's hands, and also all beauties of nature prepared by the Creator for the delight of His creatures. This is a long word; but, as far as my taste and judgment go, it is justified. I know of no other one thing so beautiful, so glorious, and so powerful."

Michigan possesses many attractions for the summer tourist and health seeker, particularly after the summer has advanced a little—after one has had time during the early summer to "do" New York, as it were: for the great lakes, which hold Michigan by many beautiful facets, serve to keep back the spring temperature. The land warms up more slowly than that which is otherwise situated, and makes the enjoyable season a little later. The extent of the lake coast of Michigan is over eleven hundred miles. Besides the four great lakes—Superior, Michigan, Huron, and Erie—and the smaller one, St. Clair, which form so large a part of the lower border of the State, there are hundreds of smaller lakes and straits which greatly contribute to the beauty of the scenery. The shores of these have been greatly improved during recent years. The southern portion of the lower peninsula, now the garden orchard of the Northwest, formerly encumbered with swamps and unhealthful, is for the most part well drained and highly healthful.

The islands are very numerous, and some of them have been converted into delightful health resorts. The principal are Isle Royal and its dependent islands in Lake Superior; Beaver, Fox, and Manitou Isles in the northern part of Lake Michigan: Bois Blanc and Mackinac Islands in the Mackinaw straits; Drumond Islands in Lake Huron, and the Sugar Islands in the Straits of St. Mary. These islands, as a whole, and several places on the lake shores, are remarkable for the beauty of the scenery and improved advantages as summer health resorts.

Petoskey, once the site of the largest Indian village in the State, built on the succession of natural terraces rising from the beach of Little Traverse Bay, is near the centre of what may be called the health-resort region of Michigan. Its location is at once commanding and beautiful. The cool, invigorating breezes from Lake Michigan and Little Traverse Bay, its pure water, and the absence of malarial shores make it a natural sanatorium. Radiating from it in nearly all directions, railroad and steamboat lines lead to the various surrounding resorts, fishing and bathing grounds.

The Harbor Springs branch of the Grand Rapids and Indiana Railway, built near the shore and in some places on the beach of Little Traverse Bay, puts Petoskey in close touch and pleasant communication with all the points of the bay. During the summer season a suburban train service is maintained between Petoskey and Bay View, Roaring Brook, Wequetonsing, Harbor Springs, Harbor Point, Oden Oden, and Bear Lake, and commutation tickets at cheap rates are sold, enabling visitors to reach these points with great convenience and at slight expense. There are many good hotels and pleasant boarding-houses, and visitors are certain of accommodations suitable to their taste and purse. The principal hotels are the Arlington, Imperial, Cushman, Occidental, Clifton, and National.

Mackinac Island, situated in the Mackinaw Straits, is reputed to be the coolest and, since its great improvement and supervision as a State park, one of the cleanest and most healthful summer resorts in the country. Unlike that common to the seaside, the atmosphere of Mackinac Island is said to be crisp—though we have no record to this effect—and invigorating. It is, above all, commendable to the victims of *hay fever* and all such ills as are more or less due to dust in the air, of which the atmosphere here is almost wholly devoid. The island is covered with a dense growth of beech, birch, maple, and arbor vitæ; and the hard, smooth roads, winding gracefully about the different points of interest, make driving and wheeling a great pleasure. The many points of interest round about are Arch Rock, a natural bridge of rocks on the northern cliffs; Fort Holmes, the remains of the old British fort; Sugar Loaf, a huge rock, the shape suggesting the name; and the panorama of the commerce continually passing through the straits. Among the other hotels offering excellent accommodations are the Astor, Island, New Mackinac, Mission, New Murray, Palmer, and New Chicago.

Les Chêneaux Islands, about one hundred in number, fourteen miles distant from Mackinac Island, near the shore of Lake Huron, are noted for the excellent fishing they afford. The islands, being close together, form a good shelter from heavy winds, and permit all kinds of boating with safety. All necessaries for fishing can be procured at the hotels—Elliot, Les Chêneaux, Bethel, and Islington. The Les Chêneaux Club has a commodious, homelike clubhouse on Marquette, the largest of this group of islands. The islands are accessible by a double daily line of boats from Mackinac Island.

To *Cheboygan* is one of the most restful and beautiful day's rides to be found anywhere: and one of the most delightful excursion trips in Northern Michigan is that from Petoskey to Cheboygan *via* the Island Route Company's steamers, which make daily trips during the summer season. One may take the Grand Rapids and Indiana Railway to Oden Oden, and go thence by one of the little steamers through Crooked Lake, Burt Lake, Indian River, Mullet Lake, and Cheboygan River, to Point aux Pins—a beautiful cottage resort on the south side of Bois Blanc Island opposite Cheboygan. "The Pines Hotel" furnishes good accommodations to guests at moderate terms.

Charlevoix, a town of two thousand inhabitants, eighteen miles southwest of Petoskey, on the sandy shore of Lake Michigan, is a favorite resort for Chicagoans. Pine Lake, with three miles of sandy beach, at the eastern boundary of the city, has for its outlet into Lake Michigan Pine River, which broadens into Round Lake about midway between the two large lakes. Here on the terraced shores of the river and lakes are located many beautiful villas and excellent hotels.

These resorts have all the attractions which a pure, cool summer air, good hotels, and pleasant surroundings can give them. Adequate railway and steamer service is provided between Petoskey and Charlevoix.

Mount Clemens, situated twenty miles northwest of Detroit, on the line of the Grand Trunk Railway, has become a popular summer resort during recent years, on account of the *mineral wells* there. It has also been placed in easy communication with Detroit by means of a splendidly equipped electric railway.

The Clinton River runs through the heart of the town and winds itself over seven miles of length before it empties into Lake St. Clair. The air-line distance from the town to the lake is two and one-half miles, over which a local electric line furnishes a frequent service to a terminal on the beach known as Lakeside. Here a hotel and casino have been erected, where refreshments, music, and other entertainments and amusements are liberally dispensed. Lakeside is in sight of the famous St. Clair Flats, the Mecca of sportsmen and fishermen. Little steamers make the run from Lakeside to the Flats in an hour, passing through the United States ship canal and Little Venice, where hundreds of summer cottages and clubhouses line the deep-water channels running through the Flats.

The town has six bathhouses adapted to the requirements of patrons, twenty-two hotels, and many boarding-houses. Each bathing-establishment is under a separate ownership and management, and draws its water from an independent well. The wells vary in depth from twelve to fifteen hundred feet. The analyses of the different "springs," while showing in each instance a varying quality of saline and calcareous elements, are yet so nearly alike as to admit of no particular choice.

The hotels are in many instances connected with the bathhouses by covered passageways, and in two cases hotel and bathhouse are under one roof. The excellence of the hotels is a particular merit of the town. There are a half-dozen of them and they are unsurpassed in Michigan.

The following recent analysis of one of the wells gives:

	Grains Per Gallon.
Sodium chloride	5957.350
Magnesium chloride	1656.200
Calcium chloride	4128.530
Calcium sulphate	143.430
Magnesium carbonate	0.070
Calcium carbonate	0.910
Ferrous carbonate	8.540
Magnesium iodide	0.070
Magnesium bromide	8.540
Silica	28.090
Alumina	42.070
Total	11,973.800
Sulphuretted hydrogen gas	40 cubic inches.

In the construction of these wells, which are entirely artificial, sometimes a considerable difficulty is encountered, as they have to be piped to their full depth; first through the silex, which is about one hundred feet deep; then the bedrock, which is composed of limestone and sandstone. At three hundred and fifty to five hundred feet usually are found pockets in the rock containing illuminating gas; this has to be double piped away for heating purposes and to prevent its mixing with the true mineral water. At a depth of from one thousand to fifteen hundred feet water is reached that is almost buoyant enough to float the body. It is chiefly useful in the treatment of rheumatic and gouty affections and chronic cutaneous diseases; and is also commendable in cases of lead and mercurial poisoning that occur among metal workers and other artisans. The baths are used at any temperature deemed to be the most efficacious for the elimination of the poison.

Wisconsin, too, has many attractions for the summer health tourist, but this sketch has its limitations; and to these—for this season at least—a mere introduction must suffice.

Green Lake is a beautiful sheet of water about four hours distant from Chicago and two from Milwaukee. The railway ride, along the shores of Lake Michigan and Lake Winnebago and through picturesque hills and valleys, has many attractions. The lake is ten miles long, with an average breadth of about two and one-half miles, with shores of rare beauty, in a delightful summer atmosphere of about 68 F., eight hundred feet above sea level. Dartford, a flourishing town on its banks, a station on the Sheboygan and Fond du Lac Railway, supplies excellent and abundant hotel accommodations, boats, and other facilities for enjoyment. Oakwood, Sherwood Forest, Pleasant Point, Maplewood, and Lake View are all well-appointed hotels on the shores.

The River Scenery of Wisconsin has long been noted for its remarkable beauty and for the extensive river dalles or rapids. In the St. Louis River are dalles which have a descent of three hundred and fifty feet. The dalles of the St. Croix are almost as great and all are alike picturesque.

Wisconsin River presents many grand views. Beginning in Richmond County, its banks rise from two hundred to two hundred and fifty feet; and in Sauk County, where the river passes through a narrow gorge, the banks reach an altitude of six hundred feet. Grandfather Bull Falls are a series of turbulent rapids, succeeded by a series of wild cascades dashing through a gorge a mile and a half long and with walls one hundred and fifty feet in height—an almost bewildering scene, than which it is difficult to conceive anything more likely to stimulate healthy emotions. But we must here forego further reference to the summer health resorts westward.

New England still maintains her pre-eminence in the superior improvements of her natural conditions.

Newport, R. I., everybody knows—that is, everybody who has been there knows—is unique. The charms of the natural scenery round about; magnificent ocean views, shores of alternating rock masses, ledges, and sandy beaches; historic remains, memorials, and ancient institutions; and, through the excellence of the hotel accommodations and liveries, the facilities for enjoying these attractions are different in their excellence, for the most part, from those of other watering-places. But a carriage tour of the city and its outskirts reveals an additional and wholly unique feature—that the summer sojourners here, instead of occupying the hotels, have built summer homes for themselves suited to the most elaborate conditions of all that that word and wealth combined implies; and that they here live for half the year, dispensing lavish hospitality among themselves, entirely free from the elbow jostling of hotel life common to other summer resorts. An attempt to describe the sumptuous homes, the elegance and splendor of their surroundings, equipages and outings, recreations and assemblies, would be futile. They are rarely if anywhere else equalled, and nowhere excelled. This unique condition is doubtless due to

the just appreciation of the delightful summer climate and exquisite cleanness of the soil of Newport's particularly favored situation, on the southern extremity of Rhode Island (the kernel of the State so named is here referred to), a bit of territory fifteen miles long by four miles wide, in the waters of Narragansett Bay, by which its shores are continuously washed and purified.

Newport is distant from New York *via* the New York, New Haven, and Hartford Railroad, one hundred and sixty-five miles; from Boston, seventy-one miles; from Providence, thirty miles. Hotels: Ocean House, Aquidneck, Central, Perry, Kay Street, Cliff Avenue, and United States. There are numerous excellent boarding-houses and a dozen or more restaurants.

Narragansett Pier is in sight of Newport; rather, Newport is in sight of it, for some of the habitués of Newport rarely refer to Narragansett Pier without speaking of this view as its chief charm. But Narragansett Pier has other advantages, and some of which Newport is devoid.

It is situated on the west shore and near the mouth of Narragansett Bay; it has a clean and beautiful beach, safe and good bathing. And here bathing is the fashion—it is what tourists stop here for. There is a long string of bathhouses, and everybody goes to the beach at noon, when the scene becomes very lively and picturesque, for the ladies' bathing-suits are pretty. But there are enough of all sorts to amuse the hundreds of spectators who occupy chairs on the platform in front of the bathhouses or sit under tents erected on the sand.

The hotel accommodations are abundant and excellent, affording carriages for pleasant drives round about, and boats for sailing, rowing, and fishing.

The Green Mountain Range, that extends through Vermont, across Massachusetts and Western Connecticut, nearly to Long Island Sound, constitutes the *Berkshire Hills*—a region proverbial for its healthfulness and a justly popular summer health resort. All along the valley of the Housatonic River, where it winds through the hills, from Pittsfield, near its source, through Lenox, Stockbridge, Lee, Great Barrington, and Sheffield, into Connecticut, the scenery is attractive; and the towns mentioned are so beautifully situated, and excellent hotels and boarding-houses so numerous, as to render them eminently commendable. The altitude is about twelve hundred feet above sea level; the temperature is cool, about 68° F.; and the air relatively dry. The local sanitary conditions generally are exceptionally good; the soil is well drained and clean, and the water supplies are well protected and pure. The roads are excellent and the drives beautiful.

Pittsfield, Lenox, and Stockbridge are classic ground, through association with Longfellow, Holmes, Miss Sedgwick, Hawthorne, and others, of whom lively recollections and good stories add to the attractions of visitors. A story is told of Fanny Kemble, whose favorite summer resort was Lenox, that on her first season there she employed a self-respecting villager, who had a comfortable turnout, to drive her about. He, feeling it to be his duty to make the drive as entertaining as possible, began to call her attention to the beauty of the scenery—which she wished to enjoy undisturbed—and to tell her who lived in certain houses as they passed along; until finally Mrs. Kemble, being unable to stand it any longer, said, in the high-tragedy manner somewhat peculiar to her: "I have engaged you to drive for me, sir, and not to talk." The driver ceased talking, pursed up his lips, and in all their subsequent drives his only remarks were such as he found necessary to address to his horses. At the end of the season he handed in his bill for the summer services. Running her eye down its awkward columns, she paused at an item that she didn't understand. "What is this, sir; I cannot comprehend it." With equal gravity, he replied: "Sass, $5. I don't often take it, but when I do I charge." She paid the bill without comment, and continued to employ the same driver during many summers she spent there.

The Shore Resorts begin in the environs of Boston, and thenceforward are almost coequal with the Massachusetts coast line. *Nantasket Beach*, at the mouth of the harbor under the lee of Nantasket promontory, is one of the most picturesque on the whole Atlantic coast; nor is it surpassed in facilities for enjoyment—bathing, boating, and fishing, and all sorts of entertainment. It is reached by both steamboat and railroad lines throughout the season, and patronized by immense throngs of people. *South Shore*, a reach of coast between Nantasket and Duxbury, is dotted with summer dwellers from end to end, while the beaches are enjoyed by thousands of transients. *Plymouth* is so generally regarded as the Mecca of the descendants of the Pilgrims that other summer tourists rarely think of going there. Yet Plymouth is a delightfully situated town, and the wonder is that it is not a favorite summer health resort. It excels in both land and water attractions. Its shore and ocean attributes are supplemented by delightful inland drives and excursions passing through extensive forest groves. The summer climate is delightfully cool and healthful. Hotel accommodations are adequate and economical.

Nantucket is a realm by itself, a nest on the bosom of the ocean, thirty miles from the mainland, and consequently affording a veritable ocean atmosphere to the sojourners there, devoid of dust, germs, and soil emanations. Summer rest, recreation, and entertainment are here obtainable under such circumstances as are well calculated to promote health of both body and mind.

Martha's Vineyard is a little nearer to the mainland than Nantucket, but possesses the same advantages, and is alike commendable to persons who would enjoy the benefit of the ocean atmosphere with all the adjuncts of a thoroughly equipped summer health resort.

Buzzard's Bay fittingly supplements the attractions of the islands just above designated and other salient points in the waters and along the shores, from New Bedford on the one side and Woods Holl on the other, comprehending the sporting-ground *par excellence* of the summer tourist who would combine fishing, sailing, and cruising with delightful conditions of scenery and climate. At Woods Holl, the headquarters of the United States Fish Commission, Falmouth, Cataumet, Pocasset, Wenaumet, Monument Beach; and, on the opposite shore from New Bedford, Fairhaven, Mattapoisett, Marion, Tremont, Wareham, Onset Junction—there is no lack of accommodation suited to the taste and purse of tourists, accessible by the New York, New Haven, and Hartford Railroad and its branches.

From the seashore resorts of Massachusetts the summer tourist may well pursue his course, *via* the same lines of travel, farther northward to those of *Maine*, and feel quite sure that he will fare no worse; or he may skip those of Massachusetts and go direct from New York to Portland, Me., by one of the stanch steamships of the Maine Steamship Company, touching at Cottage City (Martha's Vineyard) *en route*.

Portland is a healthfully situated city on the central peninsula of *Casco Bay*, gently sloping on both sides to the water's edge, thus affording excellent drainage for the city, flanked on each side with a score or more of islands with promontories, cliffs, wild rocks, bluffs, hills, valleys, forests, soft verdure, and green fields—health inspiring in its every aspect.

Cape Elizabeth is at the southern side of the bay with good bathing and fishing facilities. Scarborough

Beach, Old Orchard Beach, Saco Pool, near Biddeford, Kennebunkport, Wells Beach, York Beach—all offer seaside enjoyments with commodious accommodations under the most healthful conditions.

Bar Harbor, taken altogether, is the most delightfully situated summer health resort on the Atlantic coast. It is a nook of Mount Desert Island, the largest of the group of islands in Frenchman's Bay. There is here a singular grouping of ocean, lake, and mountain scenery in a delightfully salubrious summer climate, with a temperature of about 66° F. There are adequate and excellent facilities for every healthful enjoyment. The area of the island is about one hundred square miles. Its highest peak reaches an altitude of over fifteen hundred feet, and leading to it are many winding paths, delightfully tempting to healthful exercise. On the other hand, for those who are not able to take such exercise, it would be difficult to find a seashore summer climate more restful and recuperative to the overwearied or invalid inlander than this is, or one with superior facilities for securing the best results.

Besides, Maine has hundreds of beautiful lakes and rivers amid delightful scenery, famous fields for summer sportsmen.

The Rangeley Lakes consist of a chain of lakes linked together by narrows and streams, altogether forming one continuous lake-locked watercourse, forty miles in length, and varying in breadth from a mere streamlet to three or four miles, but boatable for the whole length, amid wild and romantic scenery. They have long been famous as prolific trout waters. All along there are hotels, boarding-houses, and camps, with accommodations and supplies suited to the requirements of tourists or sojourners. The region is accessible by the Bangor and Aroostook Railroad and connections; or by the Maine Central to Farmington, and thence by stages.

Moosehead Lake nestles in the wildest and most secluded part of Maine's forest region, hemmed in by rugged mountains and lofty hills and covered with dense vegetation. The grandest of the mountain peaks is Mount Kineo, a bold, rugged bluff, at the base of which is the Kineo House, a commodious and well-equipped hotel of two hundred and fifty rooms, conducted in first-class style. The lake is forty miles long, from two to fifteen miles in width, and studded with many beautiful islets. It is accessible by the Bangor and Aroostook Railroad. And here is landlocked apparently an inexhaustible fishermen's harvest of salmon, trout, togue, and other fish—always abundant, but capricious, affording the usual variety in fishermen's luck—on some days, or at some chosen spot, not a bite; but on other days and at the same place, a surfeit.

Besides the Kineo House, at $3 to $4 a day, comfortable accommodations are supplied at a less price by the Winnegarnock, Moosehead Lake, Monticello, and several other hotels and many boarding-houses. Other fishing and hunting grounds in the vicinity are accessible by special routes at command.

The White Mountains, comprehending an area of about fifty miles in length by thirty miles in width, have long been among the most famous of summer health resorts. There are about twenty peaks with altitudes ranging from 3,000 to 6,285 feet above sea level, with corresponding degrees of mean summer temperature, 62° to 45° F., and a relatively dry atmosphere. The summer tourist to this region, who would see the most by the way, setting out from Boston, *via* the Boston and Maine Railroad, travels through the busy cities of Lowell, Nashua, Manchester, and Concord, to Laconia and Weirs. At the last-named place, on the beautiful Lake Winnepesaukee, he may make an agreeable halt, where connection is made with the lake steamers to Plymouth, and thence north through the Pemigewasset Valley to North Woodstock and through the Franconia Notch to the Flume. Waterfalls, lakes, and beetling cliffs are visible on every side, and the wonderful masterpiece of nature's sculpture, "The Old Man of the Mountain," appears on the dizzy height bordering Profile Lake, and near by the beautiful scenery of Echo Lake. The western branch runs *via* Woodsville and Bethlehem Junction to Bethlehem, a delightful summer resting-place; thence to Sugar Hill, Littleton, Fabyans, and the Mt. Pleasant Plateau—from which the finest of all views of Mt. Washington may be had. From this point the traveller proceeds by way of the wonderful Crawford Notch pass, sometimes called the gateway to the White Mountains. And here is one of the oldest, most commodious, and best-appointed hotels of the region.

Another and with many travellers a favorite route from New York to the White Mountains is over the New York, New Haven, and Hartford Railroad as far as Springfield, Mass., and thence by way of the Boston and Maine Railroad through Greenfield, Brattleboro, and Windsor, to Wells River, where there are commodious hotels; and from this place communication is easy with the Jackson Falls House, situated in the heart of the mountains, and hence with all points of interest throughout the region, and with hotels and boarding-houses suitable to the taste, time, and purse of the tourist, at almost every turn.

Colorado Resorts are more particularly noted for consumptives than for other invalids, and for all seasons than as exclusively summer health resorts; but they are here referred to with special reference to the opportunity for personal observation by the members of the American Medical Association, in relation with the forthcoming meeting of the association at Denver. Collectively they are chiefly esteemed on account of the altitude above sea level, and the rarity and relative dryness of the atmosphere on that account. In this regard the superiority of the climate of Colorado is urged on the same false basis as was that of Minnesota forty years ago, insomuch so that the health officers in localities where boards of health have been organized are careful to distinguish the deaths from consumption of recent settlers from those of older residents or natives; moreover, it shows a mortality from other causes quite as great as, or even in excess of, that of other localities under wholly different climatic conditions.

Denver, situated on the South Platte River, fifty-three hundred feet above sea level, fifteen miles distant from the base of the Rocky Mountains, is a typical Colorado—indeed Rocky Mountain—health resort; not perhaps wholly in the lay of the land, for there are doubtless some Rocky Mountain health resorts more favorably situated, with reference to a pure-water supply and soil drainage, than is Denver. And *this it is:* the local condition with relation to a pure water supply and its protection, and the disposal of waste of every kind, from which the health seeker nor health preserver, as the case may be, should never allow his attention to be diverted by the praises of the climate or anything else. Denver has been unfortunate in this respect, and it as well behooves the members of the American Medical Association as of other persons who would enjoy the delightful climate of Denver to beware of impure water.

Colorado Springs, seventy-five miles south of Denver and at seven hundred feet greater altitude, is rather more favorably situated with regard to a clean soil and pure water supply, but the authorities there, like those of Denver, have concerned themselves as little with regard to the purity of the soil and the purity of the water supply as they have with the purity of the atmosphere, and with the usual result—the prevalence of

typhoid fever and other intestinal diseases. Recently, however, there has been considerable improvement in these respects. The water supply has been protected, the sewerage extended, and more attention given to surface cleanliness. The mean summer temperature of Colorado Springs is 63° F., and the relative humidity fifty-one per cent.

The attractiveness of the city altogether has been much improved. There is abundant and excellent hotel accommodation, and there are many boarding-houses.

Manitou, five miles distant from Colorado Springs, is situated in a sheltered valley at the foot of the mountains, at an altitude three hundred feet higher than Colorado Springs. Here are situated the *Manitou Springs,* recently improved and an increasingly popular resort. There are eight acidulated soda-and-iron springs, varying in temperature from 44° to 59° F. The water of one of these, the Navajo, is in taste and composition similar to Apollinaris. The chemical constituents of the four springs chiefly used, according to a recent analysis, are as follows:

Grains Per Pint.	Shoshone.	Ute Iron.	Navajo.	Manitou.
Carb. of sodium.....	6.20	4.13	8.75	3.35
Carb. of lithium.....	Trace.	1.25	0.02	0.02
Carb. of calcium	7.60	3.20	9.06	7.75
Carb. of magnesium .	.....	1.20	2.20	1.08
Carb. of iron	.....	3.70	Trace.	....
Sulphate of potassium	0.35	1.10	1.15	1.00
Sulphate of sodium..	2.60	2.20	1.25	1.65
Chloride of sodium ..	3.00	3.10	2.75	2.35
Silica	Trace.	1.00	0.20	0.15

Manitou is a town of about three thousand inhabitants and has several good hotels; the most commodious, the Manitou, is in relation with the springs. The climate here differs somewhat from that of Colorado Springs, notwithstanding its proximity. The valley is more sheltered from the winds, but damper, on account of more frequent mountain showers and the brooks that flow through the streets. Only about a mile distant, and but four miles from Colorado Springs, is the *Garden of the Gods*—a famous fantastic rock formation, of imagined resemblance to all sorts of animals and objects.

West of Manitou, as the railroad steadily climbs around Pike's Peak, rising higher and higher, there are several attractive summer health resorts for tourists in the midst of the grandest of mountain scenery.

Manitou Park, a green *valley* seventy-eight hundred feet above sea level, surrounded by mountains covered with evergreen forest trees, is but a few miles distant from Manitou, by stage trips daily. Here there are well laid out and very fine drives overlooking the magnificent scenery, a commodious hotel with many cottages, tennis courts, golf-links, and other amusements for the accommodation of summer tourists; and views of mountain scenery limited only by the power of vision.

Indications for Resection of the Urethra.—1. In impermeable strictures. 2. In cases in which the stricture is elastic and immediately recurs after an attempt at dilatation, and above all in cases in which at the same time an ulcer or a suppurative urethritis exists back of the stricture. 3. When the stricture is of a peculiar character, diaphragmatic with an excentric opening, valve-like, or something similar, whereby we are enabled to enter one day and not the following. 4. When severe pain or hemorrhage from granulation masses renders a systematic bougie treatment impossible. 5. When a fistula remains permanently back of a stricture, as the remains of a peri-urethral abscess or an external urethrotomy.—Roosing, *Klinisch-therapeutische Wochenschrift,* No. 7, 1898.

ON CUTANEOUS BURNS.

By ELLICE M. ALGER, M.D.,

INSTRUCTOR IN DERMATOLOGY, NEW YORK POLYCLINIC; ATTENDING PHYSICIAN, DEMILT DISPENSARY.

Burns and scalds are among the commonest of the surgical cases which the general practitioner has to treat; the great majority of his cases being of that class, perhaps extensive but not deep, which do not endanger the life of his patient, but which cause immense primary discomfort with the promise of considerable secondary deformity.

The standard text-books on surgery reserve most of their space for the management of those severe cases necessitating actual surgical interference, and say very little about the treatment of these more moderate lesions, and still less about their pathological anatomy.

The scientific study of cutaneous burns dates from the time when Rayer brought forward his classification, which was afterward modified and popularized by the elder Hebra. It divides all burns into three classes or degrees, according to the depth of tissue destruction. In the first class are included those characterized by simple reddening of the skin; in the second those in which vesicles and bullæ form; and in the third all those in which destruction of tissue is enough to cause the formation of scars.

This classification is a happy one, for, while all burns have certain common characteristics, those of each degree have special features in addition, both clinically and microscopically, which form a basis for modifications in treatment.

Burns of the first degree are often trifling affairs, but when extensive may be productive of great discomfort and even some constitutional disturbance. The skin becomes decidedly hyperæmic and somewhat swollen, presenting an appearance not unlike that of erysipelas, but not so sharply defined. A decided sensation of burning is experienced by the subject, which may be unbearable. Pressure momentarily drives the blood away, leaving a dirty yellowish stain, and when the pressure is removed the blood courses slowly back. After the lapse of a few hours or days the redness is gradually obscured by thickening of the corneous layers of the skin, the swelling gradually disappears, and at the same time that the epidermis becomes thickened it begins to be exfoliated, a process that becomes more and more rapid until a normal skin is revealed. By comparison with the unburned skin, an increased amount of pigmentation can usually be demonstrated.

In burns of the second degree the skin is from the first considerably reddened, and, within a time varying from a few minutes to a number of hours or days, vesicles or bullæ appear, either flaccid or tense. In regions covered by thin skin, many of these bullæ soon rupture and discharge their serum, and only tags and shreds remain. The size of the vesicles varies greatly, and also depends largely upon the thickness of the skin—those in thinner regions appearing very rapidly and becoming very large, while those in thicker portions are much later in occurrence and smaller in size, because the damage has been chiefly confined to the horny layer and the exudation is therefore smaller, while the resistance to bullous formation is correspondingly greater. Eventually the blebs rupture and suppurate if left alone, or dry down in the form of crusts and scales, which finally drop off. Very naturally burns of the second degree, if extensive, may be productive of very great agony and shock from the first, and may be later accompanied by complications which will be referred to again. The secondary burn, involving as it does no essential part of the skin, does

not of itself cause the formation of scar tissue; but when a secondary pyogenic infection of the burned surface ensues extensive scars may be produced.

Burns of the third degree vary very much in their appearance, particularly in color, in different cases. Sometimes the skin is an ivory white, is swollen, and with the course of the vessels is plainy marked in reddish-brown lines. Again, it may be brown or even black. The skin is dry, hard, and devoid of sensation, unless some portion has been less severely burned. It is absolutely impossible to predict the exact extent of the injury, but in the course of a few days the dead tissues begin to separate from the living, and after the usual process of suppuration the slough is cast off and scars form. When an extensive burn of this sort becomes infected and suppurates freely, the stench is simply frightful. In a good many cases after granulation has begun certain deeper portions of the skin, such as the hair follicles and glandular appendages, are found to be still alive, forming centres of epithelial cell proliferation and lessening the amount of cicatricial tissue. Naturally burns of the third degree heal much more slowly than those of the first two and produce extensive scars, the after-contraction of which can sometimes be obviated by early care, but which often produces deformity requiring surgical interference. The pain in these cases is not a marked feature at first, for the whole skin with its nerve terminals is dead, but after the dead tissue has sloughed away the fresh granulations are exquisitely sensitive.

Pathology.—Clinically burns of the first degree, whether produced by dry or moist heat or by action of the sun, present about the same appearance, but pathologically there is a decided difference. A sunburn is not necessarily a burn at all, being frequently entirely independent of the action of heat, and being especially marked in certain skins exposed to the action of light reflected from snow and ice, even though the temperature be many degrees below zero. A burn of this variety is probably due to the action of the violet rays of the spectrum on skins predisposed to the process, and is most plausibly explained by the theory of chemotactic action of the actinic rays, which is capable not only of causing the development of cutaneous pigment, but when long continued of causing true inflammation and exudation. The pigment must be regarded as being produced from the disintegrated red blood cells. Burns of the first degree which proceed from the direct application of heat are much better understood. The first effect of heat on the skin is the marked stretching of the horny layer, which when the heat is dry remains stretched and loses its elasticity; when the heat is moist the elasticity is regained. (This is easily demonstrated by the effect of a curling-iron on the horny layers of the hair.) This stretching and swelling cause a distinct separation between the horny and prickle-cell layers, and in this process the prickle cells are stretched till they assume a spindle shape, but without necessarily losing their vitality. The papillæ are also thickened and swollen, though their vitality is not affected. These are all primary changes, due to action of heat alone, for they can be demonstrated on the cadaver.

Secondary inflammatory changes begin at once in the living subject. In the neighborhood of the burn the whole cutis swells, the blood-vessels dilate and the leucocytes assume a marginate appearance, the connective-tissue cells become larger and more numerous, and the epithelial cells begin to show karyokinetic figures. Later on the young epithelial cells begin gradually to push off the dead cells which they are to replace. Throughout there is no impairment of any vital portion of the skin, and of course no scar results.

The pathological process in burns of the second degree is at first very similar in character. The primary effect is again the stretching of the horny layer, which, if the heat has been dry, remains somewhat raised and inelastic. At the same time the heat, being greater than that necessary to cause a burn of the first degree, has caused the death of the prickle-cell layer, whose individual cells are found stretched or broken as before. At the same time, if the heat has been intense (a hot iron, for instance), there is not infrequently developed from the moisture in the tissues enough steam to cause the immediate appearance of vesicles. But the formation of true burn vesicles is a later and different manifestation, and must be considered as the result of chemotaxis or of colliquative degeneration following the injury of more or less tissue. Here we can trace a clear distinction between the action of dry and moist heat. In the dry burn the horny layer remains stretched and inelastic, and between it and the next layer is quite a cavity. As a result, the exudation even if slight is spread pretty evenly between the two. Therefore we may find a good many flaccid bullæ, because the epidermis was stretched over comparatively large areas, while the exudation was not great enough to make the bullæ tense. Unless very full the bullæ of a dry burn tend to be flat topped.

In the scald, the horny layer is stretched, but retains its elasticity and at once spring back into place. As a result, when exudation occurs the size and shape of the bullæ depend entirely on the amount of fluid first appearing in the centre, where the skin pressure is least, and gradually extending toward the margin, where pressure is greater. From the fact that the elastic horny layer keeps a constant pressure on the fluid, these bullæ are, unless ruptured, always tense and dome shaped.

In all burns of the second degree there is a marked dilatation of the blood-vessels and lymphatics beneath and about the lesion, and the papillæ are swollen and œdematous.

In burns of the third degree the marked variation in color in different cases, or even in different parts of the same subject, has already been referred to and is perhaps susceptible of this explanation. When the skin is subjected to moist heat of a high degree for a time, whether in the living subject or in the cadaver, it is converted into a gelatinous mass, white in color and almost transparent, while the blood in the vessels is coagulated and becomes a dirty brown. This is the clinical picture of a severe scald. In the same way, when the skin is subjected for a short time to a high degree of dry heat, a good deal of steam is evolved, as is evidenced by the occurrence of bubbles in the tissues. Practically it is scalded in its own juices, and the appearance is the same. When this dry heat is longer continued, this moisture evaporates; the skin dries and becomes brown, with the course of the vessels no longer distinguishable; and finally, when carbonization has taken place, the color is even black.

The microscopic changes are said to be characteristic, and even in them the same distinction between the action of moist and dry heat prevails.

A word must be said here as to electrical burns, though there is as yet no thorough understanding of their nature and pathology. Clinically they may present symptoms of either of the three degrees, but microscopically they will probably differ from ordinary burns, because of the action of the current itself on individual cells, aside from its heat effects. These are almost entirely confined to the skin and adjacent structures, for electricity develops heat only in the presence of resistance, and it is a well-known fact that the skin offers this in a far higher degree than does any other body tissue. Conversely, the other effects of electricity are more likely to show themselves in the

subcutaneous tissues, which offer almost no resistance and are therefore the favorite paths of the current.

The amount of moisture and salty excretion from the surface glands should theoretically lessen the resistance and with it the severity of the burn, but practically, where so many factors are involved, it cuts but a small figure. Owing to the interference with cell life and the possible blood coagulation in tissues which are not actually burned, it is impossible to forecast the result, but it is almost certain to be worse than in any other variety of burn. Even if deep tissues do not slough away, their vitality is impaired and repair is sure to be very slow.

The prognosis of burns depends largely upon the condition of the patient and the extent of surface involved, rather than upon its depth. As a general rule, burns involving one-third to one-half the cutaneous surface prove fatal. Such a patient, after the relief of the first pain, becomes quiet and easy for a few hours. His urine is scanty, albuminous, and bloody. In five or six hours perhaps he begins to vomit, and a stage of depression ensues, followed by one of restlessness and delirium with spasmodic muscular contractions. Respiration is shallow and the pulse bad. Death occurs in from eighteen to forty-eight hours. The cause of such results from extensive superficial burns has been much debated, and is not by any means settled. According to Von Loeser, death results from the great destruction of blood cells, with a consequent failure of oxygenation and nutrition. Hoppe-Seyler ascribed it to the retention in the body of products of tissue change, especially ammonium carbonate; others to the destruction of so many sweat glands producing a condition akin to that of the physiologist's varnished frog. According to Silbermann, many thrombi form in both veins and arteries, especially in the branches of the pulmonary artery, and eventually cause a venous stasis combined with arterial anæmia. This would account for the congestion of internal organs and for the dyspnœa, anuria, cyanosis, and coma which are so often the results of severe burns. Portions of these thrombi become detached and lodge in various organs. The perforating ulcer of the duodenum, occurring as late as the tenth day, often shows a clean-cut margin strongly suggestive of previous embolism. Lustgarten ascribed death to ptomain poisoning, while Erichsen, perhaps conveying as much definite information as the rest, endeavored to prove shock the cause of death.

Clinically it is rare to find a burn the lesions of which are entirely confined to any one degree, very frequently all three being found in contiguous locations. The treatment of them all must therefore be considered at the same time. In the milder and less extensive cases the pain present is the principal thing to be combated, and this indication is best met by the exclusion of air by oils or very fine powders. In an emergency common flour, thickly dusted over the surface, is temporarily effective. The well-known Carron oil, equal parts of linseed oil and limewater, is perhaps the most popular dressing we have; but it is a nasty, greasy, ill-smelling mixture, and I much prefer other dressings—as, for instance, a ten-per-cent. aqueous solution of ichthyol, with the addition of a little starch and egg albumen. In the more extensive burns the indications for treatment are three: first, to relieve the pain, which is almost always intense; second, to prevent infection, which is certain to produce cosmetic defects and may cause grave constitutional disturbance; and third, to hasten the process of repair by accelerating cornification. For the relief of pain immersion in water is one of the oldest and most effective methods, but must be in most cases merely a temporary expedient, for the simple wet dressing does not by any means answer the same purpose and has the disadvantage of hindering repair. However, in those very extensive cases in which life itself is in danger, there is no treatment for a moment to be compared to Hebra's continuous bath. In all cases of severe burning antisepsis should be carefully maintained, but it should be remembered that absorption occurs very readily from burned surfaces, and such antiseptics as carbolic acid and bichloride should be used with very great caution, if at all. Creolin is a very serviceable antiseptic, and has some analgesic effect. Formalin, even in very weak solutions, is so irritating at times as to be absolutely unbearable. I have gradually come to consider picric acid the best all-around dressing for burns, for several reasons.

It is a yellowish, crystalline powder, produced by the action of nitric acid on phenol, and is readily soluble in water in almost any proportion. It is a fair antiseptic, a good oxidizing agent, and has to a very high degree the power of coagulating albumin. It has recently been reintroduced by the French school of dermatologists, who advise its use in burns and many erythematous skin diseases, in solution of from two per cent. up to saturation. It has the disadvantage of staining the skin a bright yellow, which would militate against its use in slight burns of the face or hands. I have used it in a good many forms, but have found the combination with citric acid, as devised by Esbach for the detection of albumin in the urine, by far the most satisfactory:

℞ Acidi picrici	10
Acidi citrici	20
Aquæ	ad 100

Without any elaborate attempt to cleanse the skin of any except the worst of the extraneous matters, any bullæ should be opened with an antiseptic needle, freely but without any special attempt to express their contents. The fluid should be sopped on freely, care being taken that it reaches the interior of every vesicle. Picric acid alone is a rather weak acid, and coagulates albumin but poorly in an alkaline medium. The citric acid acidulates the alkaline exudate, which the picric acid promptly converts into an antiseptic coagulum, capable of excluding the air and resisting infection. The combination, after a momentary smarting, relieves the pain more quickly and completely than anything I have ever tried. After the excess of fluid has drained off, the part may be covered with soft gauze and not disturbed for several days. It makes a clean, comfortable dressing, and I have never observed any toxic effects. After the first dressing it should be reapplied every two or three days, only to those areas where exudative fluid has formed.

Picric acid is a good cornifying agent, and therefore hastens granulation, while its antiseptic action renders it especially valuable in those cases in which large granulating surfaces are suppurating. Here we must often stimulate granulation by use of nitrate of silver or balsam of Peru, while not infrequently we must avail ourselves of the resources of the surgeon and have skin grafting done. Large granulating surfaces should be dressed a part at a time, and dry powders will be found much preferable to ointments, which tend to confine irritating discharges near the surface.

117 East Twenty-Sixth Street.

Measles versus Scarlet Fever.—The facial eruption is important when the previous history is obscure and doubt may exist between measles and scarlet fever. The region of the nose is almost always occupied by the eruption of measles, and left free in scarlatina, which frequently, indeed, affects the face, but very little or only with a flush of indifferent appearance.—H. Bryan Donkin, "Diseases of Childhood," p. 184.

WERLHOF'S DISEASE (PURPURA HÆMORRHAGICA).

By CHARLES H. LEWIS, M.D.,

NEW YORK,

VISITING PHYSICIAN TO COLUMBUS HOSPITAL.

This disease, first systematically described by Werlhof in 1775, is usually classed under the purpuras and known as purpura hæmorrhagica. All purpuras being hemorrhagic to a greater or lesser degree, the latter name carries no special distinctiveness, except what it inherits by common usage. The dominant features are those of a highly infectious disease, with hemorrhages from the mucous surfaces. Since the first recognition of the disease by Werlhof, up to a comparatively recent period the literature on the subject has been sparse, and mainly confined to citing cases and theorizing as to their etiology, with incidental remarks on treatment.

Lockwood,[1] in an excellent *résumé* of the subject, recommends the usual grouping of Werlhof's disease with the purpuras, and would further broaden the class so as to include scorbutus.

Simplification in medical nomenclature is a "consummation devoutly to be wished," but the three following cases present a clinical picture which does not resemble the simple purpuras or the purpuras attending rheumatism, in any respect except in the eruption. Furthermore, although these cases impress one as being types of a most virulent disease, the skin ecchymoses, in two cases at least, were neither numerous nor large. Indeed, it seems difficult to trace a closer relation between the ordinary skin purpuras—whether due to mechanical, neurotic, toxic, or cachectic causes—and these cases than exists between the ordinary pustule and the pustule of small-pox.

Cases of true purpura hæmorrhagica are rare. During the past year, three cases only were noted out of some twenty thousand general medical cases occurring in nineteen hospitals in this city. The infrequency of true Werlhof's disease and the present unsettled state of our knowledge of its nature would seem to warrant the report of the following cases:

Case I. occurred in the practice of Dr. Frederick Spring, of Naugatuck, Conn. The patient, J. W——, a woman, aged thirty-seven years, of healthy family antecedents, enjoyed good health up to a year prior to her present illness, during which time she suffered from some gastric and hepatic disorders, with occasional attacks of jaundice. There was no rheumatism, but she had some general muscular tenderness. No hæmophilic tendency was ever noted by the patient or by the physician, whose observation extended over some eight years, and included attendance on one stillborn child, four years prior to the present illness. The patient was supplied with every comfort of life, and the hygienic and sanitary surroundings seemed perfect. In August, 1893, when I saw the patient in consultation, she presented no purpuric spots, and no mucous hemorrhages had appeared. The temperature was slightly elevated and the pulse weak. No material information was elicited on physical examination. The surface of the body had a dark icteric hue, somewhat mottled, but was entirely free from cutaneous and mucous extravasations. She seemed greatly debilitated, however, and impressed one as suffering from some grave disorder, the character of which at the time was not recognized. On the following day, I am informed by Dr. Spring, purpuric spots appeared in abundance over the surface of the body, and free hemorrhages set in from bowels, mouth, nose, bladder, and uterus. The profuseness of these hemorrhages, despite all treatment, was appalling, and ushered in the beginning of the end, which occurred two or three days later. The intellect was clear to the last. No great elevation of temperature was noted, and the patient apparently died from cardiac failure due to loss of blood.

This case is instructive as illustrating the late appearance of the purpuric spots, and the sudden onset and extensive source and amount of the bleeding.

Case II.—H. D——, a man of Italian birth and of the same residence up to six months prior to his admission to Columbus Hospital, October 11, 1896. He was a mason and lived in the upper part of the city. Family history negative. The patient stated that he had had two illnesses somewhat similar to the present. There was no rheumatic, malarial, or specific history. His diet has been ample and varied. The present illness dated from six days before his admission to hospital, and consisted of pains throughout the body, some vomiting, and a feeling of general malaise. On the admission the temperature was 104 F.; pulse, 114. Physical examination revealed nothing of importance, except a few ecchymotic spots varying in size from mere points to that of a split pea, and located on the anterior surface of the arms and chest. The gums were slightly swollen, but there was no ulceration or retraction from the teeth. No mucous ecchymoses were noted. The urine was blood colored, contained fifty per cent. in volume of albumin, a few hyaline casts, and was filled with red corpuscles. During the following days the temperature gradually fell, until it reached the normal point one week after the man's admission. At this time the patient developed a stupor, from which he was roused with great difficulty. Coincidently the left pupil became largely dilated, with no reaction to light, and left ptosis appeared, with traces of left facial paralysis. He now passed blood from the bowels as well as from the urethra. When roused he complained of general muscular pains and headache. Two days later a few ecchymoses appeared on the legs; at the same time the temperature began to rise and assume a remittent type, reaching 103° F. on October 28th. The urine continued bloody, and occasional and moderate hemorrhages from the bowels persisted. From this time on all symptoms gradually improved except the skin ecchymoses, which were well marked on November 15th. The patient left the hospital November 22d, quite well except for the fading ecchymoses.

The points of interest in this case are, subjectively, the muscular pains and headache; objectively, the presumable occurrence of a hemorrhage involving the nuclei of the third nerve, and occurring when the temperature was normal. At this time coma seemed imminent and death certain.

Case III.—F. P——, a man, aged twenty-nine years, laborer. He was born in Italy and lived there up to four years ago, when he came to this country, and was admitted to Columbus Hospital from his residence, Rock Hill, N. J., June 14, 1897. The family history was immaterial. Prior to his present illness, the patient had always been well. He acknowledged no fault of diet or habit, except excessive smoking. Two weeks before his admission he experienced pain in the throat and about the right tonsil. Two days later bleeding from the nose and mouth set in, which continued with more or less severity. With the advent of the hemorrhages the patient noticed a few bright purple spots on the anterior surface of the right arm, followed a few days later by similar ones scattered over the legs and trunk. Except for the sore throat, no pain or tenderness of any description was experienced. The bowels were regular and the stools natural; the appetite was good; temperature, 102.2° F.; pulse, 88. Except for the sore throat, the patient said he "felt quite well." Physical examina-

[1] MEDICAL RECORD, February 7, 1891.

tion of internal organs revealed nothing significant, except an increased splenic dulness. The surface of the body exhibited a moderate number of purple spots, of somewhat irregular outline, ecchymotic in character, more abundant on the chest and about the wrists and ankles. The ecchymoses were of varying size, the largest on the arm being about two centimetres in diameter. It had a purple centre, with a yellowish-green margin. The tongue and throat presented small submucous extravasations. The right tonsil was enlarged, and had black hemorrhagic spots on the anterior surface, with some surface clots. The breath was very fetid. The gums were rather spongy, but not ulcerated. The intellect was unimpaired. The urine, red in color, was filled with blood corpuscles, and had about forty per cent. of albumin in volume. Hæmoglobin, thirty-eight per cent.; red corpuscles, 2,852,000 in a cubic millimetre.

January 18th, general condition failing. No pain, no hemorrhage except in urine. Temperature ranged between 101° and 103° F. Anæmic; corpuscles, 1,372,000.

On June 20th the patient died, apparently from exhaustion.

The treatment was iron and mineral acids for the hemorrhages, a hydrozone mouth wash, and the ordinary stimulants for the heart. The absence of muscular pain and the uninterrupted clear intellect up to the last contrast sharply with the history of Case II.

Autopsy by Dr. Farquhar Ferguson twenty hours after death. Rigor mortis well marked. Body well nourished. Surface of body and extremities presented a number of hemorrhagic areas, one millimetre to one centimetre in diameter. Numerous punctate hemorrhages over visceral pericardium.

The heart muscle was seared and the left ventricular cavity opened with a sterilized scalpel. A nutrient agar tube was inoculated from the blood in the ventricle. The heart muscle was intensely anæmic; the ventricle was moderately dilated, with a few hemorrhages in the subendocardial tissue. The valves were normal.

There were two areas of hemorrhage beneath the pleura of the right lung over the lower lobe, in diameter three millimetres and two millimetres respectively. There was no hemorrhage of the left lung or pleura, but considerable œdema.

The spleen was dark colored in spots, and double the normal size.

Kidneys: Capsule not adherent; intensely anæmic, with extensive hemorrhages around the pelves.

Stomach: Extensive hemorrhages in mucous membrane.

Mucous membrane of upper duodenum pigmented.

Suprarenal capsule fatty.

Numerous hemorrhages were scattered over the anterior peritoneum, and a large retroperitoneal hemorrhage covered the entire posterior surface of body.

Liver and pancreas intensely anæmic.

Aorta normal.

Intestines: mucous membrane blood stained, otherwise normal.

The inoculated agar tube after a few days presented a white surface growth, which when microscopically examined was found to be a pure culture of staphylococci. A gelatin tube inoculated from this growth after three days showed a rapidly growing germ which liquefied the culture medium. This microscopically appeared identical with the agar growth. The cocci were then injected into the abdomen of a rabbit, but with negative results. Injected into the ear, they produced abscesses, from the pus of which the organism was demonstrated by microscopical examination, and later by culture methods.

By these experiments the organism was identified as the staphylococcus pyogenes albus.

In the above procedure two sources of error are recognized: 1st, accidental infection in transferring the blood from the heart to the culture tube; 2d, the possibility of blood infection after death—involving a period in this case of about twenty hours. As regards the first, I can only say that the same care was observed as is practised in reinoculating tubes in the laboratory. As to the second, so far as I am aware no data are on record. The purity of the culture, however, and the protection afforded it from outside contamination by a healthy heart, would warrant the inference that the micro-organism was present during life. At the same time it is regretted that the living blood was not also bacteriologically examined.

Germs of various kinds have been found in the blood in Werlhof's disease; notably, streptococci, staphylococci, pneumococci, and bacilli of different dimensions.

Letzerich[1] isolated a bacillus closely resembling in shape the anthrax bacillus, which he considered peculiar to purpura hæmorrhagica, and which, inoculated in rabbits, produced mucous hemorrhages.

Watson Cheyne[2] described a short bacillus which he found present in the blood of two cases. A microscopical examination of the hemorrhagic areas showed the capillaries completely blocked by this germ.

Lebreton,[3] in a case which ended in recovery, demonstrated the staphylococcus albus in cultures from the blood sown on agar and bouillon. He also found the same organism in the urine.

Angel Money[4] reports negative bacteriological studies in two cases.

Whether any specific germ can be assigned as the *sine qua non* of true Werlhof's disease is at present extremely doubtful. That there is some change in the composition of the blood—a fluid normally sterile and germicidal—which renders it tolerant to micro-organisms in large numbers, seems equally certain. Whether this change is effected by the germs or by their toxins, or they themselves are the result of transformed conditions due to unknown causes, must be settled by further investigation.

The immediate cause of rupture in the vessel walls is also undetermined. Hyaline and amyloid degeneration of the arterial coats has been demonstrated; also endarteritis, and emboli formed from the germs themselves. In the latter case the mechanical action of the emboli seems sufficient to account for the rupture.

Unfortunately in the first two cases there is no record of the blood examination. In the third case the hæmoglobin was thirty-eight per cent., and the red corpuscles numbered 2,852,000 per cubic millimetre, falling two days later to half the number. In a fatal case reported by Billings,[5] the corpuscles fell to 696,000 per cubic millimetre; the hæmoglobin to seventeen per cent.

Carrières'[6] case registered 3,325,000.

As to treatment, the best results seem to be attained with the iron preparations.

Quite recently M. Pigot[7] reported a case which presented immediate and rapid improvement after the subcutaneous injection of blood serum. This treatment was instituted after two days' use of the ordinary remedies without effect. An injection of two

hundred and fifty cubic centimetres on three consecutive days effected a cure.

Contemporaneously Jaunin,[1] following Alexin, in one case reports somewhat less brilliant results with fresh calf's marrow.

28 West Sixty-First Street, New York.

PROGRESS IN THE TREATMENT OF DISEASES OF THE EAR.

By HERBERT J. HOPKINS, M.D., C.M.,

PITTSBURG, PA.

So slow has been the advance from year to year of improvement in the treatment of diseases of the ear that it has been almost imperceptible: yet the final result is startling in its revolutionary radicalness.

The recognition of the great value of excision of the drum and ossicles in chronic suppuration of the middle ear, and the practical restriction of the use of that operation to that disease, were only finally attained after much uncertainty.

It was long believed that the tympanic membrane and chain of ossicles were essential portions of the ear; that their destruction meant also the destruction of the sense of hearing. This having been disproved, the reaction was to the other extreme, and excision was done in many widely different affections, particularly in that most common cause of deafness, chronic catarrhal otitis.

The applicability of the operation having been eventually defined, the resources of the aurist were very materially increased.

It was only after prolonged and painful groping in the dim realms of the unknown that suppuration, with accumulation of pus in the mastoid process, could be conceived and looked at in the same light as abscess formation in the soft tissues, and the logical treatment, incision and drainage, resorted to, without much timorous reluctance—such was the dread inspired by the interposition of an ossified stratum of tissue, requiring the use of drills or gouges before the pent-up matter could be reached and evacuated.

But the greatest change was yet to come with the wonderful advance of therapeutics in the neighboring organs, the nose and throat. The causative influence, in suppuration of the ear, of enlarged tonsils and adenoid vegetations was then only fully appreciated; as was the bearing of obstructive lesions of the nose, as represented by hypertrophic rhinitis, deformities of the septum, polypi, and other growths, in that dread disease—chronic catarrhal otitis.

To-day an examination of the ear involves a thorough exploration of the adjacent cavities of the nose and throat, and appropriate treatment should any abnormality be discovered which might interfere with the natural patency of those passages. Thus if hypertrophic catarrh or enlarged turbinates be present, the judicious use of the caustic point (chromic acid) is indicated.

Should adenoids, enlarged tonsils, polypi, or other tumors be found, they should be removed. Spurs and ridges on the septum yield readily to the septal saw, as do the obstructing portions of a deflected septum —the object of these manœuvres being to restore the normal lumen of the passages, for any unnatural alteration in atmospheric pressure during inspiration and expiration reacts detrimentally upon the structures of the middle ears and Eustachian tubes.

The old-time specialty, "the ear," would hardly be recognized now in the modern progressive one, "the ear, nose, and throat."

Progress of Medical Science.

Contribution to the Study of Enteritis with Streptococci in Nursing Children.—Drs. J. L. Hirsch and E. Libman (*Centralblatt für Bakteriologie*, October 2, 1897, No. 14, pages 369 and 376) report the clinical history of a little girl of eight months, fed on ordinary cow's milk, who was affected with green diarrhœa, vomiting, fever, and abundant diaphoresis, and who succumbed at the end of three weeks. The stools showed epithelial cells, pus corpuscles, and streptococci associated with other bacteria. Streptococci were also found in the contents of the stomach and in the blood, and at the autopsy they were encountered in association with the bacterium coli commune in the heart, lungs, kidney, and spleen. In the intestinal tissue, on cutting, they were found but rarely; a few chains were found in the submucous coat and at one point in the subperitoneal lymphatics. On the contrary, the stools, examined several times in the course of the disease, contained streptococci of almost pure culture, forming long chains of from three to twenty elements. On artificial media the chains are shorter and do not exceed ten elements. One or several elements of the chain often show a tendency to transverse division, and this gives to the preparation the appearance of a checker board. Morphologically this micro-organism is very much like the streptococcus involutus of Kurth, but is distinguished by the characteristics of the culture and by its slight action on mice. On mushroom in plates it does not give colonies visible to the naked eye; but under the microscope, after twenty-four hours' incubation, small, light brown, coarsely granular colonies are found. On agar in puncture it develops very slowly. The most favorable medium seems to be sweetened bouillon, which is somewhat disturbed after twenty-four hours and a sediment is thrown down. Inoculated in white mice, this micro-organism produces a fatal diarrhœa; the streptococcus is found in the dejections and in the blood of the heart. This micro-organism differs from the streptococci described thus far and also from the streptococcus pyogenes. Tavel and Eguet published, in 1895, eight analogous cases, but they thought that the streptococcus of enteritis in nursing children was identical with the intestinal diplococcus that normally inhabits the intestines. Now the microbe of Hirsch cannot be compared to the species that Escherich has described as normal in the intestines of healthy nursing children; that is, the streptococcus coli gracilis and the streptococcus brevis. Boocker first described specific enteritis due to streptococcus infection, and separated it from other summer diarrhœas of nursing children. Libman has added to the communication of Hirsch two cases of enteritis with streptococci. He is able to report from the autopsy that the microbe, rare in the stomach and in the upper part of the small intestines, increases in abundance toward the cæcum and gives the appearance of a pure culture. In the upper part of the colon small follicular ulcerations are found, filled with specific microbes; these spread into the mucous, submucous, and muscular coats by way of the lymphatics. They develop but poorly on gelatin, either on the surface or in punctures. On potato a fine, bright, and moist coating is formed, composed of small white points. They develop admirably on mushroom, if the serum of human blood has been added.

Diabetic Albuminuria and its Treatment.—Dr L. Goudard (*La Presse Médicale*, December 15, 1897) distinguishes two great nosological varieties of diabetic albuminuria: a functional albuminuria and a lesional albuminuria; this division is, moreover, not absolute.

Functional albuminuria may be met with in four different conditions: it may be complicated with simple fatigue of the kidney, with phosphaturia, with organic disassimilation, or with hyperchlorhydric dyspepsia, so frequent in those affected with glycosuria. If neglected this functional albuminuria may be transformed into a lesional albuminuria. This latter corresponds with lesions of nephritis, which may exist at first and be accompanied by all the symptoms of Bright's disease; the history of the patient often shows arterial sclerosis, arthritis, alcoholism, etc. The kidneys of diabetics may present lesions which are not common to diabetes, such as fatty emboli, amyloid degeneration, abscesses, and tuberculosis of the kidney, and especially interstitial and parenchymatous nephritis; or the special lesions of this affection, such as hypertrophy of the kidney, the lesion of Ehrlich, and the cellular necrosis of Ebstein. Lesions of nephritis are usually albuminogenous, but there are reports of diabetic albuminuria without renal lesions. From a clinical point of view one may distinguish a slight albuminuria which would easily pass unperceived, and a grave albuminuria in which the quantity of albumin eliminated in twenty-four hours occasionally exceeds two or three grains; this grave albuminuria is frequently accompanied by symptoms of Bright's disease. Mild albuminurias are almost always functional, while grave ones are rarely so, and many functional albuminurias develop into nephritis. The quantity of albumin eliminated, the presence of cylindrical epithelium in the urine, alkalinity of the urine, and cardiac and vascular manifestations indicate lesional albuminuria. Chemical analysis of the urine will show phosphaturia and organic demineralization; gastric symptoms show hyperchlorhydria. The treatment of diabetic albuminuria is based on the nosological division established above. In functional albuminuria the antidiabetic diet should be rigorously enforced. At the outset medical treatment deals with the first stage, in which antipyrin and bicarbonate of sodium are administered. If glycosuria diminishes perceptibly or disappears at the end of three or four days, we pass from this treatment to the treatment of the albumin. On the other hand, we may begin with the second step and give sulphate of quinine and arseniate of sodium. The treatment of phosphatic albuminuria comprises, in addition to diet, an arsenial potion accompanied by pills of the extract of cinchona and sulphate of quinine. At the end of ten days these are replaced by the glycero-phosphates and later by the hypophosphites. In albuminuria complicated with organic demineralization, it is necessary to restore by appropriate diet the saline principles which are wanting in the organism; milk and bouillon will be found excellent for this purpose. Albuminuria of dyspeptic origin may be alleviated, independently of the medical treatment of hyperchlorhydria, by the division of nourishments into very small quantities taken at frequent intervals. In grave functional albuminurias we should treat alternately the diabetes and the albuminuria; during three days we should prescribe antipyrin, then put the patient upon a milk diet and give him antidiabetic treatment, and continue to repeat this order. The treatment of lesional albuminuria is the same as that of Bright's disease; we do not here take into account diabetes, but administer a milk diet exclusively unless there is some contraindication, such as an uncomfortable repugnance to milk, in the face of certain cachexias, gastric troubles, diminution of urea, too great an increase in sugar, or an insufficient diminution of the albumin.

The Treatment of Impetigo by Electricity.—Dr. J. Levezier (*Le Nord Médical*, December 15, 1897), although he does not pretend that this is the only treatment for impetigo, thinks that it has advantages which warrrant its being acknowledged as a therapeutical agent in this affection. The following effects are observed: 1. A diminution of the itching is noted; this relief is often obtained at the first and always at the second séance. It frequently happens that the pruritus ceases entirely after the first application of electricity, and the patients often express astonishment at the results. In children this improvement is witnessed by the fact that they become less restless and make no attempts to scratch. If this was the only effect produced, electricity would be worthy a place as one of the therapeutical agents used in combating this affection, but the desirable results by no means end here. 2. The secretion ceases after a short time; sometimes after the second or third application desquamation takes place rapidly, especially over smooth regions where the eruption is recent; the crust dries up and falls off and is not renewed; and if it does not fall off spontaneously, as when it is situated in the beard or hair, moistening it with an oil facilitates its removal. The aspect of the crusts is changed in a remarkable manner after the first or second séances. From moist, agglomerated, and large fragments, they become dry, friable, and the fragments resemble grains of sand, thick and dry; these signs make it evident that the secretion that produced them is drying up. 3. The erythema follows a like diminution; the areola which surrounds the impetiginous plaques becomes pale, without entirely disappearing in the beginning. After the cure is complete and the crusts have fallen off, the trace of the primitive lesion persists in the form of a roseate spot, which soon becomes pale. Here great variations are noted, not only between different patients but even in the same subject, between one plaque and another. Over fleshy regions a light erythema persists for two or three days after the crust has fallen off; in the face it does not. Very often as soon as the crust falls the adjacent skin assumes its normal color. 4. In impetigo the hair often becomes dry and discolored, and it has been noted that under this treatment it becomes darker and more oily. It seems to grow faster and to become thicker. This fact corresponds with that often observed in the treatment of alopecia in children, and in the course of certain general diseases such as rachitis and scrofula. 5. Impetigo has an influence on the lymphatic glands in the affected region. These ganglia become indurated, and it is not rare to find them like a string of beads, especially along the sterno-mastoid muscle. As the crust dries and the skin repairs itself, the ganglia diminish in volume and hardness, and if they persist they are perceptible only on minute palpation. 6. Electricity acts as a stimulus to the organism. It is evident that the short duration of treatment does not allow the production of definite results, but it is nevertheless true that there is a notable increase in the appetite, that there is greater regularity in sleep, and that a general sense of well-being renders the patient less irritable.

Diagnosis of German Measles (Rötheln). — Dr. Blaschko, of Berlin, as a result of years of practical experience, considers rötheln a weakened form of measles. He diagnoses rötheln when during the course of a measles epidemic the children have a slight fever and a reddish eruption with an elevation of the cutaneous papillæ, without any eye pains, coryza, or catarrh of the air passages; when the appetite and general condition do not suffer, the redness becomes of lighter color in a few days, and the skin desquamates very slightly or not at all; and when the child has had measles before.—*Deutsche Medizinal-Zeitung*, No. 14, 1898.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 28, 1898.

THE INHUMANITIES OF WAR.

WHEN one pauses to consider that the warfare now engrossing the attention of this country was undertaken largely from humanitarian considerations, the suggestion that anything approaches inhumanity in our conduct of the struggle would scarcely be entertained.

Never before in the history of contention between nations have the conditions been such as to call for greater foresight in the care of those fighting, as well as of those for whom the fighting is being done. The great advances in the science of field surgery, the greater facilities for quick and competent relief, the wealth and oft-proven charitableness of our citizens, and, above all, the principles involved in the contest, make it imperative that no needless suffering be permitted.

Over two thousand competent physicians and surgeons have offered their services to the government; hundreds of able, willing, and patriotic nurses have enrolled themselves as anxious to go to the front. Money is being freely contributed for supplies, medicines, ambulances, and ambulance ships. Experience has taught the necessities of adequate hospital care, while the dangers of campaigning in tropical climes and of unsanitary camp arrangements have been made a matter of lifelong study by those in charge of the medical service of the army.

Despite all this, no one doubts that much hardship and suffering will be the lot of our soldiers by land and our sailors by sea. It is the unnecessary suffering which will be inexcusable, and the authorities cannot be held blameless if all available resources are not utilized to reduce the latter to a minimum. Let no such protest be entered against our medical department as that recently made by English journals against their own war office and military advisers for "sweating" the medical staff and sending out expeditions without provision for the sick and wounded. Among recent inhumanities of war we find record of the death of Captain Dunning, of the Royal Fusileers, several days after being wounded in an expedition sent out without any medical officer, and whose life it was thought might have been saved if surgical skill had been at hand. *The London Lancet* refers in eulogistic terms to the heroism in battle of Dr. Duran, of the Spanish army, who, despite a shattered knee-joint, quickly bound up by the aid of his orderlies, proceeded under the fire of insurgents to carry out no less than twenty major operations, including abdominal suturing and the care of compound fractures. Such heroism is indeed praiseworthy, but what can we say of the inhumanity of making it a necessity for a wounded surgeon to continue at his post, caring for others, instead of being cared for along with them?

The inhumanity of making war with explosive bullets and those resembling them in their bone-shattering and tissue-tearing powers cannot be too strongly condemned; but to send expeditions into foreign and unhealthy regions without surrounding them with all the precautions and means of relief which forethought and knowledge can supply, is to wage war in a manner at variance with present-day enlightenment and ill becoming our position and claims of high humanitarian sentiments.

PHYSICAL CONDITION OF VOLUNTEERS.

THE numerous discussions bearing on the physical degeneration of the average up-to-date American citizen have recently had a very practical demonstration of fact in the number of rejections for unfitness for military service, as the result of test examinations of recruits. Lieutenant-Colonel Mans, U. S. A., who has charge of the enlisting-bureau, found that it was necessary to examine seventeen thousand applicants in order to obtain twelve thousand who were fit for field duty. The results show in the main that the ordinary militiaman who represents the average metropolitan is by no means up to the requirements of a first-class soldier. In other words, it would appear that the best is done with the material at hand. The influences of city life in causing a lack of physical development and vital power are plainly manifested in contrasting the number of acceptances from country regiments as compared with those from the large cities.

It has long been admitted that the best blood comes to us from the rural districts, where healthful surroundings, outdoor life, and moderate living make the sum and substance of that vital resistance to degenerative influences which is capable of meeting all the ordinary strains of modern civilization. This is one reason why the country lad makes his mark and succeeds where the city-bred youngster fails. In a generation or two the enervating influences of city life tell in an unmistakable way upon the physical development of the sturdy yeoman, who then becomes narrow chested, weak kneed, short sighted, and is no longer in the fore in the race. This fact is strikingly exemplified in the alarming proportion of rejections in city regiments, to which reference has been made. From such a point of view, it is quite evident that the city man is losing his physical grip, for reasons obvious to all who study his habits and note the ultimately pernicious influences of his depressing environment.

The Study of Psychiatry.—The University of Jena has decided that students of medicine shall henceforth be required to pass a satisfactory examination in psychiatry before obtaining a degree.

ON ANTISTREPTOCOCCIC SERUM.

In *The Lancet* for April 9th is a well-written paper by Dr. Louis Cobbett, reviewing the experiments made with antistreptococcic serum, and asking whether from the result of these experiments it has been proved that it should be used in the treatment of streptococcal diseases in man. It is shown that the verdict of the different experimenters is unanimous that the antistreptococcic serum is incapable of protecting against every streptococcus which is pathogenic to man. Dr. Cobbett gives his conclusions on the matter as follows:

"The serum has already been somewhat extensively used by medical practitioners, in some cases with apparently good results, in others without obvious effect. I do not intend to discuss the reports of these cases, for I think that it is very difficult to deduce the value of this treatment from the results of its application to human disease, for cases of streptococcal disease do not run any definite course. Who can say when the course of erysipelas will be stayed or when in puerperal fever the temperature will suddenly fall? These things occur without regularity, and are apt to be put to the credit of any remedy which may have been used. Moreover, the rate of mortality of streptococcal diseases or of any group of streptococcal diseases is not known. The statistical method is therefore not applicable to the estimation of the worth of any remedy applied to them. We never know in any given case whether the disease is due to the streptococcus or to some other organism; and even if we could make sure of this it appears that it would still be necessary to decide what kind of streptococcus it was due to before the right serum could be applied. We can therefore hope to gain but little evidence of any value from the experimental use of the serum in cases of human disease. The value of the remedy must first be clearly determined by experiments on animals. Until it has been shown beyond the possibility of doubt that the serum will protect them from and cure them of artificial streptococcal infections, until the opinion of experimental observers is unanimous in its favor, it is not yet ready for the physician. . . . It has been shown that even when the serum is most active it will not protect against all streptococci; that its power of protecting even against the kind of streptococcus used in the immunization of the animal which provided it does not approximate to the power of the antidiphtheria serum against the toxin of the diphtheria bacillus. Much, therefore, remains to be done before the serum can be used in cases of human disease. The possibility of an antistreptococcic serum has been demonstrated, but the remedy is yet in its infancy. For its infancy the laboratory is its proper place." These are timely words, and in view of the present regrettable custom of using and advertising as remedies and cures various antitoxins whose worth has not been clearly proved are amply justified. Much harm, too, is done to the reputation of experimenters by their proneness to give to the world as authentic and reliable the results of their incomplete researches. Doubtless this is due to the fear that they may be forestalled, and thus miss the opportunity of immortalizing themselves as pioneers in scientific research. Nevertheless, the fact is undeniable that in the majority of cases it would be far better for themselves, the profession, and the general public if they would be content to bide their time. As Dr. Cobbett goes on to say: "Already the medical world does not sufficiently discriminate between a remedy of astounding value, such as the antidiphtheric serum, and the hosts of other antiserums for syphilis, tubercle, cancer, etc., with the result that many practitioners still hesitate to use the former, regarding it merely as a fad of the day, and many lives are thus lost. The antistreptococcic serum cannot then be recommended in cases of human disease. In the mean time the physician may reasonably hope to obtain some day a specific remedy for these diseases, justified by the measure of success which the serum has already attained in the laboratory."

News of the Week.

Shell Wounds in the Bombardment of San Juan de Porto Rica.—The casualties in the bombardment of San Juan amounted to one man killed and five wounded. The action lasted nearly three hours, the following vessels participating: the cruisers *New York*, *Detroit*, and *Montgomery;* the battleships *Iowa* and *Indiana*, the monitors *Terror* and *Amphitrite*, and the torpedo boat *Porter*. Only two shells from the enemy's batteries struck the ships, one shell striking the *New York* and one the *Iowa*. The shell which injured the *New York* was a cast-iron eight-inch one. It struck a stanchion and burst, the fragments flying in every direction. One fragment struck a man just behind one ear and emerged at the other side of his head. He died almost instantly. Another fragment struck another man in the lower third of the thigh. The missile entered posteriorly and emerged anteriorly. The femur was comminuted. The fragments were resected and the bone ends wired together by the surgeons on board the *New York*. The same man received a flesh wound in the calf of the other leg from another fragment of the same shell. The third man wounded by this shell received a flesh wound only. The shell which struck the *Iowa* entered the superstructure and burst. A piece of this shell wounded a marine in the right elbow from behind. The external condyle of the humerus, the head of the radius, and part of the ulna were shattered and carried away. Efforts are being made to save the arm. Another man was wounded by a splinter from one of the steel girders of the superstructure, which was detached by the shell. He received a lacerated and contused wound of the back, which laid bare the ribs, but did not injure them or the deeper structures. Another man was wounded in the foot, but with no bone involvement. All the wounds are doing well and are aseptic seven days after the receipt of the injuries. (From our special correspondent.)

Delicacies for Sick Sailors.—The Colonial Dames of America have raised an emergency fund for the

purpose of supplying fresh fruit, vegetables, and other delicacies to the sick and wounded on board the hospital ships. Should there be a speedy termination of the war, it is proposed to use the money for the relief of the distress caused by it, and for soldiers who may be left in Cuba. Five hundred dollars has been already sent to Surgeon-General Van Reypen, and a carbonating-plant will be placed in the new hospital ship recently purchased from the Maine Steamship Company. Contributions can be sent to the Knickerbocker Trust Company, No. 234 Fifth Avenue, "for credit of Mrs. Lewis Livingston Delafield, chairman, hospital-ship fund committee of the Colonial Dames of America."

Mt. Sinai Hospital, New York.—Drs. Henry W. Berg and David H. Davison have been appointed adjunct attending physicians to Mt. Sinai Hospital.

Heat Prostrations.—The first day of summer in 1898 in New York City was May 19th. On that day eight cases of heat stroke were reported to the police, and many others doubtless occurred which were not reported.

Another Hospital Ship.—The *John Englis* of the Maine Steamship Company has been purchased for use as a hospital ship for the army. It will take about three weeks to fit her up. She will have a refrigerating plant, a distilling apparatus, and machinery for carbonating water, the latter presented by the Colonial Dames. There will be accommodations for five hundred patients. It is the purpose of the war department to use the *Englis* not only as a hospital ship, but also as an ambulance ship to transport sick soldiers to Tampa. The *John Englis* was built in 1897, and is 300 feet long, 46 feet beam, and of 3,000 tons. She has a speed of 15 knots. Dr. George H. Torney will be surgeon-in-chief, and will have five assistants. There will be twelve nurses on the ship. Although it is contrary to army regulations to enlist women for nurses, it is said that six from the Johns Hopkins Hospital, Baltimore, have secured permission from the war department to join the corps of nurses to be assigned to the ship. The other six will be men taken from the hospital corps. The name of the ship will be changed to the *Relief*.

The University Medical College Trouble.—The Medical College Laboratory of the City of New York, constituting the former faculty of the University Medical College, has brought an action in the supreme court against the New York University, to which it recently conveyed all its property, to have that conveyance set aside for breach of trust, to compel reconveyance to the plaintiff, and to enjoin the defendant from disposing of the property or collecting the rents pending the suit. The property in dispute consists of the building in East Twenty-sixth Street, together with its apparatus and furnishings, the estimated value of which is $150,000.

Homœopathists and the Medical Services.—We read in the Philadelphia *Ledger* that a committee representing the Homœopathic Medical Society of Germantown recently visited President McKinley, to present the claims of homœopathic physicians to recognition in the medical service of the United States army and navy. The chairman of the delegation presented a statement to the effect that homœopathic physicians, though as patriotic a body of men as any, had been led to believe that they could not obtain positions in the army or navy. The President inquired whether any homœopathic physicians had ever gone up for examination for the position of assistant surgeon, but the committee was unable to say whether any had done so. It was then suggested by the committee that the questions in therapeutics in the examinations for surgeons be made applicable to physicians of the homœopathic school, as the two schools differed only in the question of the application of remedies to disease. The President asked whether these questions were really such as were inapplicable to applicants of that school. To this the delegation was forced to reply that it did not know, as no member of the committee had ever seen the questions.

Dispensaries Enough for the Present.—At a recent meeting of the New York state board of charities, held in this city, the incorporation of the following institutions was approved: Industry Colony Association, of this city; Pelham Summer Home for Children, at Pelham Manor; Bloomingdale Day Nursery, of this city; Friendly Aid, of this city; and Marien-Heim of Brooklyn. The board disapproved the incorporation of the West Side Clinic and Dispensary, on the ground that it is "an unnecessary extension of medical charity in the city of New York."

Mortality in War.—Since the outbreak of hostilities with Spain an effort has been made to learn accurately the mortality experienced during the civil war in this country. The *Evening Post* says that the commissioner of insurance of Wisconsin has contributed some interesting statistics on the subject, estimating the number of enlistments (reduced to a three-years' basis) at 2,320,272. The mortality is estimated to have been as follows:

Killed and died of wounds	110,070
Died of disease	224,580
Accident and all other causes	24,872
Total	359,522

These figures being reduced, the death rate for a three-years' term is as follows:

	Per 1,000
From battle	47
From disease	97
From other causes	11
Total, all causes	155
Average, per year	52

Medical College Consolidation.—At the graduating exercises of the Medical College of the New York University, one evening last week, the chancellor, the Rev. Dr. Henry M. MacCracken, announced that a consolidation of the medical department with the Bellevue Hospital Medical College had been effected, and that the resulting institution would be called "The University and the Bellevue Hospital Medical

College." Dr. Edward G. Janeway, it was stated, would be the dean of the faculty, and seven professors of the present University Medical College would have places in the new staff, while from Bellevue, as previously constituted, would come twenty-one full and adjunct professors, and thirty or more lecturers, instructors, and assistants. It is gratifying to learn that the number of medical schools is not to be increased by the quarrel in the university, but the infliction of such a name upon the community is little short of an outrage.

The Late Dr. I. N. Quimby.—At a special meeting of the committee on necrology of the Hudson District Medical Society, held at Jersey City, May 7, 1898, to take action on the death of Dr. Isaac Newton Quimby, the following resolutions were unanimously adopted:

"*Whereas*, We have learned with deep regret of the death of our beloved member, Dr. Isaac Newton Quimby, a man meriting the respect of his professional colleagues and the general public; be it therefore

"*Resolved*, That in the death of Dr. Isaac Newton Quimby the society has lost a most earnest worker and its members a congenial friend.

"*Resolved*, That the profession at large has cause to regret his death and the people of this city have lost a public-spirited citizen, one who continually guarded the public health and strove to advance the welfare of the community.

"*Resolved*, That these resolutions be spread in full upon the minutes of the society and a copy be sent to the family of our deceased brother, the city press, the medical journals of New York, Philadelphia, and Chicago.

"J. M. Rector, M.D., H. Spence, M.D., H. H. Brinkerhoff, Jr., M.D., J. A. Exton, M.D., *Committee*."

A New Constant-Current Ear Syringe or Injector.—The address of Dr. Henry W. Wandless, author of the article with this title in the Medical Record of May 21st, should have been given as 39 West Thirty-sixth Street, New York City.

New York State Board of Health.—At the annual meeting of the State board of health, held May 20th, Dr. Daniel Lewis, of New York, was re-elected president of the board, and Drs. F. W. Smith, of Syracuse, and S. Case Jones, of Rochester, were selected as tuberculosis commissioners.

Roentgen Rays in War.—A cable to *The Sun* announces that the first report of the use of the Roentgen rays in warfare was made on May 20th, at the United Service Institution, London, by Surgeon Beevor, who described the results of their use in the recent frontier campaign in India and gave lantern views. Many important cases consisted of bullet wounds received by officers and men, who were injured in the bones, joints, and internal organs. Their injuries but for the *x*-rays would have resulted in the amputation of limbs and probable loss of life. The pictures shown included wounds in the arm, leg, chest, back, finger, and other parts. The most remarkable results, perhaps, were obtained in locating a bullet embedded in the backbone, another in the hip, and in the case of an Indian soldier who was shot in the foot, pieces of the bullet lodged in the back of the heel; also in the case of General Woodhouse, who received bullet wounds in the leg and arm at Dargai. In all the instances enumerated the bullets were after the use of the *x*-rays successfully removed, the men subsequently rejoining their comrades at the front. The portable apparatus weighs eighty to one hundred pounds.

Health Department Appointments.—Dr. Henry W. Burnard has been appointed medical inspector, and Drs. Salvador Gomez and Edson S. Chick have been appointed school inspectors for Brooklyn by the board of health of this city.

Dr. Marietta Hatfield.—It is with much regret that we learn of the massacre of the doctor at Rotofunk, Sierra Leone, Africa. Dr. Hatfield was a graduate of the Cincinnati Women's Medical College. Dr. Archibald, another female physician, also suffered death in the same manner at the same place. They were missionaries of the United Brethren Church.—*Cincinnati Lancet-Clinic.*

Burning of a Hospital.—Fire destroyed the greater part of St. Hyacinthe's Hospital in La Providence, Quebec, on May 16th. The number of inmates who were known to have been burned to death was ten, of whom five were Sisters of Mercy. Twelve were seriously injured, and several others are missing.

A Bequest to the Presbyterian Hospital.—The will of the late William Whitewright, filed recently in the surrogate's office, contains a bequest of $50,000 to the Presbyterian Hospital. This money is to be used for the maintenance of free beds to be known as the "Whitewright beds," in memory of the father of the testator.

The Washington State Medical Society.—At the ninth annual meeting of this society, held in Seattle on May 10th and 11th, the following officers for the ensuing year were elected: Dr. Henry Wells Dewey, Tacoma, *President;* Dr. J. W. Hickman, Tacoma, *Vice-President;* and Dr. Chas. McCutcheon, *Secretary*. Tacoma was chosen as the place of meeting in 1899.

The Maine Medical Association.—The forty-sixth annual meeting of this society will be held at Portland on June 1, 2, and 3, 1898, under the presidency of Dr. W. K. Oakes, of Auburn. The annual oration will be delivered by Dr. Roswell Park, of Buffalo, N. Y.

The Ontario Medical Association.—The eighteenth annual meeting of this society will be held at Toronto on June 1 and 2, 1898, under the presidency of Dr. Wm. Britton, of Toronto.

The American Academy of Railway Surgeons.—The next meeting of the American Academy of Railway Surgeons will be held in Chicago, October 5, 6, and 7, 1898, under the presidency of Dr. R. Harvey Reed, of Rock Springs, Wyoming. The secretary is Dr. D. C. Bryant, of Omaha, Neb.

Clinical Department.

ALCOHOLIC AMAUROSIS RESULTING FROM WOOD-ALCOHOL POISONING.

By CECIL MacCOY, M.D.,

JUNIOR ASSISTANT PHYSICIAN, BINGHAMTON STATE HOSPITAL,

AND

F. M. MICHAEL, M.D.,

OPHTHALMOLOGIST TO THE BINGHAMTON STATE HOSPITAL.

D. T——, aged twenty-one, single, attendant; mother dead, father dead. He had had the diseases of childhood excepting measles, and occasionally suffered from what appeared to be a specific eruption, but denied ever having had syphilis. He was a young man of good habits, using liquor and tobacco sparingly. His eyesight was always good.

On July 1, 1897, about 5 P.M., when convalescing from measles, on being denied a visit from his sweetheart, he secretly drank about sixty cubic centimetres of Columbian spirits mixed with water and sugar. Two hours later, having experienced pleasurable effects, he again diluted sixty cubic centimetres of the spirits with water and sugar; this he imbibed. Soon after having taken this second drink the patient became highly exhilarated, and, avoiding the nurse, found his way to a stable not far distant, where he secreted himself — then well intoxicated—in the hay loft. Here he slept profoundly for ten hours, dreaming all the while that some one was very sick. On awaking he found himself the subject of his dreams and sought his bed, where he was at once seen by a physician, who, not being able to discern any definite cause for the patient's violent emesis and gastric pain, prescribed morphine sulphate, 0.02 gm. ($\frac{1}{3}$ gr.), and cocaine hydrochlorate, 0.012 gm. ($\frac{1}{5}$ gr.), in capsule, to be followed by olive oil, 200 c.c., in half an hour. The temperature at this time was normal; the pulse was 100 and wiry; the respiration was somewhat difficult, and the pupils were slightly dilated.

Twenty-four hours after having taken the Columbian spirits, he complained of loss of sight, and on examination of his eyes we found total mydriasis in both eyes—no reaction to light or accommodation; right vision, none; left vision, none. Ophthalmoscopic examination revealed double optic neuritis with congested retina.

During the next twenty-four hours the patient's urine was examined. The quantity was normal; traces of albumin and epithelium were present, with great excess of uric acid, urates, and calcium oxalate.

For seven days amaurosis remained complete, while the symptoms of gastro-enteritis, contracted arteries, etc., were combated symptomatically by emulsion of milk in olive oil, glonoin, potassium iodide, and leeches. On the eighth day the patient complained of hallucinations of vision; he said crowds of people were floating about the room, though there was no perception of light and the temperature was normal. Owing to the fact that this patient had in past years shown symptoms of specific disease, on the remission of the painful gastro-enteric symptoms the doses of potassium iodide were gradually increased. Ophthalmoscopic examinations were made daily, showing the discs becoming better outlined and the retinal congestion subsiding. By the fourteenth day faint perception of light was noticed, and then strychnine sulphate, 0.003 gm. ($\frac{1}{20}$ gr.), was given three times a day, in addition to the potassium iodide. On the eighteenth day perception of light of both eyes increased slightly, though with no marked change in the discs or retinæ.

Three weeks after poisoning himself the patient was able to see moving objects, count fingers six inches away, and recognize friends close by. The doses of strychnine sulphate were now gradually increased until 0.01 gm. ($\frac{1}{6}$ gr.) was administered daily. To control the persistent mydriasis 0.06 c.c. (℥i.) of a 1 to 500 eserine-sulphate solution was dropped in the eyes twice a day.

During the next six weeks the patient experienced varying periods of temporary improvement, when he was able to recognize friends ten feet away and distinguish the hills and trees on the horizon. His best vision was during the early evening and at night when in a moderately light room. Occasionally in the morning he would complain of flashes of light followed for hours by total blindness, though this condition gradually disappeared as the day advanced.

On September 20th, two and a half months after he had taken the wood alcohol, we found total mydriasis in both eyes—no reaction of pupils to light or to attempts at accommodation; media clear; anterior chamber of normal depth. Right vision, counted fingers at six inches; left vision, perception of light. Both visual fields were greatly contracted; in the left the field was entirely peripheral. He could not distinguish colors with either or both eyes. Ophthalmoscopic examination showed atrophy of both optic nerves with atrophic excavations of both optic discs. The right optic disc had an abrupt and deep excavation similar to that of glaucoma. The lower part of the cup was strongly and thickly pigmented with black. This shaded off upward to about the horizontal diameter of the disc, above which the discal surface was of a whitish or very pale gray. The excavation of the left optic disc was more shallow and saucer-like, the whole surface being of a pale gray color—none of the black pigment having been deposited there as in the right. In both eyes the retinal veins, especially the principal ones, were either of normal size or slightly enlarged, while the retinal arteries were greatly diminished in size.

Here we have a young man of average good health who, when suffering from a disease in which the eyes are particularly sensitive, poisons himself with one hundred and twenty cubic centimetres of wood alcohol. Within twenty-four hours he becomes totally blind. This amaurosis continues for two weeks, at the end of which time is born perception of light. Three weeks from the date of poisoning, the patient has his vision increased to a condition in which he can distinguish light and shadow, and count fingers held close to his eyes. From this time to the present date, February 15, 1898, both eyes have remained in essentially the same pathological condition as described in our last examination noted above.

UNUSUAL SYMPTOMS PRODUCED BY PILOCARPINE.[1]

By MATTHIAS LANCKTON FOSTER, M.D.,

ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL.

IT is difficult to find in the materia medica a drug of which the physiological action is supposed to be known with a greater degree of certainty than that of pilocarpine. Depression and profuse perspiration are the characteristic symptoms it produces, and in the few cases in which contrary symptoms have asserted themselves they have been ascribed to the presence of jaborine, another alkaloid of jaborandi, isomeric with pilocarpine, but productive of symptoms which resemble those produced by atropine. The following case is, therefore, of the greater interest, because of the peculiar toxic symptoms which were exhibited and the

[1] Read before the section on medicine, Academy of Medicine, February 15, 1898.

improbability that they can properly be referred to the presence and effect of jaborine.

A man, fifty-one years of age, in good general condition, was admitted to Dr. Pomeroy's service in the Manhattan Eye and Ear Hospital, August 24, 1896, and placed under my care. The right eye was hopelessly blind: the sight of the other had very recently been lost on account of a detachment of the retina. At the time of his admission direct vision of the left eye was reduced to perception of light, and excentric vision was $\frac{3}{200}$. The patient was placed in bed, his eyes were bandaged, and twelve minims of a four-grain-to-the-ounce solution of pilocarpine hydrochlorate, equivalent to one-tenth of a grain of the drug, was injected subcutaneously, but no diaphoresis was obtained. On the following day, August 25th, fifteen minims ($\frac{1}{8}$ gr.), on the 26th eighteen minims ($\frac{1}{7}$ gr.), and on the 27th twenty minims ($\frac{1}{6}$ gr.) were injected beneath the skin, but no perspiration or other physiological symptom characteristic of the action of pilocarpine was produced. On the 28th the injection of twenty-three minims (a little less than $\frac{1}{5}$ gr.) caused some perspiration. On the 29th twenty-five minims ($\frac{5}{24}$ gr.) induced a slightly increased amount of perspiration, but no noticeable depression or other untoward symptom. On the 30th twenty-six minims ($\frac{5}{23}$ gr.) was injected at 6:45 P.M. At 7:30 the patient was unconscious, with a pulse of 120 and some twitching of the muscles, but with no trace of perspiration. An ounce of whiskey was given and heat applied to the limbs. At 8 o'clock the pulse was 126 and the respiration 29. At this time $\frac{1}{8}$ gr. of morphine with $\frac{1}{100}$ gr. of atropine was given subcutaneously. An hour later the patient vomited, but there was still no perspiration. At 11 P.M. the temperature was 102.6° F.; respiration, 34; pulse, 128. Twenty minutes later, when I saw him, the patient could not be roused from his unconscious condition, was breathing very rapidly, and had a rapid, strong pulse. The skin was very dry and hot; the mouth and tongue were very dry wherever the mucous membrane was exposed to the rapid current of air, but elsewhere were moist; the face was very slightly flushed, and the pupils were not affected. Examination failed to reveal any œdema or other trouble in the lungs.

The symptoms bore so close a resemblance to those of atropine poisoning that I immediately made a close investigation to determine whether this drug had been given by mistake, and after I had become satisfied that such was not the case $\frac{1}{120}$ gr. of atropine was injected and a sponge bath was given. At midnight the temperature was 102.8° F.; pulse, 134; respiration, 40. At 1 A.M. the temperature was 102.6° F.; pulse, 116; respiration, 52; the skin showed signs of perspiration. At 2 A.M. the temperature was 103.5° F.; pulse, 112; respiration, 48; perspiration still slight. At 3 A.M. the temperature was 102° F.; pulse, 108; respiration, 44. The patient was now perspiring profusely, breathing quietly, and about this time regained his consciousness. The temperature then fell steadily until in four hours it was normal, while the respiration regained its normal rate with even greater rapidity. During this day the patient was much nauseated, vomited once, had diarrhœa, and suffered from very marked general depression. At noon there were a sudden rise of the temperature to 100.5° F., and about as sudden a fall after vomiting. Examination of the urine failed to reveal any renal trouble.

Medication was discontinued until the morning of September 2d, when one-seventh of a grain of pilocarpine caused perspiration for twenty minutes. From September 3d to 11th inclusive one-sixth of a grain was injected daily and caused prompt and free perspiration for from twenty to thirty minutes. On the 12th a fair perspiration for twenty minutes was noted, but on the four succeeding days little or no perspiration was induced by the same dose. On the 16th I found that the direct vision had improved to $\frac{1}{200}$. On this day I punctured the tunics of the eye, evacuated a considerable quantity of subretinal fluid, and replaced the patient in bed. The daily dose of pilocarpine was increased $\frac{1}{120}$ gr., again induced free perspiration, and was maintained three days longer, when all treatment was stopped. The final vision of the patient was $\frac{20}{200}$, which has been maintained to the present time.

The peculiar toxic symptoms exhibited by this patient are susceptible of at least three methods of explanation, viz.: first, that the solution used was made of jaborine, instead of pilocarpine; second, that the primary symptoms produced by the action of pilocarpine, which ordinarily, if they exist, are of exceedingly brief duration, were remarkably prolonged; and, third, that they were unique and dependent upon the individual idiosyncrasy of the patient.

In regard to the first explanation, it is highly improbable that the solution was one of jaborine, because the use of an ordinary dose of the same solution in the treatment of other patients in the hospital was productive of the symptoms usually ascribed to the physiological action of pilocarpine, with no observed trace of those which assumed such alarming proportions in this case; and also because the ultimate effect of the drug upon this patient was that of pilocarpine, although this effect was delayed and preceded by a series of very unusual symptoms.

It has been asserted by some observers and denied by others that the primary effect of pilocarpine is to determine a rise of temperature quickly followed by a fall, and it may be admitted as a possibility that the symptoms narrated were due to a prolongation of such a primary effect. But as it is a matter of doubt that such a primary effect exists, I am unable to consider this explanation satisfactory.

It seems more reasonable to ascribe this effect to the idiosyncrasy of the patient. A very large dose was required to induce any diaphoresis; the system stubbornly refused for several hours to yield to the influence of a larger dose, and afterward showed a noticeable tendency to become habituated and to make less response to the presence of the drug.

22 East Forty-First Street.

STRICTURE OF THE URETHRA IN A YOUNG BOY.

By C. E. IDE, M.D.,

CHICAGO, ILL.

The subject of urethral stricture in children has recently begun to receive the attention which it deserves, and I report this case in the endeavor to assist in making the records as complete as possible.

On February 10, 1896, Charles P——, aged ten, was brought to me by his mother, because the act of urination was painful. The history which I obtained was as follows: Some months before (about a year, the exact date not being remembered), a painful swelling had appeared near the end of the boy's penis. This was treated with "home remedies," until there was a profuse discharge of pus from the urethra. The latter finally ceased, although the act of micturition was painful for some time. Just before the boy came to me the pain and burning recurred. On examination I found a dense stricture, about an inch from the meatus, which would scarcely admit a No. 10 bougie. It might, of course, have been a case of congenital stenosis of the urethra; but there had not always been the dysuria; the trouble started up acutely not long before, and the obstruction was firm, as of scar tissue.

The condition was treated by gradual dilatation, and after three treatments the boy passed out of my sight. I saw him occasionally after that, and both he and his mother reported him as better of his trouble.

As I look back upon the case now I am led to believe that urethrotomy would have been the better procedure to follow, since the stricture was so firm and unyielding.

OPERATION FOR ABSCESS OF THE BRAIN.

By JAMES SPENCER BROWN, M.D.,

ATTENDING SURGEON TO MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.

THERE is something exceedingly attractive about brain surgery, and the reason can possibly be expressed by a single word—pique. Defeat is not a pleasant subject for an evening's reverie, but it is a great stimulant for renewed and greater efforts. The brain has not escaped from that boldness which cleanliness has brought to all fields of surgery, and improved methods of technique have witnessed improved results. However, the review of a large number of brain operations brings the conviction that there is one fact thoroughly expressed: either the results are brilliant achievements or they are flat failures. The reason for there not being a middle line is exceedingly simple, when one considers that the tissues under the knife, destroyed cortical centres or disorganized motor tracts, are not replaced. The following case of brain abscess is reported, first, because it seems worth while to report those cases in which cerebral localization has succeeded in guiding the operator to the exact site of softening; and, second, because drainage which seemed perfect during life was demonstrated at the autopsy to be quite the contrary.

J. T——, aged fifty, a native of England, with no history of syphilis or other serious illness, intemperate, was admitted into my service at the Mountainside Hospital, August 16, 1897, at 8 P.M., with a history of having attempted to commit suicide by jumping head down from a bridge into a sluiceway, striking his head upon a rusty iron spike. There was a large compound depressed fracture over the right occipital region; the patient was rational, but excited and talkative. He had walked at least a mile to the station-house, and had been conveyed in an ambulance from there to the hospital. There was little if any shock. Chloroform was used for anæsthesia, and the head was shaved and cleaned in the usual way. The mud and sand from the brook had been ground into the wound, so that it was with some delay and difficulty made clean. Without much trouble, with the rongeur forceps and elevator the depressed fragments were elevated and removed; the dura was not injured, although the inner fragment was close to the superior longitudinal sinus. The wound was now cleaned with hydrogen dioxide and washed with several quarts of sterilized water, and the scalp was brought together with silkworm-gut and silk sutures. The recovery from anæsthesia and the history of the first three days of his stay in the hospital were quite uneventful. On removing the dressings for the first time on this day I was not much surprised to find slight wound infection, because of the nasty condition of the tissues at the time of operation. Drainage was at once instituted, and all went well until August 31st (the wound at this time being nearly healed), when he complained of intense frontal headache and of cold feet and legs, and said that he had no power in the leg and arm of the left side. For the last week there had been a rise each day in the temperature, which did not exceed 99.6° F. Ptosis of the left eye was manifest; sensation seemed normal; the reflexes were apparently alike and normal; there was certainly loss of muscular power on the left side. The chart showed a temperature of 99.4° F.; pulse, 100, strong and full; respiration, 16.

During the following forty-eight hours the patient's suffering from cephalalgia was intense; the paralysis had now become complete upon the left side, and there were added anæsthesia and hyperalgesia at different points.

On September 3d he was seen by Dr. Frederick Peterson, the consulting neurologist of the hospital, whose report was as follows: "There is complete paralysis of the left arm and leg. He cannot stir them voluntarily; there are considerable anæsthesia over the paralyzed limbs, slight analgesia in places, and hyperalgesia in others on the left side. The plantar and cremasteric reflexes are normal; the knee jerks are subtypical, slightly greater on the left side; the wrist jerks and elbow jerks cannot be elicited on either side. There is no aphasia, no involvement of the face or tongue, and the mind is clear. The pupils are of medium size and react normally. There is no evidence of great intracranial pressure in the pupils or pulse. There is no symptom of cortical irritation. The temporal half-field of vision of the left eye is lost; the right seems normal. He hears a watch at only one-half the distance with the left ear as compared with the right. The taste seems normal on both sides of the tongue. The fundus is slightly cloudy."

Diagnosis, abscess deep in the brain in the region of the posterior part of the internal capsule. I advised if the patient got worse to trephine in the parietal region considerably back of the motor region, and insert an exploring needle down into the supposed site of the abscess.

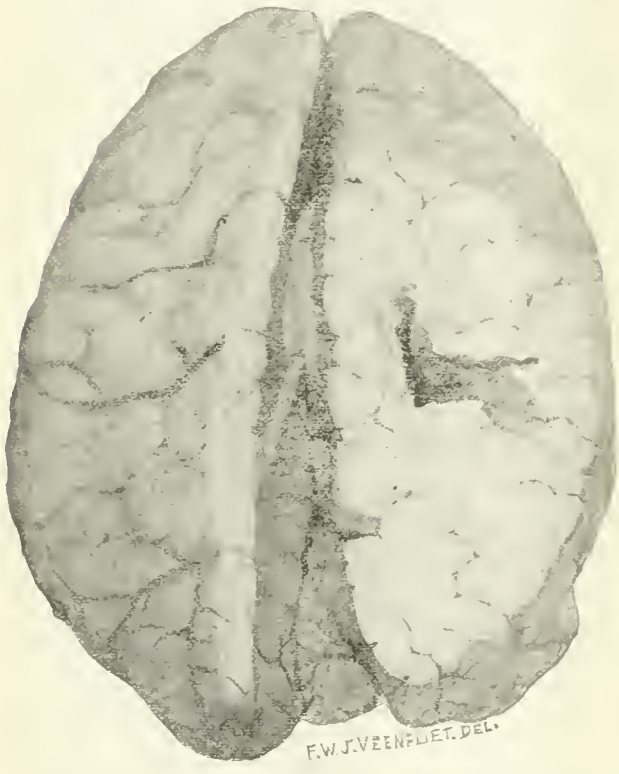
On the next day, there being no improvement, the patient was subjected to the following operation: The scalp having been reshaved and cleaned, it was thought best to endeavor to reach the abscess through a new route, so as to avoid the infected tissues, in the belief that the abscess was deep in the brain in the posterior part of the internal capsule. A flap of scalp was raised over the posterior temporal region and a button of bone removed from a point two and one-half inches behind the auditory canal and one and three-fourths inches above Reid's base line. The dura appeared quite normal. Upon incision of the dura the brain bulged into the opening, showing pressure from below. A director was gently pushed inward, downward, and forward, and when it was at a depth of one and one-half inches there was noticed a dark serous fluid running along the groove. A probe was now passed along the groove of the director and the two instruments were separated. It was estimated that the abscess contained about two drachms of pus and broken-down tissue. The cavity was washed out with sterile salt solution and the abscess drained with about a dozen strands of silkworm gut; plain sterile gauze was packed about the opening in the brain, and both gauze and strands of silkworm gut were brought out at the lower angle of the wound. The upper portion of the scalp wound was brought into apposition and a bountiful dressing of plain sterile gauze applied. The patient recovered from anæsthesia promptly with but little shock. The following morning he was able to flex the leg upon the thigh and move his fingers.

From this time on till the day of his death there was to all appearances a steady improvement. His temperature remained nearly normal, never rising above 99.4° F.; his pulse was always at 90 beats a minute, strong and full; his headache was relieved; he gained sufficient power in the arm and hand to use them quite freely; the leg could be moved from one position to another. The dressings were changed upon the second day; they were saturated, and there was every reason to believe then and at all subsequent

dressings that drainage was complete. At the second dressing, because of the displacement of the silkworm-gut drain, a tube made of folded rubber tissue was employed. On the morning of August 12th, eight days after the last operation, he complained of headache and a feeling of dizziness; his speech was noticed to be thick, and there was a lateral deviation of the tongue. The former good motion of the hand was lost and it could be moved only with the greatest effort. The wound was examined and the abscess seemed to be well drained. Within two hours from my leaving the hospital he had a severe chill, his temperature running up to 105.6° F.; his pulse became weak and rapid, and he gradually sank into a state of coma, and died at twelve o'clock that night.

Necropsy, eighteen hours after death, was made by Dr. R. C. Newton. The following notes were made upon the condition of the brain:

"Upon removal of the brain the pia and dura are



firmly adherent to the skull—first, about trephine opening; and, second, about seat of original injury. There is a general meningitis over the posterior part and base of the brain. The abscess, which before the autopsy was commenced seemed to be well drained, is found to contain an estimated amount of pus of not less than two ounces; there is a communication between the abscess and the surface of the brain of not less than one-half inch in diameter. Upon removal of the upper portion of the right hemisphere the abscess is cut into, but it does not communicate with the pia at the site of the original injury by at least one inch; it does not open into the lateral ventricle; the wall of the abscess is very necrotic."

From the foregoing report it is seen that up to the morning of this man's death he was apparently making a very satisfactory recovery from a very serious condition, when in reality he was storing up in his brain septic matter which sooner or later must cause intoxication, and by absorption and extension to neighboring important tissues surely destroy life. By referring to reported cases it will be seen that it is not uncommon for these injuries to terminate in exactly this way, and it is therefore pertinent to ask the question if there is not a better way to drain these deep abscesses of the brain than that which was employed in this case. Probably the question can be answered in the affirmative when the abscess cavity is so situated that it is not asked that pus shall drain up hill; in the absence of such a favorable location, would it not be better to employ capillary drainage through a rubber drainage tube filled with gauze, using a tube as large as possible without making serious brain pressure? The accompanying illustration, drawn from nature, shows exceedingly well the position of the abscess.

A CASE OF GRAVE GENERAL PERITONITIS, APPARENTLY DUE TO APPENDICITIS; RECOVERY WITHOUT OPERATION.

By SAMUEL KOHN, M.D.,

NEW YORK.

Twenty-five years ago, at a time when the opium treatment of peritonitis, thanks to the genius of Alonzo Clark, had established for itself a firm place in therapy, the publication of a clinical history such as is herewith presented might not have aroused much interest; but to-day, when the treatment of this dread disease has been relegated almost entirely to the domain of surgery, it being merely a question of diagnosis as to its origin—whether appendical, ovarian, uterine, intestinal, gastric, or what not—before laparotomy is promptly and definitely decided upon, the record of a grave case, whose successful outcome in recovery was evidently due to medical treatment alone, will command attention. The salient points in the history are as follows:

C. S——, aged nine years, was taken sick, September 7, 1897, with colicky pains radiating from the umbilicus all over the abdomen. The boy was living at Arverne-by-the-Sea, Long Island, with his parents, at the time. The physician from Rockaway Beach, who was summoned to attend him, administered a mild laxative, which was without result. The following day pain became more intense, the patient crying to be relieved: a high enema was given, with very slight result. The pain still continuing in the evening, the doctor gave a small dose of morphine hypodermically. The following day, September 9th, the pain having shown no signs of abatement, Dr. Welt-Kakels, the family physician, was summoned from New York; she diagnosed the case as one of septic general peritonitis due to appendicitis. On the following day, September 10th, she saw the patient in consultation with Dr. F. Lange, who confirmed her diagnosis, after making two exploratory punctures, one in the lumbar region, the other per rectum. The first yielded, I was told, a dark brown, ill-smelling, semifluid material, probably fæcal matter from the large intestine; the second yielded nothing. The outcome of the consultation was, as to diagnosis, general septic peritonitis due to appendicitis; as to prognosis, so grave as to make an operation unwarrantable, in view of the low vitality of the patient; as to treatment, ice and morphine.

At 4 o'clock, A.M., September 11th, the patient's sufferings became so severe that he cried aloud for relief. I was sent for and saw him then for the first time. He lay in the dorsal decubitus, his limbs flexed upon the abdomen, which was so distended as to appear globular and tense. He was constantly emitting shrieks, begging to be relieved of his pain or to be put out of existence. His face was anxious and sallow; the cheeks were sunken; the tongue was dry; the limbs were very much emaciated. Temperature, 101.5° F.; pulse, 130, small and thready; respiration, 36, shallow. "Green-paint" vomit had been occurring at frequent intervals during the past twenty-four

hours. From the boy's mother I ascertained the history, substantially as above written, up to the time of my visit, and it was confirmed by the physicians previously in attendance.

In view of the intense pain which the patient was suffering, I did not hesitate long as to the line of treatment to be followed. With Dr. Lange's disinclination to operate in mind, the decision to put the little patient under the influence of morphine as quickly as possible was reached. The enormous quantity of morphine required to keep the patient narcotized and the pain under control constitutes one of the most interesting and instructive features of the case. One-fourth of a grain of morphine was injected hypodermically (4 A.M., September 11th) and an ice bag was applied over the region of the appendix.

Before the history is proceeded with, several points deserve mention. The last fæcal stool which the patient had was on the 7th of September; on the 9th and 10th of September he received each day one-fourth of a grain of morphine hypodermically from Dr. Welt-Kakels; on both days high enemas were administered, without effect. From the 7th to the 21st of September the patient passed neither flatus nor any intestinal contents per rectum; on the latter date, owing to the repeated small enemata of olive oil which had been administered during the two weeks, several evacuations, consisting of liquid fæces and mucus, accompanied by flatus, took place. From the 21st of September to the 1st of October absolutely nothing passed per rectum. It seemed to me that, on the 21st of September, the contents of the bowel below the seat of obstruction were evacuated; for, if the bowel had been pervious throughout its entire length, the constipation would not have persisted from the 21st of September to the 1st of October, in spite of every effort to move the bowel; the conclusion was fully warranted, therefore, that the bowel, above the seat of obstruction, had not been evacuated in the twenty-four days from September 7th to October 1st, at which latter date the first copious fæcal movement during the boy's illness took place.

And now to continue with the record. At 3 P.M., September 11th, the pain again being severe, the signs and symptoms not varying much from those noted in the morning, one-fourth of a grain of morphine was again injected; one hour later pain was still agonizing. The respirations had diminished to 20; the pulse was 100, and the temperature 101° F. I ordered one-sixth of a grain of morphine per orem every two hours until the pain should be relieved. On the morning of September 12th, although 1½ gr. of morphine had been given per os during the night, no effect whatever was to be noted in the reduction of pain and tenderness in the abdomen. Respirations, 15; pulse, 100, small but regular; temperature, 101° F. The abdomen was intensely distended. September 13th and 14th, he received each day 1½ gr. of morphine hypodermically, representing six hypodermics of one-fourth grain each during each twenty-four hours; this resulting in a sleep of two or three hours' duration each day. On the 14th of September the respirations went down to 10; the temperature was 102° F.; pulse, 130, thready. Several attacks of vomiting, the material being of a dark brown color, ill-smelling, evidently fæcal in character, occurred. Pain, when the child was awake, seemed more intense. There were great restlessness and extreme tympanites. The patient seemed on the verge of collapse.

On September 15th. As an example of how frequently and in what doses morphine was administered at this period, I will present from the clinical notes the history of this day: "12:30 A.M. Temperature, 100° F.; pulse, 140; respiration, 12. Patient awoke, screaming with pain. Gave one-fourth grain of morphine hypodermically. 2 A.M., pain; ¼ gr. 3 A.M., pain; ¼ gr. 4 A.M., pain; ¼ gr. 5 A.M., pain; ¼ gr. Respirations, 10; pulse, 120; slept two hours. 9:30 A.M., pain; ¼ gr. 10:30 A.M., pain; ¼ gr. 11:30 A.M., pain; ¼ gr. 12:30 P.M., pain; ¼ gr. Patient very weak. Administered one-half pint decinormal salt solution per rectum. Patient slept two hours." In twelve hours the patient received two grains of morphine hypodermically, but, as will be seen later on, he was to receive larger doses still.

September 16th, condition and treatment practically unchanged. September 17th, the patient vomited fæcal matter several times. The vomited material was reddish-brown, intermixed with blood, and was intensely fetid, like long-retained fæces. Abdominal pain was very intense. In the course of the day he received seven injections of morphine, each of ½ gr., making 3½ gr. for the twenty-four hours.

"September 18th, 3½ gr. morphine in the twenty-four hours hypodermically; fæcal vomiting continues; pain under control; but as soon as the patient is allowed to come out of the morphine narcosis he cries with pain. Abdomen so distended that the cutaneous veins are put on the stretch; the apex beat is displaced upward to the region of the nipple; the integument of the thorax is markedly œdematous, from interference with the cutaneous circulation in the abdominal parietes. September 19th and 20th, fæcal vomiting ceased; otherwise the condition remains unchanged. A total of 3½ gr. of morphine given hypodermically each day; patient again on the verge of collapse. September 21st, patient passed some flatus from the bowel; had one slight and two fairly copious fæcal movements, at 1 A.M., 3 A.M., and 5:25 A.M."

As stated previously in this paper, these movements seemed due to evacuation of the bowel below the seat of obstruction; for, ten days previous to this, an enema of olive oil had been given three times daily (℥ i.). This small quantity of olive oil was retained for an hour or two nearly every time, but was rejected at once now and then; warm decinormal salt solution (about one-half pint) was injected into the rectum once daily, for about five days previous to the 21st of September, and usually was retained. To these frequent enemata I attributed the movements from the bowels which occurred September 21st; from then on, until the 1st of October, the bowel was perfectly occluded.

From September 14th to September 21st, fæcal vomiting occurred at frequent intervals, proving that above the occlusion the intestine was emptying itself per os.

September 21st, pain severe; three grains of morphine in the twenty-four hours. September 22d, pain so much increased that morphine was injected in one-grain doses, seven times in the twenty-four hours, making seven grains in all. September 23d, severe pain over the bladder; micturition attended by the most excruciating pain, showing extension of the peritoneal inflammation to the bladder. Examination of the urine negative. I ordered calomel, one-half grain every two hours; after twelve powders had been given without any visible effect, no more was administered. During the twenty-four hours seven grains of morphine was injected hypodermically.

From this date until the 1st of October the patient received his hypodermics of morphine regularly, but in gradually diminishing doses. On the latter date, October 1st, he received only two grains in the twenty-four hours. During this week abdominal pain was constantly present, the patient begging for relief as soon as the narcosis was on the wane. No other measure which was tried could replace the morphine in relieving the pain. The abdomen remained enormously distended by meteorism; the temperature fluctuated between 100° and 102° F.; the respirations at times

were as low as 8; the pulse varied between 90 and 120, but was, although weak, always regular. Warm saline enemata, each of one-half a pint, were given once daily during this last week (September 23d to October 1st), but without any evacuating effect. The vesical pain disappeared entirely September 26th.

On the 1st of October the patient had two large, black, tarry-looking movements from the bowels; the distention of the abdomen commenced to diminish. Thereafter the bowels moved daily, until convalescence was established. The abdominal pain did not cease entirely until October 15th. Up to this date morphine, in small doses, was daily given to relieve it. The abdomen became flatter from day to day, until it had so far sunken (October 15th) that it formed a veritable deep basin, and the emaciated little fellow looked like a child in the last stages of marasmus. His appetite improved, and he progressed gradually to health and strength, which can be said to have been restored about the middle of November. He is now stronger and heartier than he ever was before in his life.

The measures aside from injection of morphine resorted to were, as has already been mentioned, the ice-bag for the first two weeks; later hot fomentations and turpentine stupes; olive-oil enemata; warm saline enemata, used more for the purpose of giving water to the parched tissues than to move the bowels; in the third week, small doses of calomel frequently repeated.

The diet consisted, early in the disease, of half an ounce of boiled milk, with one drachm of lime water, every two hours; a drachm of brandy in half an ounce of iced water every two hours. The vomiting and retching made it exceedingly difficult to nourish the patient during the first two weeks. The enemata of sweet oil and decinormal salt solution undoubtedly aided us materially during this period in sustaining the patient.

This case seems remarkable in several respects. First and foremost, the enormous quantity of morphine which the little fellow consumed, and tolerated, amounting to ninety grains in the twenty-four days from September 7th to October 1st, or an average of nearly four grains a day, is extraordinary. This tolerance of morphine, in a boy of nine years, is explicable on two grounds: first, that the peritoneal inflammation, with its attendant intense pain, produced such an excitant effect on the nervous system as to make it tolerant of the drug; and, second, that the feeble circulation did not permit the absorption of the drug rapidly enough to produce a lethal effect. It seems to me that such tolerance of morphine as this boy exhibited is not frequently mentioned in the literature of the subject. In the administration of the drug I was guided by the degree of pain the patient suffered; the pulse and respiration were carefully watched, but at no time were these so depressed as to cause the least anxiety.

The long duration, twenty-four days, is explained by the wandering character of the inflammation. The pain was first complained of in the appendical region, then in the hepatic, then in the gastric, finally in the vesical. These changes in the site of the inflammation were accompanied by exacerbations in the temperature and pulse.

The brain was clear during the whole course of the disease, except when the boy was thoroughly narcotized, and even then, when roused, he could answer intelligently any question put to him, and with a clearness of cerebration which was painful to the questioner.

The second interesting question is in regard to diagnosis. Did we have to deal with a case of appendicitis? Inquiry into his previous history reveals the fact that since his fourth year the boy has been subject to severe attacks of intestinal colic; that in his sixth year he had an attack similar to the one through which he has just passed, but much milder. Pain, "green-paint" vomit, and fever characterized that attack, which confined him to his bed for one week; opium and ice constituted the treatment for this attack. This previous history, evidencing a recurrent tendency, strengthens the diagnosis of appendicitis as made by Dr. Lange. It was impossible for me to make an accurate diagnosis at my first visit, or, in fact, at any time, because of the immense distention of the abdomen and its exquisite tenderness to the gentlest palpation; deep palpation was out of the question because of the patient's agony. The apparently collapsed condition of the patient when I first saw him led me to believe that a small perforation of the appendix had already taken place; but the subsequent course negatived this idea.

To conclude. A case of grave general septic peritonitis, due to appendicitis, was here presented, distinctly unfavorable as to prognosis. The condition at the onset of the disease was such that one of our most brilliant surgeons advised against operation. That the heroic treatment by large doses of morphine to which the writer was emboldened at this juncture saved the patient's life, is beyond the question of a doubt. The history of this case can with a good and clear conscience be added to the volume of evidence in defence of the opium treatment of peritonitis.

805 Madison Avenue.

THE USE OF ERGOT TO OVERCOME INERTIA OF THE UTERUS DURING LABOR.

By S. S. CARTWRIGHT, M.D.,

Roxbury, N. Y.

After the careful use of ergot in the above cases for several years, I wish to give my experience to the profession. It is often the case when women have borne four or five children that in succeeding labors the pains are feeble and slow, but an examination reveals a dilatable os and no obstruction. In such cases my plan is to give from ten to fifteen drops of fluid extract of ergot. The ten-drop dose is generally sufficient, but this can be repeated in an hour if no effect is produced. I never exceed fifteen drops at a dose. The effect of this generally is that in less than an hour the pains become stronger and regular, and in from two to three hours the labor is completed. The pains in these cases never become continuous, like the pains from large doses of ergot, but there are always distinct intermissions. I regard this use of ergot as perfectly safe for mother and child, never having had a stillborn child in any of the cases in which I have administered it, and I have never had to give over two doses.

Acute Otitis Media.—I have seen the following simple device, always convenient, give grateful relief: A piece of cotton is placed lightly in the mouth of the canal. A pipe is filled with tobacco and lighted. Then a piece of clean cloth is placed over the mouth of the pipe bowl and gently blown through, while the lip piece of the warm stem rests against the cotton pledget. This filters the warm smoke through the cotton into the canal, and a grateful sedative effect is soon obtained. I do not remember having seen this remedy mentioned in the books, but I have witnessed its efficacy in the absence of other remedies. The practice indulged in by the laity of pouring oils, etc., into the ear is a vicious one, since these become rancid, irritate, and predispose to a subsequent inflammation. Poulticing is also bad, for it favors suppuration and perforation of the drumhead.—Dr. Seth Scott Bishop, "Diseases of the Ear, Nose, and Throat." p. 72.

Society Reports.

MARYLAND PUBLIC HEALTH ASSOCIATION.

Annual Meeting, Held at Baltimore, May 11 and 12, 1898.

Dr. William H. Welch, president, spoke of the work of the association, which was started only last year, saying that it already had quite a large membership.

The Sweat Shop in its Relation to Public Health.—Dr. Gichner said that a sweat shop was a place where a number of persons worked under pressure for a minimum wage and comforts were not considered. The work done was generally contract work. It was usually done in shops at home, and the dangers were from working at home. The condition of affairs in New York was very bad; in Baltimore it was not so bad, on account of the small houses and the cheap rents.. Some of the worst sweat-shop houses brought better rents than many larger houses, on account of the enormous number of persons which could be crowded into a small space. The speaker then described the sweat shops of Baltimore. They were in the congested district, but there were not much diphtheria and scarlet fever, and the child mortality was not very high. There was very little insanity and the general moral tone was not so low as one would expect. Consumption, however, was on the increase, but the disease was not carried away from these shops by the clothes, on account of disinfection accomplished with the hot heavy iron. While these people were a menace to the community in a certain way, still the bad effects reacted principally on themselves. It was extremely hard to do anything for them through the health department, because they were dependent on their work and resisted every attempt at inspection.

Dr. Rosenthal then spoke on the same subject, and said that those who worked in factories were usually fairly well provided for, while those who worked in their own shops and for wages were usually the worst off. They worked from twelve to fifteen hours a day, and in winter the rooms were almost air tight; men were smoking cigarettes and probably spitting all over the floor.

Need of a Hospital for Infectious Diseases.—Dr. John S. Fulton said that cases of infectious diseases were usually reported by physicians, but any attempt to quarantine the family was fruitless and the disease might be or was actually carried in numberless ways. The cost of an infectious-disease hospital would be necessarily great at first, but not so much as dealing now with individual cases. Such a hospital must be accessible, and almost every one objected to a hospital near them. Everything should be free in this hospital, and the city should bear all cost. Persons who desired special accommodations and private rooms would necessarily have to pay for them.

Dr. William Royal Stokes then pictured the ideal infectious hospital, in which a patient would be brought into an observation ward and kept there until the disease had declared, when the person would be sent to the proper ward.

Dr. C. Hampson Jones related some of the difficulties the health commissioner met with in carrying out his work.

Dr. William J. Todd said that infection was often carried by innocent persons to other innocent persons.

Dr. William H. Welch said that the absence of an alarming tone in the papers of Drs. Gichner and Rosenthal was very gratifying. The fact that the clothing was sterilized by the hot iron and the hot room before distribution was exceedingly interesting, and it had never occurred to him before. Nevertheless, danger from tuberculosis to those working in sweat shops was a real one and it was an important matter. He said that the dangers from the dried sputum in spreading tuberculosis were not so great as the dangers from coughing: in the action of coughing and sneezing and hawking one sprayed from the throat a fine moisture, which, emitted from the mouth, floated in the atmosphere for many hours. Indeed, this, according to Flügge, was more dangerous than dried sputum. Probably this might explain the great danger of contagion in small rooms like the sweat shops. In New York the board of health had power to close a room where a patient with tuberculosis had died; that was to say, in tenement houses or small lodging-houses. These premises were disinfected and cleaned by the health board, and kept vacant for a time at the expense of the owner. The need of a hospital for infectious diseases in Baltimore did not call for much discussion.

Dr. William B. Canfield thought that the subject of sweat shops should be considered from all sides, to be practical. He had not noticed that in any of the papers read any reference had been made to the origin of the sweat shop; there must have been some reason for calling it into being, and he thought it was partly because of late there had been a greater demand for cheaper clothing both for men and women, but especially for men, and this demand could be satisfied only by working the poor people in the shops. He thought that every man or woman who bought cheap clothing helped the sweat shops.

Vaccination and Revaccination.—Dr. William J. Todd, of Mt. Washington, said that vaccination and revaccination were not sufficiently regarded at the present time. Too often certificates were given when there had been no proper vaccination. He thought that revaccination should be done at least once in every twelve years, and oftener in many cases.

School Inspection.—Mr. Charles R. Hartshorne, school commissioner of Montgomery County, said that the results of school inspection in the short time this had been carried on showed many sanitary defects in the buildings.

Dr. Augustus Stabler, health officer of Brighton, spoke of the defects in the heating of public buildings. The floor was usually cold, except within a few feet around the red-hot stove. The air soon became impure, windows were opened, and cold draughts came in and often caused illness.

Mr. Hartshorne said that the necessity of revaccination was very important. He had been vaccinated himself many times, and had a number of beautiful scars. He had good reason to believe that revaccination was of use, but there should be some modification of the law. Some physicians gave a certificate as soon as vaccination was done, without seeing if it had taken or not. Physicians should revaccinate in every case in which the vaccine did not take. There ought to be a provision for revaccinating once in every five or ten years.

Periods of Incubation and Infectiousness.—Dr. Charles W. Mitchell, of Baltimore, then made some remarks on this subject. He defined the period of incubation as the time between the entrance of the poison into the body and the appearance of the disease. This varied in different diseases and in the same diseases under different circumstances. The period of infectiousness was that during which the patient retained the power of conveying the disease. Some of the discharges might contain the disease and might spread it long after persons believed it to have passed. The infectiousness was just as dangerous in mild cases as in severe ones, and mild cases were the most dangerous because people did not recognize them. He protested against the practice which was so prevalent.

of exposing children to contagious disease in order to let them get over it. In the outbreak of a disease some mothers would put other children in the same room and the same bed so that they could have all the trouble of nursing them at once. This had too often caused the death of one or more of the children.

The Sanitary Treatment of Water-Borne Wastes in Town and Country.—Col. George E. Waring then delivered an address on this subject. He said that while we often paid attention to sanitary matters in the house, we neglected them outside. Sewage was unpleasant to the sight and to the smell, and, still further, it furnished a growth of bacteria harmful to man. When foul liquid was thrown upon the ground it gradually lost its power of harm, but when discharge took place in a cesspool dangerous putrefaction soon set in. The cesspool was a source of danger in every place. The only proper disposal of sewage, as far as was known, was to bring all of its organic contents into close contact with atmospheric air under conditions suitable for bacterial oxidation. There could be no proper disposal that did not secure rapid resolution into elements. All decaying matter should be put in the way of being destroyed most quickly. If sewage be allowed to trickle over crushed stone so arranged that air would penetrate all crevices, it would soon pass away as pure as water, leaving deposited on the stones a layer of sludge which was soon oxidized. Colonel Waring then described a system of his own for disposing of sewage from country houses. This could be put up at a small cost.

The address was received with great applause.

Public Baths in European and American Cities.—This was the subject of a paper read by Mr. T. M. Beadenkopf. He spoke of the difficulty that boys had in Baltimore in securing an opportunity to swim, as they were always driven away by the police. By the aid of several gentlemen he had secured the erection of some bathhouses, which was the beginning of a system of public baths in Baltimore. Europe was far ahead of this country in the system of public baths. London was said to have expended $2,500,000 in this deserving charity; it also had washhouses where soiled clothing was laundered by the poor people, who paid a small sum for the privilege. This yielded a large revenue to the city. He thought that the showerbath was especially successful when introduced into the schools.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. George H. Rohé; *Vice-Presidents*, Dr. Edward M. Schaeffer, Mrs. Daniel Miller, Miss Eliza Ridgely, Mr. Charles R. Hartshorne, Dr. Augustus Stabler, Dr. Howard Bratton: *Secretary*, Dr. John S. Fulton; *Treasurer*, Dr. L. Gibbons Smart.

KENTUCKY STATE MEDICAL SOCIETY.

Forty-Third Annual Meeting, Held at Maysville, May 11, 12, and 13, 1898.

The society met in Knights Templar Hall, and was called to order by the president, Dr. Joseph M. Mathews, of Louisville.

Diagnosis and Treatment of Osteomyelitis.—This paper was read by Dr. James B. Bullitt, of Louisville. He said that there was nothing new to be gleaned relative to the diagnosis and treatment of this affection. To treat the disease effectively, it was necessary to possess a clear conception of the nature of the tissues involved, and of the cause and character of the affection. After giving the usual definition of osteomyelitis, the speaker proceeded to the consideration of its cause. The femur was most often the seat of the disease. The tendency to infection in the long bones was in direct ratio to the rapidity of the growth of such bones. Males were more frequently affected than females, in the proportion of 3.38 to 1. The disease showed a special predilection for certain areas, as the mountainous southern regions of Germany, the north coast of Germany and Switzerland, where regular epidemics of the affection occurred. While oftentimes a primary, it occurred also as a secondary disease, being prone to follow measles, scarlatina, small-pox, and typhoid fever. The treatment of osteomyelitis was essentially surgical. In the rapidly progressing, fulminating type of the disease, early surgical interference was not only requisite for the preservation of the limb or joint, but for saving life itself.

The Rational Therapeutics of Some of the Animal Extracts.—Dr. R. Alexander Bate, of Louisville, contributed a paper with this title. The author presented a *résumé* of the therapeutics of thyroid and suprarenal extracts. The thyroid extract had been observed by him to produce daily evacuation of the bowels, diuresis at first, cheerfulness and amiability, smoothness of the skin, restoration of the color of the hair in one case, restoration of normal temperature in a case of diabetes insipidus and obesity in which the usual temperature was 97° F., and a slight diminution in the weight of obese subjects. The drug was contraindicated in exophthalmic goitre and in all diseases of the heart other than those dependent upon faulty changes. He reported a case of Addison's disease in which amelioration of the symptoms followed the use of the suprarenal extract.

Dr. R. C. McCord, of Lebanon, made some remarks on the subject of the utility of blood clot in the treatment of wounds. He said that Schede had used moist blood clot for closing spaces in the soft parts, but particularly in bone, without inflammation and suppuration. He had used the same method of treatment in one case, with a very satisfactory result.

Syphilis.—Dr. Henry Plummer, of Harrodsburg, read a paper on the origin of this disease. The origin of syphilis, he said, was involved in impenetrable darkness. As to the present extent of syphilis, the speaker stated that there were 250,000 adulterous people within the city of New York alone, exclusive of the 40,000 prostitutes and their customers. According to statistics, there were between 2,500,000 and 3,500,000 syphilitic people in America alone. The total number of women in Japan who practise prostitution was over 1,400,000. The author emphatically asserted that if there was no syphilis there would never be any lupus, leprosy, cancer, scrofula, rickets, or curvature of the spine.

Dr. C. C. Lewis, of Stamping Ground, had often thought that syphilis was like almost any exanthematous eruption; that no matter in what quantities the iodides or any other remedies were given, the disease would run its course. He did not believe that the disease was curable.

Dr. T. B. Greenly, of Meadow Lawn, had treated several cases of the disease continuously for two years, at the end of which time there were no manifestations of it nor any signs of recurrence.

Dr. George E. Davis, of Lawrenceburg, could not agree with the reader of the paper that scrofula, tuberculosis, and other diathetic conditions were due to syphilis. Errors of nutrition were responsible for many of the chronic as well as acute troubles encountered by the physician.

Dr. John A. Lewis, of Georgetown, considered syphilis the gravest problem confronting the physician to-day, in that it concerned his neighbors, his friends, his household. Physicians were the ones to educate the people relative to the terrible ravages wrought by this disease.

Eye Strain as a Cause of Nervous Diseases.—Dr. A. G. Blincoe, of Bardstown, read a paper on this subject. The speaker said that two years ago he had given the results of treatment of sixty-one cases of headache by correcting refractive and muscle errors, about forty per cent. being cured and fifty per cent. benefited. For the past two years he had treated seventy-three cases of headache and various nervous troubles by the same methods, with fully as good results. Of these four were cases of neurasthenia; two patients were cured and two benefited. Two were cases of vertigo, and both of these terminated in recovery. There were one case of chronic chorea of two years' duration, and one case of cramping of the muscles bordering on the same; both patients were cured. In one case of cerebral hyperæmia with mental derangement and delusions, the patient was cured; this patient received the bromides and ergot in addition to the eye treatment. Two cases of epilepsy, both of which seemed to have been benefited, were also treated.

Ether Pneumonia.—Dr. James M. Anders, of Philadelphia, said that many cases of pneumonia followed the administration of the anæsthetic. Attention was directed to the importance of employing experienced and skilled anæsthetists for major surgical operations, at all times if possible. The prolonged and unnecessary use of the anæsthetic was condemned.

Dr. James B. Bullitt said surgeons were becoming more and more impressed with the importance of the idea that an experienced man should be selected to administer anæsthetics. During the administration of any anæsthetic for a major operation the body temperature was reduced materially, perhaps from three to five degrees, and consequently artificial means should be provided for keeping up bodily temperature during operations. One of the frequent sources of infection during anæsthesia was inspiration into the lung of infectious matter from the mouth and nasopharynx.

Dr. W. L. Rodman said the lesson to be drawn from the deductions of Professor Anders' contribution was that surgeons should not be lulled into a false security by the safety of ether and keep a patient under the influence of an anæsthetic an hour or two hours, when one-half of the time would suffice for the completion of the operation. Many cases of pneumonia undoubtedly followed the prolonged use of the anæsthetic.

The President's Address.—This was delivered by Dr. Joseph M. Mathews, in which he spoke of the splendid work accomplished by the State board of health in completely ridding Kentucky of quacks.

The Pathology and Diagnosis of Diphtheria.—Dr. C. W. Aitkens, of Flemingsburg, read a paper on this subject. The true diphtheria bacillus could be cultivated through numerous generations, and after an interval of some months it was still capable of producing the true disease—not merely its local symptoms, but the constitutional ones, and eventually paralysis. There were no pathognomonic signs to rely upon at the bedside in cases of diphtheria, yet there were sufficient diagnostic marks to make the physician apprehensive of this disease. It was not an easy matter to differentiate diphtheria from follicular tonsillitis at first, but when the two affections were compared in typical cases the difference was sufficient for the clinician to decide even at the bedside.

The Treatment of Diphtheria.—Dr. S. G. Dabney, of Louisville, read a paper, of which the following were the conclusions: 1. For prophylactic purposes, quarantining the patient and the use of cleansing and antiseptic applications to the nose and nasopharynx of healthy children in the household and the attendants were sufficient ordinarily in private practice. In public institutions, or whenever these measures could not be carried out, antitoxin should be used for immunization, the dose being from fifty units in a young infant to three hundred in a child between four and ten years of age. 2. In nasal and pharyngeal diphtheria the essentials of treatment were antitoxin and, when indicated, stimulation internally, with cleansing irrigations or mild antiseptics locally. As stimulants, strychnine and arsenic held first place. In septic cases the tincture of iron was of special value. 3. In laryngeal cases the administration of antitoxin should be prompt, and the dose should be fifteen hundred units. Calomel should be given at the outset and the patient kept in an atmosphere of steam. These measures would often avert the necessity of operation, but, whenever the breathing became labored and the patient restless and distressed, a tube should be inserted. It was best to leave the tube in five days. 4. In all cases reasonably certain of being diphtheria, antitoxin should be used promptly without waiting for the confirmation of the diagnosis. 5. There was absolutely no proof that antitoxin increased the danger of heart or kidney complications, but on the contrary there was strong evidence that it helped to avert them, if used early.

Membranous Croup and Intubation.—Dr. G. G. Thornton, of Gravel Switch, said that he had never seen a patient with membranous croup get well who was not intubated, although he was aware of the fact that there were some who did. He believed that by studying the anatomy of the pharynx and larynx, and mastering the technique of the operation, any physician with ordinary skill could do it. It was best for beginners to leave a thread in the tube and bring it out at the left corner of the mouth and fasten it by pasting it to the face by a piece of adhesive plaster. This facilitated removal of the tube, if necessary, by any one—by a member of the family in the absence of the physician, should occasion demand it. While not all patients intubated would get well, the operation could be so quickly and easily done and the dangers were so few that it was always justifiable when indicated.

Influence of Age, Sex, and Race in Surgical Diseases.—Dr. W. L. Rodman, of Louisville, read a paper with this title. The author said that negroes were practically immune from varicocele. An analysis of five hundred cases operated upon showed not a single instance of this condition in negroes, there being only one case encountered in a mulatto. Extensive correspondence by the author with eminent surgeons in large Southern cities had corroborated this statement. The colored race was far less frequently affected with gall stones than were the whites. Of one hundred and six cases of gall stones, not one was met with in the negro. Tetanus was more frequent in negroes than in whites. The causes for this were given. Enlargement of the prostate was comparatively common in the white person after fifty, but was rarely seen in the negro. The author had searched the records of the Louisville Hospital for ten years, but had been unable to find a single case of enlarged prostate in the negro. Congenital deformities, such as harelip, cleft palate, spina bifida, etc., were far less frequent in the negro, according to the experience of Southern practitioners, than in whites. Not a single case of harelip or of cleft palate in the negro had been operated on in the Louisville Hospital for the last ten years. The speaker had never encountered clubfoot or spina bifida in the negro in the last ten years. Other surgeons corroborated him as to the rarity of these affections in the negro race. Very few cases of erysipelas occurred in colored persons. Aneurism, on the other hand, was far more common, almost three to one, in the colored than in the white race. Three times as many cases occurred in men as in women. Stone in the bladder was much more frequent in the white than in the negro race.

Dr. S. G. Dabney, in the discussion, said that tra-

choma was almost unknown in the negro. Another point bearing on racial proclivities was that phlyctenular ophthalmia was far more frequent in the negro than in the white race.

Dr. J. H. Letcher's observations on the rarity of varicocele and of enlarged prostate in the negro were confirmatory of those related by the writer of the paper.

Dr. T. A. Reamy, of Cincinnati, had never seen a case of varicocele in the negro. He recalled a case of congenital clubfoot in a negro. He cited one case of harelip in a negro and one of double harelip with cleft palate. Rickets was very common in the negro, as compared with the white race.

Dr. J. N. McCormack, of Bowling Green, reported two cases of harelip in the negro.

Dr. Rodman, in closing, stated that Dr. Hunter McGuire, who had had an extensive experience in bladder surgery, had never seen a case of enlarged prostate in a full-blooded negro.

Deflection of the Nasal Septum.—Dr. Thomas C. Evans, of Louisville, described an operation that had given him great satisfaction in all cases of deflections of the nasal septum. The method he described was substantially that devised by Dr. Asch and presented in a paper before the American Laryngological Association in 1890.

Obstetrical Outfit.—Dr. Henry E. Tuley described an obstetrical outfit. He said an aseptic accouchement was the great desideratum. The obstetrical outfit had been designed with several ends in view, and its contents had been chosen with regard to the true and economical needs of the accoucheur, patient, and nurses. It was packed in a hermetically sealed box after thorough sterilization, and was not to be opened until needed by the physician or nurses. Each outfit contained half a dozen lochial pads, obstetrical bed pad, five yards of sterilized gauze, half a pound of absorbent cotton, one dozen large safety pins, one dozen small safety pins, fountain syringe, nail brush, nail file, antiseptic soap, antiseptic tablets (bichloride), tube with vaseline, one ounce of Squibb's chloroform, six ounces of saturated solution of boric acid, sterilized tape for cord, cord dressing, Credé eye solution, and a pipette.

Extra-Uterine Pregnancy.—This paper was read by Dr. F. F. Bryan, of Georgetown. From being a clinical curiosity, extra-uterine pregnancy was now a fairly frequent condition, in that it occurred once in five hundred pregnancies. Surgery was the true method with which to deal with ectopic gestation in any and all of its phases.

The Midwife and Midwifery.—Dr. L. C. Wadsworth, of Newport, read this paper. The author's object in discussing this subject was not to crowd the midwife out, but to have her better qualified for the important duty she performed, and by this means to place midwifery upon a par with the other branches of medicine.

Officers.—The following officers were elected for the ensuing year: *President*, David Barrow, of Lexington; *First Vice-President*, H. K. Adamson, of Maysville; *Second Vice-President*, James B. Bullitt, of Louisville; *Treasurer*, C. W. Aitken, of Flemingsburg; *Librarian*, B. W. Smock, of Louisville.

Place of meeting, Louisville, 1899.

To Prevent Poisoning.—A safety cork has been invented with an anchor attached, which, in preventing withdrawal to a distance from the bottle, gives warning, as does also the click of the anchor within the bottle. This device should prevent self-poisoning by those who take medicines in the dark and by those who are blind, but it will scarcely save the deaf, particularly if they happen to be dumb at the same time.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 16, 1898.

George Tucker Harrison, M.D., President.

Dislocation and Fracture of Humerus; Excision.—Dr. John F. Erdmann exhibited a sailor, forty-nine years of age, who, nearly six months ago, while at sea, had fallen and injured his shoulder. He had no medical attention on board ship, and after four months came to New York and was brought to the Gouverneur Hospital with the right arm stiff and semiflexed. On March 31st, when he was first seen by Dr. Erdmann, an attempt was made, under anæsthesia, to reduce what was supposed to be a subclavicular dislocation. Failing in this, he had cut down on the anterior border of the deltoid, and exposed the head of the humerus. This revealed a fracture of the humerus in addition to the subclavicular dislocation. He excised the head of the bone, at a point about one inch below the anatomical neck. Primary union occurred throughout, and at the end of the third week passive motions were begun. About a week later there was considerable induration about the shoulder, and a small quantity of pus was discharged for a few days. Since that time the motion of the arm had steadily improved. Dr. Erdmann said he had presented a similar case to the association some time ago, in which he had removed half of the glenoid fossa and all of the head of the humerus, down to the surgical neck.

Extra-Uterine Pregnancy and Ovarian Cyst; Differential Diagnosis.—Dr. J. J. E. Maher presented specimens from such a case. They were removed from a woman, twenty-four years of age, who came to the clinic complaining of pain on the right side and bleeding from the vagina. Examination showed the uterus to be slightly enlarged. She thought she was pregnant about two months. On the right side of the uterus was an elastic swelling. She stated that she had miscarried last January, and that since that time there had been a bloody discharge from the vagina. For the last two months she had had morning sickness. For five years past she had had more or less dragging pain in the pelvis. At the operation it was found that there were an ovarian cyst and also an extra-uterine gestation on the right side, which had ruptured into the folds of the broad ligament.

Apparatus for Urethral and Intravesical Irrigation.—Dr. C. H. Chetwood, in presenting an apparatus of this kind, stated that according to his experience the permanganate-of-potassium irrigation was a very desirable method of treatment, but was liable to lead to unpleasant results unless the details were carried out with great care. It was unwise to attempt to overcome the resistance of the cut-off muscle by the pressure of the fluid in cases of acute urethritis. The urethra should be irrigated in sections, from without inward. The ordinary blunt-nozzled syringe was objectionable because of the necessity for withdrawing the instrument each time to fill the syringe. The distinctive features of the new apparatus were the set of nozzles and the alternating cutoff. The nozzle, he said, was made of glass, and somewhat resembled the well-known Kiefer nozzle. The alternating cutoff, as its name implied, was designed to close alternately the inflow and outflow tubes. It was so constructed as to be readily taken apart and sterilized. A height of about four feet was sufficient to wash out the meatus and one or two inches of the canal, and a minimum of five to five feet and a half would answer for the deeper portions.

Dr. Ferd. C. Valentine said that Goldberg, after collecting the results of all writers, whether favorable or adverse to the irrigation method of treating gonor-

rhœa, had found that sixty per cent. of cases of gonorrhœa were cured within ten days, thirty per cent. in fifteen days, and five per cent. after a longer time, depending upon the unruliness of the patient chiefly. By this method only five per cent. were failures. The apparatus just presented was certainly very ingenious, but had the disadvantage of requiring the use of both hands. Dr. Valentine said that it was his practice to keep the irrigator always at the same height, depending upon the stopcock for the desired variations of pressure. He considered it desirable to have the patient seated in a chair rather than standing, not only because it was easier in this position to wash out the bladder, but because some patients showed a tendency to faint during the irrigation. He then demonstrated his method and improved apparatus.

Dr. Robert Newman exhibited and described an arrangement which he employed for irrigation. It consisted, he said, of a long rubber tube arranged as a siphon, with a rubber syringe bulb attached. Any form of nozzle or cutoff could be attached to this siphon. In a few patients great difficulty would be experienced in irrigating the bladder, because of spasmodic action of the muscles. Under such circumstances, by pressure on the rubber bulb in the middle of the tubing, the fluid could readily be made to enter the bladder—far more easily than with the gravity apparatus exhibited by the two preceding gentlemen.

Dr. Chetwood said that his apparatus was intended to emphasize the advantage of irrigating the urethra thoroughly without uncoupling it or removing the nozzle. Undoubtedly the bladder and urethra could be thoroughly irrigated with the simplest appliances.

Notes on the Therapeutic Uses of the Suprarenal Gland.—Dr. W. H. Bates said he had been using an aqueous extract of the suprarenal gland for the past four years in diseases of the eye, ear, nose, and throat, and with very satisfactory results, but as he did not have the opportunity of employing it in general diseases extensively he presented the subject to his fellow-practitioners. It was essential to remember that the active principle of the gland was incompatible with preservatives, and was destroyed by heat; consequently it must be prepared freshly each time. This could easily be done by mixing ten grains of the dried gland with two ounces of water, and filtering. It was the most powerful astringent known. When a drop of a one-per-cent. solution was instilled into the eye, the conjunctiva and lid were blanched in forty seconds. This observation had been first made by him. The extract had no anæsthetic or antiseptic properties. It would whiten the granulations found in many cases of chronic suppurative otitis. If the use of the suprarenal extract improved the hearing in a doubtful case of deafness, it was evident that the condition was of inflammatory origin. It lessened the congestion of an inflamed eye sufficiently to admit of cocaine anæsthesia. As the extract and cocaine were incompatible, they should be used alternately. In strictures of the nasal duct, it would sometimes be found that instillation of the extract into the punctum exerted such a marked astringent action as to lessen the swelling of the parts and open up the passage. Other observers had found the suprarenal extract a tonic of the heart muscle, and capable of increasing decidedly the number of red blood corpuscles. Its action on the heart was much more powerful than that of digitalis or ergot. It had also been used in the unusually severe and inveterate forms of trachoma met with in the City Hospital, and had acted admirably. The best method of administering this remedy was to place a few drops of the aqueous extract on the tongue.

Dr. Jacob S. Peterson said that he had found the suprarenal extract an excellent heart tonic. Great care should be exercised in using it hypodermically, as the injections were liable to give rise to abscesses. In cases of heart disease in which he had employed it subcutaneously, he had found that the flabby heart had been toned up and an attack of angina pectoris quickly dissipated.

Dr. Bates remarked that the hypodermic use of the remedy was quite painful, and, in spite of aseptic precautions, it seemed to be specially liable to set up abscesses.

Notes on Practical Pharmaceutico-Therapeutics and New Surgical Instruments.—Dr. S. F. Brothers, under this head, described a combination of water motor and storage battery which he had found exceedingly convenient and economical for physicians' use. The chief object of his paper, however, was to enter a plea for a more general use of such active principles of drugs as the alkaloids, instead of the crude drugs themselves, and also for greater uniformity and accuracy in pharmaceutical preparations generally. For instance, he advocated the use of a series of solutions and triturations, in the proportion of 1 to 100 of glycerinated water and sugar of milk respectively. He also urged the adoption as flavoring agents of a full line of glycerinated syrups.

After some general remarks by Drs. Manley, Zwisohn, and L. Fischer, the association went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, April 28, 1898.

Edwin B. Cragin, M.D., Chairman.

Sarcoma of the Ovaries with Absence of Uterus and Vagina.—Dr. Louis J. Ladinski reported the following case. The patient, a woman of twenty-six, was of good muscular development and physique. Her sister had an infantile and retroverted uterus. The vulva of his patient was very poorly developed. The vestibule was covered with a white, glistening membrane. By recto-abdominal palpation a mass was found filling the pelvis. It was fairly movable and felt quite solid. On January 14th the woman was operated upon with the idea of making an artificial vagina. An exploration was made through an opening into the peritoneal cavity, and it was decided to operate by the abdominal route at another time, as the patient's condition was not good. Subsequently the tumor was removed by laparotomy. The larger mass measured six inches in its longest diameter, and was attached by a broad and thin pedicle to the right iliac fossa. On the left side there was a small, irregular mass attached to the upper border of the broad ligament. On exploration of the pelvis after the removal of the tumor, no trace of uterus or appendages could be found. An examination of the tumor was made by Dr. William Vissman. The larger mass was stated in his report to measure six by four by three inches. It was of yellowish-gray color, and the capsule could be easily removed. Microscopical examination showed one mass to be a sarcoma, and the other a carcinoma. Apparently the larger mass originated from the tissue of the undeveloped ovary. The speaker said that he looked upon the case as an undoubted one of complete absence of the vagina and uterus. Strangely enough, in spite of the absence of the vagina the husband of this woman stated that he had not been aware of anything unusual about the genital organs of his wife, and that sexual intercourse with her had been carried on. Dr. Ladinski said he had been unable to find any recorded case in which complete absence of the vagina, uterus, and tubes was associated with sarcoma and carcinoma of the ovary.

Dr. William Vissman exhibited under the microscope specimens from each of the tumors.

Dr. H. J. Boldt said that he had never met with carcinoma and sarcoma in the same individual. Undoubtedly one of the specimens under the microscope was a fibro-sarcoma, but the one presented as carcinoma strongly impressed him as a specimen of alveolar sarcoma.

Dr. Henry J. Garrigues expressed the same opinion regarding these growths. He said a diagnosis of complete absence of the uterus and appendages was useless if made only by palpation. In most of the supposed cases of this kind there was a very small rudimentary uterus. He had examined the patient from which these tumors under consideration had been removed, and had found that the artificial vagina had now a depth represented by the length of the two distal phalanges of the index finger. He had had one case in which, on digital examination, the finger had passed into the bladder. Inquiry showed that the urethra had been used for sexual intercourse in the absence of the vagina. In the case just presented, such a condition was not present.

Dr. Vissman said that fibro-sarcoma was one variety belonging to the spindle-cell group. In both of the tumors presented the stroma showed distinctly that they were made up of spindle cells. Sarcomata, he said, were not organized tumors; they contained tissues originating from the mesoblast. As to the diagnosis, it was more a matter of classification than of any radical difference of opinion regarding the nature of the growths.

Immersion Stand for Hands and Arms.—Dr. Philander A. Harris presented photographs of a convenient form of immersion stand for use in disinfecting the hands and arms in hospital practice. The glass jar being deep and narrow, very little fluid was needed, and the flange at the top prevented soiling of the floor and clothes. As the base of the stand was made of a heavy iron ring, there were no projecting legs; the stand was not easily overturned, and it could be readily moved from place to place by a touch of the foot.

New Operating-Table with Warming Device.—Dr. Harris also exhibited diagrams and photographs illustrating a new operating-table in use at the new Passaic Hospital. The body of the table he described as being a metallic chamber containing a coil of metal pipe, which might be connected by rubber tubing with the hot-water faucet and with the waste-pipe. A rubber diaphragm in the bottom of the chamber acted as a safety-valve. The table was supported on a triangular metal base, and the distance from the apex of this triangle to the point at which the foot piece was attached was only eighteen inches. As a result of this construction, the level of the pelvis was not materially changed in the different positions of the table. By means of a system of screws and gears the etherizer was enabled to raise or lower the table by simply turning a winch.

Dry Labor.—Dr. George L. Brodhead read this paper (see page 685)

Termination Usually Favorable.—Dr. Charles Jewett said that there could be no question regarding the theoretical dangers of dry labor, yet as a clinical fact the majority of these cases in his experience had terminated normally. He was sorry that more statistical evidence on this question had not been presented in the paper. The dangers seemed to him to depend a great deal upon the prolongation of the labor and the tetanic contractions of the uterus. He was not in favor of repeated douching. If used as a routine practice it must wash away the normal secretions, which could not be supplanted by anything better. If the normal secretions were deficient the condition would be relieved by the use of lysol, and immediate operative interference would be demanded. It seemed to him better to complete an operative delivery at one short sitting rather than to effect delivery by several stages or operations. He was not disposed to think that the child suffered as much from the pressure in dry labor as might be supposed from the statements made in the paper. Of course, it would suffer if the contractions of the uterus became tetanic. Cerebral hemorrhage had been, in his experience, a prominent cause of fœtal deaths, not only in this class of cases, but in others. The danger to the mother was chiefly that of sepsis, and yet, as the septic matter gained entrance only to the amniotic sac, there was no particular reason why infection should occur. The greater risk of sepsis was due rather to the damage that was likely to be done to the tissues in a severe and prolonged labor. These dangers could be largely obviated by the accoucheur standing ready to interfere as seemed to be demanded.

The Danger a Real One.—Dr. Ervin A. Tucker thought the question was one of very great importance, and that probably all present had lost children by not fully appreciating the gravity of dry labor. If only one child in one hundred or five hundred could be saved by due attention to certain points, it was still worthy of serious attention. Most general practitioners looked upon early rupture of the membranes as a trivial affair, and as rather fortunate, as it was apt to hasten the labor. In these cases, however, it might very properly be considered that the child was in the second stage during the whole labor—in other words, that the child was subjected to many hours of strong pressure.

A Common Cause of Dry Labor.—He felt sure that in many of the cases the cause of early rupture was to be found in chronic gonorrhœa or in the presence of some acrid discharge at the cervix. Under such circumstances the membranes became eroded and ruptured prematurely.

The Gauze Tampon.—Much could be done to save the cervix in dry labors by holding back the water so as to form a wedge. This could be accomplished by tightly tamponing the vagina. He had used this procedure in a number of cases during the past year, and with very pleasing results. The method was, after all, the familiar one so successfully used in abortions.

Enormous Doses of Strychnine Tolerated.—He had found strychnine extremely valuable to stimulate the contractions of the uterus in labor; he had given as much as one-thirtieth of a grain every half-hour for twenty or thirty doses without any symptoms of poisoning. After the second stage had been reached, he was in the habit of not waiting long in those cases in which meconium appeared and the fœtal heart changed its rate very decidedly. Even if the patient had only just entered the second stage, under such circumstances he would feel like slipping on the forceps and hastening labor.

Premature and Immature Rupture.—Dr. Albert H. Ely said there was a practical advantage in adopting Winckel's classification of these cases of early rupture of the membranes; *i.e.*, (1) premature, or those in which the rupture occurred before labor had really begun; and (2) immature, or those in which the rupture occurred before complete dilatation. In the first class the physician should be guided by the fœtal heart, the maternal pulse, and the maternal temperature in both the first and second stages. The textbooks had too often given a wrong impression by advising chloral and opium in dry labor. It seemed to him that stimulation was indicated, yet he did not favor the repeated douching recommended by the reader of the paper. If interference was indicated, it should be completed at one operation.

Caused by Deficient Cervical Dilatation. — Dr. Garrigues said he was rather surprised at the statement in the paper, that dry labor had been observed in fifteen per cent. of the cases at the Sloane Maternity Hospital. His own practice had led him to believe that it was much less frequent. In his opinion, the most common cause of dry labor was deficient dilatation of the cervix, and in nearly all cases in which the cervix did not dilate normally there was a disproportion between the fœtal and maternal parts.

Vaginal Douches.—Frequent warm douches of lysol or of creolin had the effect of making the tissues slippery; bichloride of mercury, on the other hand, had just the opposite effect, and was besides a dangerous drug for use in the vagina or uterus.

Chloral and Antipyrin Useful. — He had never made use of quinine or strychnine in obstetric practice, and did not feel inclined to try them, for the reason that when the cervix did not dilate properly he saw no reason for using remedies which stimulated uterine contraction. But he did employ such drugs as chloral and antipyrin, particularly the latter. The chloral should be given in doses of fifteen grains every half-hour; the antipyrin in doses of ten grains every hour. Not infrequently direct dilatation of the cervix by the Barnes bags or by the manual method would be required, and probably delivery by forceps or version.

Dry Labor often Indicates a Posterior Position. —Dr. Henry C. Coe said that he had found dry labor rather infrequent in private practice. Rupture of the membranes before the beginning of labor did not cause him any alarm, unless he recognized a disproportion between the maternal and fœtal parts, or an occipito-posterior position. Indeed, he had come to look upon it as an indication that such a position was probably present.

Morphine often Useful.—In many cases in which the cervix was quite rigid it seemed to him that the very best results were obtained by the hypodermic injection of morphine. He would not lay down any fixed rule, however, regarding the use of opium. If the progress was steady, though possibly very slow, and the mother and child continued in good condition, he would not feel called upon to interfere.

Another Etiological Factor.—Dr. J. Milton Mabbott said that many seemed to forget that the uterus underwent contraction at short intervals during the latter part of pregnancy. He looked upon this as a system of exercises of the muscular fibres to prepare the uterus for labor. He believed that these contractions sometimes became excessive during sleep, and by causing pressure in the region of the cervix produced rupture of the membranes, especially if the latter were thin or eroded. In his opinion, bichloride was a safe antiseptic for use after delivery.

Sceptical about the Gauze Tampons. — He was surprised to learn that the vagina could be tamponed sufficiently tightly to retain the liquor amnii and so favor dilatation of the cervix. He had always looked upon a gauze tampon as a drain, and he felt somewhat doubtful about the efficiency of such an expedient. It was somewhat different in the case of an abortion, for there the coagulation of the escaping blood tended to obstruct the flow.

Prefers the Hand or the Barnes Bags.—It seemed reasonable to suppose that much more effective dilatation could be secured by the manual method or by that almost forgotten instrument, the Barnes bag. The action of the latter was an excellent imitation of the action of the bag of waters, and it would retain the liquor amnii for a considerable time. It was also a useful device when the physician desired to leave the patient for a time.

Significance of the Umbilical Souffle.—Dr. Simon Marx thought all were agreed that premature rupture of the membranes was a pathological condition, and yet in the majority of cases the termination was favorable to both mother and child, if the accoucheur carefully watched them. Neither the rapidity nor the diminution of the number of the fœtal heart beats was so characteristic of danger as the presence of an umbilical souffle. He was surprised that the reader of the paper had made no mention of malposition of the occiput and relative or absolute pelvic contraction as etiological factors in premature rupture of the membranes. When there was an occipito-posterior position the treatment should be early version, preceded by manual dilatation of the os. So long as there were no symptoms indicative of danger to mother or child, he saw no reason for interference of any kind —even the administration of drugs and douches, as advised in the paper.

Action of Quinine and Strychnine on the Uterus. —He had used quinine a great deal, and had come to the conclusion that it did not affect the non-acting uterus. In large doses it would give a typical relaxation and contraction, in sharp contrast to the action of ergot, but it did not act on the quiescent uterus. At one time he had tried the experiment of administering quinine to a number of pregnant women in hospital for three weeks prior to confinement, and had found that their labors had been more difficult and prolonged than in the case of the other women who had received no such medication.

Favors Manual Dilatation.—If he had understood correctly, the gauze tampon was to be used as a cervical packing, which would materially soften and dilate the cervix, on the principle of the Barnes bag. Just as soon as there were symptoms of danger to either mother or child the interference should be prompt, and hence he favored manual dilatation.

Tartar Emetic Aids Cervical Dilatation.—Dr. P. A. Harris recommended tartar emetic in frequent and small doses up to the production of emesis, in cases in which the cervix did not readily dilate. This practice was based on a very large experience of a medical friend, and on a smaller but favorable personal experience.

Dr. Brodhead closed the discussion. He said that he had treated cases of dry labor both with and without douches, and had obtained better results in the cases in which he had used the douches. They must be given carefully by the physician himself. He had seen so many children born asphyxiated after a dry labor that he felt the danger to the child must be much greater than in normal labor. In his experience there had not been a preponderance of occipito-posterior positions. If the occiput was posterior, he would not interfere unless there was an indication for such action, as many such cases terminate satisfactorily without any assistance from the obstetrician, and if it was required a low forceps would usually be sufficient. When the labor had lasted for a considerable time, he would be very careful about using chloral and opium.

Detection of Spermatic Fluid.—Dr. Lecco (*Therapeutische Monatshefte*, October, 1897) claims that even after the lapse of several years spots of spermatic fluid are easily recognized. The following sensitive test is employed: Soak the spot in water, and introduce a drop of the solution between the microscopic slide and the cover glass; a drop of a saturated solution of iodine in iodide of potassium is now allowed to flow under the cover glass. A number of remarkably beautiful crystals, characteristic of spermatic fluid, will form; they are rhomboidal in form, often occurring in the form of crosses, and are of a brownish color. The same reaction was independently discovered by Florence at the same time.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ARMY SURGEONS—PROMISED REDRESS OF GRIEVANCES—A ROYAL MEDICAL CORPS—THE MIDWIVES BILL—THE COLLEGES—ALBUMOSE SPONTANEOUSLY PRECIPITATED IN URINE—COLLEGE OF SURGEONS TAXATION—PROSECUTION OF PRACTITIONERS—DEATHS OF SAMUEL GORDON, ETC.

London, May 6, 1898.

This has been an important week from a medico-political point of view. On Wednesday the lord mayor entertained a large number of medical men at a Mansion House banquet. Lord Lansdowne, secretary of state for war, was present, and explained the new scheme for meeting "the long-standing grievances," as he expressed it, of the army medical service. "We are determined," he said, "that there shall be no failure in theory or practice to treat them with the respect to which they are entitled. We propose to make a fresh start, and to form, out of the army medical staff and the medical-staff corps, a corps the officers of which will bear the same military titles as other officers of the army—always, of course, upon the understanding that those titles do not confer upon them any right to command outside it. We propose to give them those titles up to the rank of colonel." His lordship said he could not go beyond this, as the present policy is to restrict as much as possible the title of general, and to insist that no one shall rise to that rank unless he is required to fill one of a limited number of appointments, all of which involve general command in the army and fitness on occasion to command troops in the field. No departmental officers will under this system reach the rank of general officer. This will be a disappointment to many. Some of our colleges had protested against the limitation when it was rumored that the Horse Guards were endeavoring to impose it, and not a few will regret that Lord Lansdowne, who had insisted on the reform thus far, did not refuse to listen to the jealousy which has so long disgraced the military element. Lord Russell, in a previous speech, had significantly remarked that members of the medical profession held more Victoria crosses in proportion to their numbers than any other department. The dangers they incur and the devotion they exhibit are well known to the public, and the military officers who continue to dub them "non-combatants," or their V. C.'s "brave civilians," will soon experience the contempt of all reasonable men.

The war minister further stated that the title of surgeon-general is to be retained, with the rank and precedence of a general officer in the army, and perhaps this may be accepted for rank above that of colonel as satisfactory. At any rate, Sir William MacCormack, who spoke subsequently and who knows much of military matters, said the medical service owed a debt of gratitude to the minister, who, "in spite of strenuous opposition, was conceding all that the department desired."

The Queen has sanctioned the prefix royal to the new corps.

The Duke of Devonshire received a deputation on Monday of those who are so obstinately trying to force forward the "midwives registration bill." His Grace administered a cold douche, which it is to be hoped may awaken the deputants and nerve them to a better course. He told them there were no strong public feeling in favor of the bill and very little chance that it would be proceeded with; that their efforts should be directed to a future measure rather than to the present one. He flatly refused government support unless they accepted unreservedly the proposals of the General Medical Council. The council has certainly scored one in this matter.

Mrs. Garrett Anderson has definitely pronounced against the bill, in an effective letter in *The Times*. Her position as the leader of the medical women gives great importance to her views on this question, and it is refreshing to read her protest against enrolling the "Gamps" as qualified practitioners. She says the bill will not protect the poor, but will rather render it more difficult for them to obtain the services of capable midwives, while it would have a detrimental effect on the position of those women who have gone to the expense and trouble of qualifying as medical practitioners. If registered at all, Mrs. Anderson would compel midwives to act as monthly nurses. It is not easy to see how this is to be accomplished, but it would be no difficult matter to refuse all recognition to midwives and let the few there are die out, retaining the services of monthly nurses and restricting the practice of midwifery to fully qualified men and women.

The College of Physicians has appointed its usual annual dozen of fellows, and the usual amount of disappointment and vexation will be felt. I have no objection to offer to any of the new fellows as individuals, but the present system of election can never give satisfaction. Men who have done good work, taught in the schools, and maintained the honor of the profession, but refuse to cringe to the ruling clique or to canvass or dine the powerful few, are systematically passed over year after year, as if they were unworthy of the seniority they have attained.

The council of the College of Surgeons has replied to the memorial as to the franchise for the Medical Council, that it sees no reason to alter the mode of election which has lasted forty years. Some day the council will have to admit that usurpation for forty years is no justification for wrong.

Dr. Bradshaw, of Liverpool, read a paper before the Medico-Chirurgical Society, on a case in which albumose was spontaneously precipitated in the urine two or three times a week. The urine was clear in the intermediate periods, but even then contained a proteid which gave the reactions of an albumose and appeared to be the same body as that precipitated in the turbid specimens. Dr. Bradshaw suggested that the precipitation was perhaps caused by variations in the other constituents of the urine. He had found five cases recorded which resembled this in some respects, but he thought his own unique in that the albumose was precipitated in the urinary passages. In some cases disease of bones or bone marrow had been present, and in his own there were kyphosis and immobility of the lower vertebræ, but the nature of the bone affection was not evident.

The president, Mr. Bryant, thought the photographs suggested the possibility of osteitis deformans.

Dr. Sidney Martin had seen a somewhat similar case, and said he did not lay much stress on the variety of albumose found. In cases associated with new growth the rapid degeneration of the cells gave rise to the formation of proteids which could not be utilized and were therefore excreted. An albumose similar to that seen in such cases could be formed by boiling splenic extract with caustic potash.

Dr. H. D. Rolleston remarked that fifteen months ago Chataigne described cases in which the blood serum was lactescent and there was degeneration of the renal epithelium.

Dr. Bradshaw, in his reply, said there had been no sign of osteitis deformans, and it had been suggested to him that the spinal change might be senile. It was only of late years that it had been recognized that many cases of fragilitas ossium were in reality multi-

ple sarcoma of bones. To this category he would provisionally refer his case.

The College of Surgeons has been worsted in an attempt to escape from taxation on the ground that it is an institution for promoting education, literature, and science. The judge ruled that, though the college may have been at its origin principally for the promotion of science, at the present day it is granting diplomas for fees and its main object is not the promotion of science. On this part of its income, therefore, it must pay. Of course, the Hunterian Museum is exempt.

A "Dr." Leibster, who called himself M.D. of Philadelphia and medical officer of the National Medical Aid Society, but is not registered, was brought before a magistrate for holding himself out as qualified. The magistrate did not convict, and an appeal is to be made.

Much disapprobation is being expressed with the Medical Council for prosecuting a qualified and registered practitioner, holding the diploma of L.S.A., for calling himself "physician and surgeon." The L.S.A. is recognized as a full qualification in medicine, surgery, and midwifery, as the Apothecaries' Society, which grants the license, examines in all departments. The poor law and other services acknowledge it as such. The society will, of course, defend its licentiate. The council's advisers have not been successful in other actions, and in this every one I have talked with about it hopes they will again fail. With hosts of unregistered quacks preying on the profession, it is monstrous for the council to find the lawyers nothing to do except to prosecute registered men on flimsy pretences.

Dr. Samuel Gordon, of Dublin, died on Friday, aged eighty-two. He had an attack of influenza, and pneumonia ensued. No physician in Ireland was better known or more highly esteemed by his brethren. He took his M.B. Dub. in 1844, and was made M.D. *honoris causa* in 1877. He was three times president of the Royal College of Physicians of Ireland, and received numerous other honors from his compeers. He filled at various times most of the public offices open to a physician in Dublin, and in all secured the confidence and respect of every one with whom he came in contact—a great record of a career of sixty years of honorable work for the good of others.

Dr. Wall, a retired Indian officer, took his life by stabbing himself in the heart with a penknife during temporary insanity. He had a distinguished career in India, particularly working on cholera and snake bites. He was M.D. of the London University, and F.R.C.S. Eng. He had lately had hallucinations.

The death is announced of Surgeon-General James Irving, late of the Bengal army, aged seventy-five.

A LIVER WITH SIXTEEN LOBES.

To the Editor of the Medical Record.

Sir: I fail to see anything remarkable in the case described by Dr. Moses, in the Medical Record for May 7th. The cuts show an appearance more like a syphilitic liver with contractions than a liver with accessory lobes.

While it is true that in man the liver normally consists of five lobes, a typical mammalian liver has six lobes, a Spigelian and caudate as in man. In addition, the broad ligament divides the liver into two parts, right and left, each of which is subdivided into a central and lateral lobe. Some of the lower animals, *e.g.*, the camel and seal, have numerous lobes to their livers; so, even if Dr. Moser's case is one of genuine accessory lobes, it is merely an example of atavism, as in "supernumerary" spleens.

George W. Smith, M.D.

Chicago, Ill.

A CASE OF HALLUCINATION.

To the Editor of the Medical Record.

Sir: The case of hallucination related by Dr. T. J. Hutton, in the Medical Record of May 7th, is susceptible of a different explanation. The man said "that the moment he lay down in bed at night a woman dressed in black came in through his bedroom window, lay down on his bed, and kept up a conversation with him until he fell asleep, which did not occur until far into the night."

The images made on the sensory areas of the brain are permanent, and extraordinary stimulation of special sense centres, as the visual and auditory, for example, will sometimes revive the impressions of things once seen and heard, as distinctly as though the original causes were present in reality. The man saw and heard the woman, although she was absent, because his intense thoughts of her resuscitated the images of her looks and words to such a degree that they were equal to those made by her real presence. The mind can either create original images in the brain or revive those already made, with such vividness as to cause the individual affected to believe that there is an external object present exciting his senses.

Many pictures are laid away in the camera obscura of the brain, ready to be developed.

Hallucinations are the result of disordered or diseased brain centres rather than of pathological conditions of nerve fibres. The administration of potassium iodide is often a rational treatment.

G. W. Drake, M.D.

Hollins, Va.

Medical Items.

The Relation of Typhoid Mortality and Sewerage.—Typhoid fever is the sanitary index of a city. The mortality has everywhere declined with improvements in the sanitary conditions. Mr. J. W. Hill, an engineer, has recently tabulated the statistics of sixty-five cities with reference to the death rate from typhoid fever during the five years 1890–94 inclusive, and has grouped them into seven classes. I am sorry to say that Class I., comprising thirteen cities which have a death rate from typhoid fever under ten per one hundred thousand living, contains no American city. On the other hand, in Class VII., which comprises thirteen cities with a death rate from typhoid fever over sixty per one hundred thousand inhabitants, all are in this country, except Milan, Cairo, and Alexandria. The lesson of several of the European cities is worth reading. I can take time to refer only to Munich. The mortality per one hundred thousand of inhabitants in that city in 1857 was two hundred and ninety-one, and kept at a high rate until about 1865, when there was an improvement in the water supply, with a reduction of almost fifty per cent. in the number of cases of typhoid fever. After the introduction of the new system of drainage the mortality was still further reduced, and in 1887 it was only ten per one hundred thousand of the inhabitants.—William Osler, *Maryland Medical Journal*, January, 1898.

Position in Repose.—In the *London Illustrated News* a discussion has been going on as to the position of one's arms when in bed and as to the most healthy mode of lying when at rest. Dr. Andrew Wilson says that one correspondent advocates crossing the arms over the chest as an easy and natural posture; but such a position implies lying on one's back, and this is precisely the mode of repose which in the case of many persons is impossible, associated as it is with the discomforts of dreaming. The more one thinks of

it, the greater appears the probability that the arms have yet to be adjusted to the ordinary conditions of human repose—that is, if questions of comfort and adaptation have to be considered. Another person raises the question of "the proper side to sleep on." Dr. Wilson remarks: "I am afraid this latter point is strictly relative to the individual, but I fancy the majority of us incline to repose on the right side, possibly by reason of the general right-sided tendency which a human body illustrates in its ordinary working life. Our right-sidedness means the greater activity of the left brain hemisphere; in other words, we are left-brained and right-handed. It may be well if there does exist a tendency toward repose on the right side in preference to the left; the left brain half may exercise its functions here as in other matters determining the superiority of the right hand. One point mooted by a correspondent has reference to the effect which lying on the right side may be supposed to exert on the liver and digestive system at large. I am not aware that in sleep we have to take into account the affairs and interests of that apparatus, save perhaps when we indulge in late and heavy suppers and thereby produce disturbance of our hours of repose. But as the liver lies on the right side of the stomach, and as the intestine also proceeds from the stomach on the right, it is just possible such digestive action as may be carried on in sleep might be assisted by repose on that side. Animals sleep in all sorts of positions, of course, and the often apparently uncomfortable postures in which dogs and cats may be seen sleeping soundly must excite our surprise. The cat especially, by curling herself together, has learned to conserve heat in a very efficient fashion; and I have heard it suggested that feline sleep is almost a kind of asphyxia, because of the manner in which puss buries her nose and mouth in her fur and despises free ventilation and oxygen. I suspect in the case of such animals the question of heat is always foremost, and that of air becomes a secondary matter entirely."

Baldness in Women.—Women do not turn bald more frequently than men, in spite of certain modes of coiffure which more or less spoil the hair, and in spite of certain special physiological circumstances, such as pregnancy and childbirth, which tend to cause loss of hair. In female criminals baldness is less common than among the normal class.

Precautions against Malaria.—Mr. William T. Hornaday says: "After living in the most malarious jungles on earth, in the midst of miasmatic swamps, drinking swamp water, and often having to eat unaccustomed and badly cooked food, I never had but one touch of jungle fever, and that only laid me up for six or seven days. I owe my excellent health to two or three precautions. I never slept on the bare ground or in the rain, and always under shelter. I always wore light flannels next to the skin, and never slept in damp clothes. Whatever else I might have to do without, two changes of flannel underwear besides that I had on were always at hand. Take from five to six grains of quinine every morning in a cup of hot coffee, if you have it; if not, then in hot water. Have your shoes to fit you, even if you must buy them yourself, though the United States is furnishing its troops with an excellent marching-shoe. With these precautions and a dose of some light laxative once a week, there need be no more fear of fever in Cuba than there is in Missouri."

Roman Fever.—The superstition that Rome is an unhealthy place to live in is discussed by Mr. W. I. Stillman, in "Old Rome and New." Mr. Stillman has lived in Rome so many years that his judgment on this subject may be accepted as of great value. He states that the superstition as to the sanitary condition of Rome runs back into the dark ages, but is unjustified by any statistics. He says that in a residence of nearly a dozen years in the aggregate, and extending over a period of thirty years, he has never had a serious illness or a case of typhoid or malaria in his family, nor among his acquaintances has he ever known one-half dozen cases of intermittent or malarial fever, and not one of any gravity. He has repeatedly stayed in Rome during the entire summer, without any discomfort or inconvenience. He has never met with a case of so-called pernicious fever, and Dr. Drummond, who has practised in Rome for years, says he never saw a case. The statistics of the Italian sanitary department are drawn with the greatest care and exactitude, and the record of deaths from malarial fever for the commune of Rome, including the Campagna and all of the malarial districts, showed a total of only three hundred and eight out of a population of five hundred thousand, and this enumeration includes peasants who spend their lives in the marshy and fever-infected districts. Mr. Stillman says he has travelled in the worst parts of the Maremma, which are regarded as the most deadly and malarial in Italy, as late as the latter part of June, and he found the harvesters at work in gangs; and at Grosetto, the capital of Maremma, which the guidebooks tell is abandoned by the inhabitants on the 1st of May, he found the entire population on the ramparts listening to the band until late in the evening. Typhoid is common in all great cities, but in Rome less so than in most cities of its size. The water supply of Rome is probably the best as to its purity and the most abundant in quantity of any furnished to great cities. Typhoid very rarely occurs among the inhabitants of the better class, except from drinking water at some wayside spring. The sanitary laws are inflexible, and the tenant of a neglected house has always the remedy in his own hands. Mr. Stillman says: "I have no hesitation in saying a person in moderate circumstances, able to choose his quarters, can pass the months between September and July in Rome under as favorable conditions of health and comfort as in any city of Europe; and, with less precautions against the heat than in New York one must take against the cold, he may pass the entire year."

Health Reports.—The following statistics concerning smallpox, cholera, yellow fever, and plague, have been received in the office of the Supervising Surgeon-General of the Marine Hospital Service during the week ending May 21, 1898.

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Birmingham	May 1st to 13th	15

A BELIEF THAT SO-CALLED DISPLACEMENTS OF THE UTERUS ARE NOT PATHOLOGICAL.[1]

By FREDERICK PORTER HAMMOND, M.D.,
NEW YORK.

In that branch of medical literature dealing with the female pelvic viscera no theme has occasioned wider discussion than that having to do with the normal position of the uterus. It is not the purpose of this paper to enter upon the general discussion of a subject which has been passed upon in such exhaustive review, but rather to consider in brief what is pathological when the uterus is removed from its most common position, with a view to demonstrate, as effectually as possible, what seem to me gross errors entertained by some regarding the oft-mistaken malady displacement. To those familiar with the early literature when displacement received its first authentic recognition as a pathological condition my views may seem somewhat retrogressive, but, regarded in the light of research and discussion of the last decade, I think it no exaggeration of fact to say that all authors effectually substantiate each and every conclusion at which I have arrived.

In general outline topographical anatomists concede as most proper that position of the uterus which finds it not far removed from the median axis of the pelvis, with its fundus immediately below or on a plane with the pelvic brim. It presumably lies in a position of slight anteversio-flexion, with its anterior surface slightly inclined to the right. That this is the position also which a majority of clinical observers will concede as most common I am sure few will deny; but, from its immediate bearing upon the points I now have in view, it becomes necessary to mention those judicious and painstaking observers, Braune, Lushka, Cruveilhier, Henle, and more recently Henke, who hold a contrary view, asserting that the normal position of the uterus is with its fundus lying in the hollow of the sacrum. More potent still is the observation of Fritsch,[2] that "since the womb is normally movable, we cannot speak of a definite normal position. The entire number of positions of the womb are normal in different physiological conditions of the neighboring organs." Granting that all these observations are correct, and I believe all are authentic, from my own moderate experience in the clinic room, I have no hesitancy in going upon record as an extremist in harmony with the view of Fritsch, in my assertion that any position within the pelvic cavity is correct which finds the uterus retained at its proper plane of support—is physiologically normal and not an impediment to the healthy discharge of woman's normal relations in life.

In connection with the wide discussion upon the proper position of the main generative organ has arisen an equally exhaustive and varied discussion upon direction, depth, and variability in length of the vaginal canal in its passage through the various components of the pelvic floor. That it varies widely in different cases, usually according to the inclination of the pelvic axis, is a point all will concede. The only one to which I wish to call attention and which is not so forcibly dwelt upon in the literature, is the wide variability in position of the vaginal orifice, relative to its anterior or posterior situation in different women. Our text-books usually give its position as slightly anterior or median; that cases are not infrequently seen in which it lies considerably posterior to the median line, is a fact to which attention is seldom called. This observation is important with regard to prolapsus uteri, which I shall later touch upon as justly entitled to be called the only true displacement of that organ, but it is within the observation of all to have met with many cases in which the vaginal introitus appeared so far posterior as to make the introduction and manipulations through an ordinary bivalve speculum exceedingly difficult with the patient in the dorsal decubitus.

To the chief components of the pelvic floor I must refer briefly, though their analysis in detail is unimportant for purposes of this demonstration. It is the generally accepted view now among gynæcologists that the levator ani and superficial muscles form the chief supports to sustain the pelvic floor at its proper plane. Such a view is in great degree substantiated by the evils arising from the rupture of these important structures, but likewise it follows, in view of the many other important structures constituting the pelvic floor, as illogical to disregard as less important each and every element—muscular, ligamentous, connective, or areolar and adipose tissue alike—as contributing an equal share toward abdominal support. The adipose tissue, though minimum in amount, has never received its due quota of importance as the cushion and lubricant to maintain the normal tone of this area. Perhaps a more concise and just manner to pass in brief upon the pelvic floor is to say its chief factors of support are muscular only.

Among recent writers upon uterine support proper is Mackenrodt,[1] who gives his observations after a careful study of the subject, illustrating his dissections by a series of diagrams, wherein he seems to establish the fact that the stout pelvic fascia forms the pelvic floor and keeps *in situ* the various components of the pelvic viscera. His observations seem valuable, but to my mind place too much stress upon that which other observers consider as only one of the factors of perineal support, and such a theory is lacking in that one essential feature of some necessary addendum to maintain the normal equilibrium of tone in this important area. From his deductions, however, I regard this as worthy of note: that instead of the genital outlets simply passing through slits in the fascia, there are deep ligamentous bands slipping into the upper margin of the vagina and cervix uteri, and it is these which retain the uterus and vagina in their respective positions. It seems to me this is a safe and logical deduction to explain how it is that the cervix uteri and

[1] Archiv für Gynäkologie, vol. xlviii., part 3, 1895.

vagina are able to withstand the unequal strains put upon them in parturition without a rupture of their continuity. I am unable to concede much weight to the idea that the ligaments of the uterus contribute a great share as supporting agents to keep the organ at its normal plane. The ligaments are the great elastic guy ropes to sustain it in its common relations, and likewise effect reposition after a physiological transposition, but their function goes little beyond this. Their structure does not seem to warrant a contrary belief, they being little more than peritoneal folds with a few fibres of muscular and connective tissue in their meshes, with the exception of the round ligaments, and to any of us familiar with the Alexandrian operation the very length of cord which can be drawn through the ring would indicate that the purpose of these is chiefly physiological rather than anatomical. In fact, when we begin to study the anatomy of the uterus and its attachments it seems without the range of possibility to demonstrate that any of the attachments are purely of an anatomical nature, acting as agents to support it at its normal plane. Its most extensive attachment is between the bladder and uterine wall, but here even the bladder itself is a yielding organ, and the attachment involves the vagina and urethra in such a manner that it is manifestly improper to consider its relations here as of a supporting nature. The womb of necessity, from its purpose to the animal world, is a mobile organ, resting mainly upon the pelvic floor and limited only in its normal range of physiological transposition by the surrounding walls of the cavity in which it lies.

Displacements of the uterus have occupied a wide field of importance in all writings upon diseases of the female genital organs. In the historical introduction prefacing the article upon this subject in the "American System of Gynecology," we find these words: "There are passages to be found in the writings of Hippocrates, Moschion, and Ætius, which prove that inclinations of the uterus before and behind were not unknown to the ancients. It is, however, exceedingly probable that these old authors had knowledge only of the deviations which had occurred in impregnated uteri." It is a strange coincidence to my mind that in the early discussions at the beginning of this century, when displacement asserted its first authentic claim to recognition as a pathological condition, a great many of our best authors antagonized its reception with the argument that not a single symptom attributed thereto could not be logically explained by other and more definite lesions. Thus primarily in my argument am I led to believe the outgrowth of the present proportions of the evils of displacement are but the logical sequence of the large number of specialists now occupying the field of gynæcology. Does actual displacement of the uterus—and in this I include both flexion and version—ever really occur? I might exceed the judicious bounds of my better conscience and state that which later investigation might make me wish to retract did I answer this question unconditionally in the negative, but so far as an observation of several years of practical study can reveal, and this starting with an unbiassed judgment, I can only admit, with the single exception of prolapsus, that I do not believe there is truly such a pathological condition as uncomplicated displacement of the uterus throughout all medical nomenclature worthy of a moment's consideration.

In consideration of version it is only fair to admit that extremists upon the side of displacement are very liberal in granting a proper degree of variability to the angle at which vagina and cervix may be joined. They concede as proper anything between the acute or very obtuse angle. Conceiving the size of the cavity and organs with which we have to deal, anything beyond this seems approaching the impossible. I find very little said, however, upon uncomplicated version as a pathological condition, except that it often acts as an impediment to conception. It seems to me such an argument falls at once, if we consider the manner in which conception is believed physiologically to occur. There are presumably but two ways—one in which the semen is thrown directly within the uterine cavity (retroversion), the other in which the semen remains in the posterior cul-de-sac at the vaginal vault, leaving the cervix bathed in its contents, to be borne within the uterine cavity by the waving cilia of the cervix, or the inherent property which the spermatozoa possess to find their way throughout the uterus and tubes.

About flexions no end of discussion seems to have occurred. Wherever any train of symptoms seems to have appeared with a cause in the least obscure, flexion complicated or simple has proved the haven of ignorant deception. Hart and Barbour treat of anteflexion as simply "an exaggeration of the normal condition." Skene[1] especially states that flexions are not displacements, but pathological deformities of the organ itself. Yet to the clinician painful menstruation, pelvic hyperæmia, contracted os, constipation, painful and frequent micturition, all appear in the mind of the average gynæcologist as due to some degree of flexion or flexion complicated with version. Is a single one of these symptoms more common in women with apparent flexion than in those without? I answer unqualifiedly in the negative. Primarily it is said flexion is congenital and acquired; were it proved that flexions more often were present in infantile or non-developed uteri, the argument would better stand; but it is a fact too well known by all—and all have seen many cases—that infantile uteri are the most seldom displaced of all. And why? Because the influences acting upon the developed organ are absent in the immature. Were I now to accept the theory of flexion as a pathological condition, it would be necessary to find some pathological lesion present at the point where flexion is said to occur. I have carefully perused such literature as I could obtain, without finding one particle of authentic evidence to substantiate such a supposition. In some brief articles such a fact is taken for granted by some authors, but no case is verified in which disease is present at the point of flexion and some other part of the organ is not diseased as well.

It is a fact seldom sufficiently emphasized that apparent flexions are often only a deepening or shortening of the normal portio intermedia between cervix and body, so that the touch is one of firm rigidity at the junction of these two zones. This condition we may almost say is the common rule rather than the exception in women who have followed laborious occupations and married late in life. Nothing in clinical observation is more often demonstrated to our touch than the wide degree of variation in size, contour, and flexibility of the uterine neck at this point, and how often is it borne home to us upon the other extreme of cases with a long portio intermedia, in which upon the first introduction of the finger in the vagina we seem to feel the fundus lying in a marked condition of anteflexion, when the bimanual examination reveals only the normal or in some cases an apparent retroverted position. The explanation of our first erroneous impression would appear to be found in the peculiar juxtaposition of the two opposing surfaces of the bladder, the uterus being forced over upon it, and lying upon the pubic symphysis while the subject is in the erect posture, through intra-abdominal pressure; as the recumbent posture is assumed the intra-abdominal pressure recedes, but atmospheric influence

[1] Skene's "Text Book," third edition, 1898.

is sufficient to retain the uterus and bladder in their transposed position until the manipulation of the finger and hand rearranges and alters the parts.

Of the etiology adduced by various authors, whose observation is of such a practical nature as to permit them to admit that absorption or cirrhosis does not occur at the point of flexion, the most common is that in which it is accounted for by an unequal growth or arrest of development in the uterine walls. I have endeavored to find some practical verification of this supposition in such material as I have been able to obtain, and the large number of hysterectomies performed at the present day surely affords us abundant material; but to the honest investigator pursuing his research upon these lines the fact becomes the more palpable that it is almost a rule that the contour of the uterus, instead of being an oval convexity posteriorly with plane surface anteriorly, is widely variable in almost every case of a multiparous uterus. And if the theory of unequal growth or development is to hold, it seems of primary importance that its defenders should be able to prove that a majority of uteri with unequal walls are displaced. Again, arrest of development signifies at once impairment of nutrition upon the affected wall, which must act toward degenerative changes in the endometrium, and even this as a clinical symptom I cannot find either in practice or substantiated in literature by its most radical defenders.

Two symptoms above all others seem to occupy the field of literature as pathognomonic of anteflexion—dysmenorrhœa and sterility. Both are attributed to the one cause—obstruction or stenosis at the point of flexion. It is to be noted then that the flexion occurs in the immediate vicinity of the internal os, and it is precisely at this point where stenosis occurs in a majority of all other cases without anteflexion. It would again seem only logical that if the anteflexion were the cause of stenosis no relief could come except by straightening out the anteflexion. We all know how exhaustive have been the measures devised with this object in view, even to incising the cervix up to the angle of flexion, and still relief has not come. Relief more often depends upon divulsion of the os without any other measures. But then, if the theory of flexion as a cause of stenosis does not stand, another equally important element arises for sustainers of its merits, in the necessity of proof that even a majority of women with stenosis have anteflexion, and here again proof is wanting. Nor do the advocates who believe anteflexions to be a cause of dysmenorrhœa seem able to prove that even a majority of women who suffer from such a symptom have anteflexion. I cannot do better than quote from Hart and Barbour the interesting results of Vedeler: "In 37.3 per cent. (25 out of 67)"—considerably less than one-half—"of patients with dysmenorrhœa had a well-marked anteflexion, and that 33.3 per cent (46 out of 138)"—only a slightly greater difference—"of patients without dysmenorrhœa also had well-marked anteflexion;" but even with this how common Vedeler considers anteflexion and anteversion I quote from another place.[1] "Among 3,102 women examined by him he found 66 per cent. affected with anteversions and anteflexions, and only 15 per cent. in whom normal positions could be demonstrated." And yet he gives us these statistics to prove how commonly dysmenorrhœa depends upon anteflexion.

It would be interesting, did time permit, to pass in review upon the literature of observers who publish their statistics. I touch upon them merely as evidence of how deeply the errors regarding displacements of the uterus have become befogged in the errors of dissension among its defenders.

[1] "American System of Gynæcology," vol. ii., p. 1101.

It is just as erroneous to consider sterility a result of flexion as dysmenorrhœa or stenosis. Says Dr. A. Reeves Jackson in his article upon "Sterility" in the "American System of Gynæcology": "I have known many instances in which there existed a flexion so acute as to prevent the introduction of the sound and to occasion severe dysmenorrhœa, and yet conception took place shortly after marriage, without the subject having undergone any treatment whatever." "In 114 cases of sterility reported by Biegel" only "40—that is 35 per cent.—had displacement," and the further analysis shows that 26 (74 per cent.) of the displacements had simple version, and only 12 (30 per cent.) of the displacements, or 10.6 per cent. of the entire number, had flexion. And these statistics came, too, from a man who believes in displacement of the uterus as a cause of sterility, and is giving statistics as evidence of his assertion.

Retroflexion[1] presents a peculiarity in the marked degree to which the fundus sometimes falls backward in the cul-de-sac of Douglas. In some cases so marked does this appear that the examining finger seems to come in contact with the globular fundal body upon a plane even lower than that of the cervix. To assume that here we have not to deal with a pathological condition seems a radical departure from the usually accepted theory, and were it proved that any pathological change were constantly present in the uterine wall or function were impossible, I would admit a pathological condition. But what I have already said regarding anteflexion applies equally well to this condition, with the single addendum that complications are more frequent and the train of symptoms is dissimilar from that of the contiguous organs affected. It is not the general claim that either dysmenorrhœa or sterility is so frequent in retroflexion or retroversion as in the anterior inclinations. On the contrary, it is within my own experience, and verified by others, that women with retroversion are the most prolific of all, and how often is it within our observation to have patients presenting themselves with a profuse cervical catarrh, so that presumably pregnancy would be impossible, and yet within a brief time have them return to us well established in conception! The explanation is simple in view of what I have said regarding conception, and most effectually demonstrates that the apparent displacement does not in the least interfere with function. The mucous plug, so-called, being dislodged from the cervix previous to the menstrual flux, the semen is thrown directly within the uterine cavity in a coitus just preceding or following the flow. Among the most common symptoms attributed to retroversion or retroflexion, and likewise considered a prolific cause of the latter, are the mechanical obstruction they oppose to the passage of the contents of the rectum and the varied subjective sensations resulting therefrom. That the cause of retroflexion is to some extent explained by such a theory seems only a logical conclusion, if we concede that

[1] The author feels constrained, lest the reader fall into the same error of dissension as was developed in the discussion regarding whether displacement posteriorly is not at times a pathological condition, to remark here that such is by no means the case, and can arise only in the mind of any one who inconsiderately regards physiological transposition and anomalies of anatomy as interchangeable terms in this connection. To be more blunt, the uterus cannot be displaced pathologically, unless it be possibly from without its range of physiological transportation so as to destroy the function of its physiological repositions, as per paragraph 5: "the womb of necessity, from its purpose to the animal world, is a mobile organ . . . limited in its range of physiological transportation only by the surrounding walls of the cavity in which it lies." It is not claimed by the author that a retroflexion with the fundus low down in the posterior cul-de-sac is not to be looked upon as an anomaly of anatomy, but unless function is impaired or some complication present it cannot be regarded as physiologically abnormal, any more than would be a transposition of the viscera within the chest.

primarily the fundal body is retroverted and in contact with the rectal wall, so that the descending fæces are here lodged and their weight acts to bear it down into the posterior cul-de-sac. But if it be true that this is all the claim advanced in favor of its being a pathological condition, I pass upon it in such connection as irrelevant to uterine pathology. So far as my own conception of its etiology goes, the most probable cause of retroversion—the flexion arising secondarily—lies in a short posterior vaginal wall, acting in conjunction with the utero-sacral and vesical ligaments. In retroversion it is a well-noted fact that the usual patulous cul-de-sac apparent in other positions at the posterior vaginal vault is absent, and the vaginal attachment to cervix is immediate and direct. This theory, too, seems well borne out by the imperfect invagination of the cervix at the vaginal vault in cases of laceration, and the relief and reposition effected through the influence of the retroversion pessary. The inventors of this instrument of course conceived its *modus operandi* as one of mechanical leverage, but in practice, its inferior arm resting upon the pubic arch, the superior arm carries upward the posterior vaginal vault and with it the cervix, so that, gravity acting through the fundus, it falls forward in anteversion without any leverage whatever. I do not, however, wish to be understood as believing that no other influences are at work to make the womb assume its condition of retroversion. One competent observer[1] holds a view, contrariwise, that it is because of a short anterior vaginal wall, a distended bladder of necessity thus acting upon a fixed cervix to force it backward into a condition of retroversion. Due weight I also grant to the varied inclinations of the pelvis and the direction and situation of the vaginal canal, as mentioned in the first part of this paper. Many and varied are the influences at work to make the womb assume its backward inclinations—that all are physiological is my chief point of contention.

It would prove tedious were I to review at any length my own statistics. I give therefore only a few observations bearing directly upon the points in question: Of four hundred and twelve cases examined by me in which full private notes were kept, four only are recorded with displacement, and all these, needless to say, are prolapsus in varying degree. But in the physical examination where are recorded as accurately as possible the size, condition, and direction of the cervix, the relation and direction of the fundus to the cervix in each individual case, I find ten in which the angle of flexion or version is very marked and one in which the whole organ lies in a decidedly retroposed position. Of the ten, seven have anteversio-flexion and three retroversio-flexion; but in all these which even I have conceded as worthy of special note but one is recorded to have stenosis, and this as "stenosis with pinhole os," while throughout the entire four hundred and twelve cases thirty-two had a well-marked stenosis. Thus, in a review and comparison, while my statistics do not include so great a number of flexions and version as would those of believers in displacement, their general import of lesions from which symptoms might arise is in full harmony with those published by other observers.

From habit it has become the custom of gynæcologists, when a nulliparous woman presents herself giving a history of pain preceding the menstrual flow, passing away as the flow becomes established, to consider such as depending upon an anteflexion with blocking of the internal os, before even a digital examination is made, when the real condition is irrelevant to either the blocking of the os or the flexion. Whether this be true or not is most easy of demonstration in nearly all cases, by fixing or steadying the cervix before attempting to pass the probe. It is a fact seldom realized by the experienced clinician in his daily practice that many cases he passes upon as acute flexions, by reason of not permitting the passage of the probe, really have a moderately patulous os. How much dexterity is required to pass a probe within the uterine cavity with even the normal os was forcibly demonstrated to me during my early clinical experience, when I had the opportunity to observe a large number of undergraduate students in their first attempt to pass a sound. It was the exception with them that the instrument ever passed beyond the internal constriction except in the most patulous cervices, and since then in my clinic I have observed how often physicians and assistants commit the same error of passing the probe up to the internal os in such manner as to cause spasm and preclude its further introduction, and I have no doubt the same error is often committed by those of wide experience. In many cases, in my own hands at least, I have met with failure to pass the probe from the omission of that one essential rapid sweep just as the instrument was approaching the internal os, and thought I had to deal with a flexion so acute as not to permit a sweep around it, when a subsequent trial with proper procedure revealed the internal constriction moderately patulous and perforate. Another equally erroneous impression concerning flexion as a cause of stenosis is that too large an instrument is first tried, so that any definite idea of the actual calibre of the canal is precluded at once. Yet conceiving that all judicious efforts fail to pass the probe, none can deny that there is still a canal there of calibre sufficient to admit of the healthy discharge of woman's normal relations in life; else how so many who never suffer from an unpleasant symptom and bear large families of healthy, robust children? And just here comes a logical explanation of the cause of dysmenorrhœa so often misapplied to flexion. Schultze has forcibly dwelt upon it in its pathological relation to metritis, yet here evidently is a direct pathological lesion in which we have the uterine stroma as the underlying cause (other observers have explained its production from intra-uterine clots); but, physiologically considered, its most probable explanation is in an unduly intimate apposition and hyperæsthesia of the two opposing surfaces of the endometrium. That dysmenorrhœa has not the least to do with flexion is by no means an original idea advanced by myself, but is a subject discussed by all recent authors. I call attention to it as unavoidably associated with the subject under discussion. Says Dr. W. Gill Wylie:[1] "Years ago I abandoned the prevailing belief that anteflexion frequently causes dysmenorrhœa directly, by mechanically closing the canal." If we review in brief the general pelvic hyperæmia going on within the pelvic cavity for a few days preceding each monthly period, a more concise understanding of the irrelevance between flexion and dysmenorrhœa is obtained. If we conceive that the general hyperæmia has only a special predilection for the uterine mucosa and ovarian stroma, it becomes plain how two closely opposing surfaces, such as I have just mentioned, must act to increase the tension within the uterine cavity, thus producing pain as a natural result of the engorgement and swelling, in conjunction with muscular contraction, which occurs in every case. The pain subsides coincidently with the disintegration and discharge of the endometrium and by release of the transient engorgement of the utricular vessels. It is manifestly against the laws of rudimentary physics to hold that the pain is produced by a damming back of the blood within the uterine cavity until tension becomes so great as to

[1] Dr. George T. Harrison, "American System of Gynecology," vol. ii., p. 1112.

[1] "American System of Gynecology," vol. i., p. 423.

lift up the fundus uteri and the canal is sufficiently straightened to allow exit to the flow, for here is primarily an increase of weight from both the engorgement and the blood within the cavity, which, instead of tending to elevate the fundus, acts directly to the contrary and tends to lower it and thus increase the angle of flexion. It has further been pointed out in connection with the mechanical theory of an obstruction to the flow at the point of flexion[1] that fluid blood passes with ease through a capillary. Will any one hold that even stenosis or flexion so closes the os as not to make its lumen greater than that of a capillary?

It would be manifestly unjust before proceeding to the general summary did I not touch upon that one other form of displacement, so-called retroposition, to which I referred in my statistics; yet this to me seems most absurd of all. How it becomes possible to call an organ displaced which lies at the base of a truncated cone, such as the vagina is admitted to be, when the manifest mobility of that organ is limited only by the radius of the cavity in which it lies, is beyond my comprehension. We all know how yielding are the vaginal walls, so that every portion of the pelvic cavity can be palpated through its limited membranes, and yet we are told that it is displacement when the uterus lies a little posterior to the median line. To dwell further upon such a condition as pathological seems needless tautology.

Thus far not a reference have I made to pathological complications attending the uterus in its new positions or supposed displacements. This has been purposely, so that in the general summary I may consider them as a whole, for manifestly the complications attending a so-called displacement in any one position are common to all, and their discussion separately would involve needless repetition and confound the issue.

If apparent displacement of the uterus is a pathological condition, some pathological lesion should attend it in every transposed position. I am unable to find such a claim advanced by the most radical defenders of the doctrine. The diseases attending the uterus in its new position are only the same as those which occur in its most common position, nor is it within my experience to observe that they are here more violent. The chief and perhaps most common complications attributed to displacements are the perimetritic or parametritic processes going on in the surrounding cellular and connective tissues buried at the vaginal vault and cervix uteri. It is only just to admit, however, that in the recent literature the more careful observers indirectly concede that inclinations of the womb are not pathological except for the accompanying complications. For them anteversion is not a pathological condition unless the cervix be fixed. Schultze makes the observation that flexion is not pathological unless there is rigidity at the point of flexion. If this much be admitted, what more is left for the great majority of observers who would argue contrariwise regarding anteversion and anteflexion? I have previously said that in carefully perusing the literature I could not find one particle of authentic evidence in confirmation of the supposition that any particular pathological lesion is present at the point of flexion. In the literature, however, metritis seems to occupy the chief field, as presumably the cause of rigidity fixing the uterus in a condition of flexion. Now metritis is a very indefinite and vague term. A majority of observers class anything from venous stasis to the interstitial hyperplasia of Thomas as metritis, but in any stage of transition between these two extremes there is manifestly no more rigidity at the point of flexion than in any other part of the organ, and hence it is a needless confounding of the issue to consider such a condition as in any manner relevant to the displacement. Relief attends only upon a proper involution of the uterus, regardless of any attention whatever directed to the flexion. But yet an argument which might be advanced is that the metritis is the result primarily of the markedly anterior deviation of the uterus. Then must follow logically the reposition of the uterus to effect a cure of the metritis. By any one familiar with pelvic manipulation in dealing with such a condition, the procedure would be looked upon as little short of malpractice.

It is more to be deprecated than all else that our specialists of to-day, in dealing with their subjects, seem to have lost sight of the fact that the particular tissues which they treat are only a part of the general whole going to make up the animal economy; that the mucous membranes and cellular tissues of the nares, pharynx, intestines, vagina, and elsewhere partake in general of the same structure and are governed by the same general laws in one situation as in another. Particularly is dissension regarding tissue construction to be noted among gynæcologists in the wide discussion prevalent concerning the connective and cellular tissues of the pelvic cavity. As to the correctness of the terms perimetritis or parametritis, or whether we have to deal with a pelvic cellulitis or peritonitis, it concerns us little in the present discussion; it is only from deductions of the general results produced by pathological processes in other regions of the body when these tissues are affected that we are able to understand their proper relations and bearing upon lesions affecting the uterus. When they are viewed in such a light only, is it forcibly borne home to us that it is in every case the perimetritis and adhesions which produce the symptoms, and not the apparent displacement. It makes little or no difference what position the uterus is in: if it is bound by adhesions or surrounded by parametritic processes, the same train of symptoms is bound to follow, and to effect relief it is these complications which must be attacked and not the organ itself. It is true that when adhesions are present the uterus more often affords us a tangible body upon which to obtain a hold for exerting force *pro* and *con*, to break up the adhesions; but if the organ itself be the seat of metritis, endometritis, cervicitis, or endocervicitis, or if the adnexa suffer from the diseases to which they are liable, none will dare claim that these are cured by releasing the adhesions. Their treatment requires the same measures, and only the same, irrespective of whether adhesions are present or absent. It is a claim, however, advanced by most authors that displacements often result from contractions of the perimetritic connective tissues, thus compelling the uterus to assume an unnatural position. From what we know of connective-tissue contractions in other regions of the body we believe that they are largely influenced by atmospheric irritation. In the pelvis atmospheric irritation is excluded, and, so far as my own experience goes, the position of the uterus has not been in the least altered after the onset of adhesions from what it was in its original state. Let us take for example acute gonorrhœa. This is admittedly not a plastic disease—two surfaces affected with the gonorrhœal process cannot be made to adhere; and yet, as a subsequent symptom following within a longer or shorter period of time, a majority of gonorrhœal cases return to us with well-marked adhesions; but it is not within my experience, so far as I remember, to find a single case in which the position of the uterus was not the same as when the patient appeared with the initial lesion, though the adhesions were tedious and secondary in their formation. Now the explanation of the perimetritic process is simple and depends

[1] Hart and Barbour's "Manual."

upon two ways of production. The richly supplied lymphatic connective and cellular tissue buried about the vault of the vagina absorbs primarily the infectious products in which the vagina is bathed, and the disease, progressing upward and outward through the tubes, escapes into the peritoneal cavity and is precipitated into the posterior cul-de-sac; so that secondary absorption and inflammation also here occur, and the resulting perimetritic adhesions are due to the character of the tissue affected. These tissues possess an inherent property in themselves to carry on to the same end a plastic process, no matter what the exciting cause may be. It is pathologically improper to consider the process as a plastic one in its initial stages; rather it is one of an interstitial exudation between the meshes of the tissue structures. And thus in its onset, development, or maturity, there is lacking even one particle of evidence that contraction is an elementary part to which their structure would make them liable from their situation alone. In proctitis even, though the onset be more gradual and prolonged, the same result occurs, and, although here the utero-sacral ligaments with their connective and cellular structures are primarily involved, adhesion alone results, with no tendency to cause the womb to assume a backward displacement. But upon the other hand we can find an example of the very acute onset, in which the uterus is removed from its most common position, and it responds exactly with the influence of gravity and physiological cause in assuming its transposition. As a result of the craze for antiseptic irrigation following parturition, in the past few years, the gynæcologist of to-day reaps a rich harvest in the increased number of parametritic cases presenting themselves for treatment. To my mind the chief cause of this condition is the use of strong chemical irrigations immediately following delivery and during the puerperium, when the absorbents of the parturient canal are open receptacles for any infectious material which may come in contact with them; and it makes little difference regarding the onset of the perimetritic process whether we have as the exciting cause a chemical or aseptic infection, though the danger to life is much the greater in the latter. In the resulting fixation the uterus lies more posteriorly than in the other cases; in these, owing to the position of the patient upon the back it has fallen of its own weight, irrespective of any contraction of tissue, and become fixed even in the brief interim of the puerperium.

I need not review at length, after what has been said, my reasons for believing prolapsus to be a true displacement of the uterus. I am aware of the theory so beautifully dwelt upon in the manual of Hart and Barbour, where it is discussed as a condition of hernia of the pelvic floor, in which the uterus plays only a secondary part. This, it will be seen, accords with my own argument—that the uterus is not in pathological displacement unless removed from its proper plane of support; but that in prolapsus the hernia of the pelvic floor is always the primary factor seems at variance with both anatomical and physiological law. That only which is palpable in prolapsus as substantiating the theory of hernia is that descent of the organ is not possible without the complication of certain contiguous elements of the pelvic floor. But, considering what I have previously pointed out in connection with the positions of the uterus, the varying degree of inclinations of the pelvis, together with the position of the vagina and its introitus, the yielding condition of its walls, so that the uterus has not a fixed table upon which to rest—to believe that when the axis uteri is in line with the vaginal outlet it will not descend of its own weight, irrespective of influences from above or below, is beyond my better judgment. It is only from such a theory that I am able to account for those not exceptional cases in the virgin, in which distinct prolapse of varying degree is plainly present; and here evidently the pelvic floor plays not a primary but a secondary contributing part. Again, too, in my reference to uterine support proper, I could point out nothing in connection with uterine attachment which seemed to stand by itself as an anatomical factor of true support; to me the ligaments and attachments alone seemed to partake largely of physiological function, the uterus resting as a freely movable body upon the pelvic floor direct, with every attachment yielding and elastic. In prolapsus the elastic tone of the ligaments becomes impaired and the uterus falls off from its supporting plane, as it were, and descent is the logical result. That prolapsus is a pathological condition, also partaking of symptoms distinctly referable to and arising from its transposed position, and remedied only by its proper restoration, are points hardly open to denial.

In closing, I am aware that I leave unsaid anything regarding the lateral deviations or displacements of the uterus from the presence of tumors or the mechanical embarrassments arising from pregnancy when the uterus becomes lodged beneath the promontory of the sacrum. It seems to me the discussion of such conditions more properly belongs to the special subjects with which they have to deal. In one brief paper it is impossible to cover such an exhaustive field as displacements and dwell with the nicety of precision upon the anatomical and physiological data which the subject demands. I have endeavored to touch upon only the chief arguments advanced in the current literature upon displacements. That so-called displacements are not physiologically abnormal is my chief contention. While I concede that clinically we observe wide degrees of variation in flexions and versions in different cases, in all presumably some is present. We have no means of knowing precisely what are the influences producing what all concede to be a normal position, or what the exact purpose they serve the female in each individual case. That they are physiological none will contend. When they act to a degree of exaggeration they are physiological still.

ELECTROLYSIS IN THE TREATMENT OF DISEASES OF THE SKIN.[1]

By GEORGE THOMAS JACKSON, M.D.,

PROFESSOR OF DERMATOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN; INSTRUCTOR IN DERMATOLOGY, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, ETC.

When the history of electrolysis as a therapeutical agent in the treatment of some of the diseases of the skin comes to be written, the name of Dr. W. A. Hardaway will be at the head of the list of those who have taught the medical profession the value of this agent. To him we owe the practical application of electrolysis to the destruction of superfluous hair, its most important use. Not only this, but he has either originated a number of other operations or made practical suggestions in regard to them. It is not my intention to indulge in historical researches this evening, nor to quote authorities, but to give you some idea of what may be done by electrolysis, based for the most part on my own experience with it. Still I cannot let the opportunity pass without mentioning the name of Dr. Hardaway.

Electrolysis has been well-defined as electrical decomposition. We are interested in it only as applied to animal tissues. When two needles attached to the two poles of a galvanic battery are introduced

[1] Read before the Practitioners' Club of Newark, N. J., February 7, 1898.

into an animal tissue, around the negative pole (zinc element) alkalies are liberated, while at the positive pole (copper element) acids form. At the same time we notice bubbles of gas about the negative pole welling up alongside of the needle. These are bubbles of hydrogen caused by the potassium and sodium set free, uniting with the oxygen and decomposing the water in the tissues. The same chemical action produces caustic soda and potash, and these destroy the animal tissues just as they would if applied in the ordinary way.

At the positive pole oxygen and chlorine are produced. The tissues become oxidized and are more or less charred, just as after cauterization with a strong acid. At the same time the needle, if a steel one, is oxidized.

Thus are explained the phenomena met with in the use of electrolysis. The negative pole is most often used, as the scar from it is soft and pliable, just as the scar produced by a caustic alkali is softer and more pliable than is that caused by a strong acid. We notice in using a steel needle attached to the negative pole that it is readily withdrawn from the tissues, and is bright and clean. If the same needle is used attached to the positive pole, it sticks when we try to withdraw it, and we notice that it is oxidized. The skin at the point of entrance of the needle is liquefied, and a black point remains on healing. Therefore if it is considered to be advisable to use positive electrolysis, a platinum or gold needle should be employed.

Though electrolysis has been in use for more than twenty years, I meet educated physicians from time to time who know little about it and its uses. Some of them think that a faradic battery can be used, and some regard it as a species of galvano-cautery.

The battery to be used is a galvanic one: that is, one of constant current. It makes no difference whether dry or wet cells are used. I have always used wet cells — ordinary Leclanché cells. By means of proper apparatus the street current can be used.

The means of regulating the amount of current we are using are the switch board and the rheostat. My preference is for the switch board. At one time I used a rheostat, but it seemed to me that, though the current strength as expressed by milliampères was the same as by the use of the switch board, it gave more pain and caused a more lasting disturbance in the skin.

A milliampèremeter, though not absolutely essential, is a most desirable instrument. To be sure it is liable to get out of order, and may not register with absolute correctness; but without one, anything like accuracy cannot be attained. To speak of using so many cells is unscientific and inaccurate. Experience will convince you that on one patient you will get a current strength of, let us say, one and one-half milliampères from fifteen cells, while in the next patient you get the same current strength from five or six cells. The difference is dependent upon the individual, whether he is a good conductor or not, and this in its turn seems to depend largely upon the constitution of the skin. A moist, thin skin conducts the current much more readily than does a dry, thick skin. Atmospheric conditions affect the current also, but to nothing like the same extent as does the quality of the skin. In working, one must keep his eye upon the dial of the milliampèremeter, because the current sometimes lessens or increases after working a little time. Keeping the sponge electrode moistened with a soda solution will help to steady the current.

The instruments needed are, fortunately, few. They are a sponge electrode, a needle holder, needles, epilating forceps, and in my armamentarium a knife. I have found it of advantage to use a sponge electrode which is three and one-half inches in diameter. This insures a broad surface through which the current must pass, and is more comfortable for the patient and contributes to steadiness of current. If you use the small electrode furnished with the battery, some patients will rest only the tips of two fingers on the sponge, and thus reduce the amount of current. With the large electrode this is avoided. The size of the needle holder is a matter of taste. If your hand is large you should use a larger holder than if your hand is small. I use one about the diameter of an ordinary lead pencil, and about four inches long. The needles most used are what are called jewellers' broaches; Nos. 3, 5, and 7 are the most useful sizes. In some operations ordinary sewing-needles, fine cambric needles, are of use; and, as I have said already, if you wish to use positive electrolysis you have to use either a gold or platinum needle. A pair of light epilating forceps are necessary in working on superfluous hair. You should see that the blades coapt exactly and that the spring does not require much effort to manipulate it. Forceps with stiff spring tire the fingers. My knife is made by cutting off the handle of a tenotomy

Fig. 1.—Knife for use in electrolysis.

knife, such as is used in surgery of the eye, and fitting it into the needle holder. Its use will be described later in this paper.

Electrolysis is employed as a destructive agent. The advantages it has over other destructive agents, such as acids and caustic alkalies, are that its action is under the control of the operator; the amount of pain that it causes is moderate, and ceases as soon as the needle is withdrawn; and it is not liable to produce unsightly scars. The last is a very positive advantage when we wish to destroy new growths on the face. It is specially adapted to the treatment of hypertrichosis, nævi of all sorts, the dilated vessels in rosacea, fibromata and other small tumors, warts, xanthoma, lupus, milium, and molluscum. It is also one of the best means for removing powder stains.

By far its most important use is in the destruction of superfluous hair in *hypertrichosis*. So much has been written about this use of electrolysis that I feel some hesitancy in mentioning it at any length. However, as I am asked not infrequently by physicians if I think it possible to destroy hair permanently, I must presume that even in so intelligent a company as this there are some who are still doubtful whether hair can be permanently destroyed. After sixteen years of experience in this operation I am more convinced than ever that it is a most reliable one. It is tedious, and I should hail with delight any less tedious way of destroying hair. It is expensive for the patient, no matter how moderate fees may be charged; and it requires the greatest faith in the operator by the patient in some very bad cases, so that she may have the patience to endure to the end. The difficulties with which we have to contend are the impossibility of destroying every hair papilla at the first attempt, so that a certain number of hairs, varying with the skill of the operator, are bound to return; and the impracticability of destroying a non-existing hair, so that the patient must expect to have new hairs present themselves for destruction as long as the tendency to hair production continues. In young women this is our greatest trouble, as in them the beard will continue to thicken for a number of years, just as happens in the beard of a young man. If we tell our patients of these difficulties at the start, we will be able to hold them to the finish. I do not believe that the destruction of the old hairs tends to the stimulation of the lanugo hairs to any great extent. They will grow stronger after the old hairs are removed, but they would grow stronger had the old ones not been removed. Nor are scars a

necessary sequence to the operation. I have never yet heard one of my patients complain of scarring, because their faces are not scarred. That is to say, we cannot destroy a hair without destroying a minute area of skin about the hair follicle, but this is so minute that it is imperceptible in ordinary skins, while in fine skins it is only by putting the skin on the stretch in a strong cross light that the little points can be seen. On the upper lip it is extremely difficult to prevent a slight amount of scarring in some patients, but that is far less unsightly than is the hair. There are some skins that scar much more readily than others. It is good policy to tell any patient with a mustache that there is a liability of producing slight scars on the upper lip, and have it understood. This will prevent trouble in the future. The best subjects for the operation are women past middle life in whom the amount of hirsuties is usually slight, limited to a few coarse hairs on chin and lip. I always advise against operating on young women who present only lanugo hairs, because such hairs are more difficult to destroy than are coarser ones, and because they may not grow darker or coarser for years.

The *modus operandi* is doubtless familiar to all of you. The patient is seated in a chair with a head rest (I use a dentist's chair), and in a good light, but not directly in the sunlight. The hair to be removed is put slightly on the stretch by seizing it with the forceps; the needle in its needle-holder attached to the negative pole of the galvanic battery is passed down alongside the hair in its follicle and in the direction in which the hair grows, to a distance of about one-eighth of an inch; the current is completed by having the patient place her hand on the sponge electrode after the needle is in place; the gas bubbles up alongside of the needle, and in a half minute or less the hair slips out of the follicle with hardly any traction. The patient is then to take her hand off the sponge electrode, and the needle is to be removed. The current strength to be used is about one and one-half to two milliampères. If the needle is passed down alongside of the hair and the current is not completed until after the needle is in place, and broken when the hair is destroyed by having the patient take her hand off of the sponge, the operation will not prove very painful, most patients hardly seeming to mind it. If care is taken not to use high currents for a too long time, not to enter a follicle for the second time at any one sitting (and there is sometimes a temptation to do this when the needle has slipped out of the follicle before the hair has been destroyed), and not to remove the hairs in close proximity at the same sitting, there will be little danger of scarring. In working on an ordinary case it is my custom to remove every other hair over a certain part of the face, and afterward to take out the rest. When time permits, it is well to allow at least four days to pass between operations on the same side of the face. The after-effect of the operation on the skin varies with the patient. In some the redness caused by the current passes away very quickly, and the reaction is very slight. Most patients are not so fortunate, and the skin will show red spots looking not unlike acne and lasting for a week or more, while in some small pustules will form. If the operations are too near together in point of time, there will be generally considerable inflammatory reaction; and if at the same time with the frequent operations the hairs are removed too close to each other, superficial ulceration may result. In this way the deforming scars, seen as the outcome of some operator's work, are produced. If the surface to be worked on is thoroughly disinfected before we begin to work, the liability to the formation of pustules will be lessened. For the past year I have bathed the parts operated on with peroxide of hydrogen immediately after operation, and it has appeared to me that my results, as far as reaction is concerned, are better than before. Hot water and a zinc lotion, or cold cream used by the patient at home, will aid in combating the inflammatory reaction.

The destruction of *nævi* next claims our attention. We have vascular, pigmentary, and fibrous nævi to remove. Against all varieties electrolysis is a reliable agent. Should the nævus take the form of telangiectasis, that is broken veins, showing as a central dark red point with radiating vessels in all directions, it is readily destroyed by passing into the central point the end of a fine cambric needle, or of broach No. 3, attached to the negative pole of the battery, and allowing a current of one and one-half or two milliampères to pass for half a minute. The central point will be destroyed and the vessels radiating from it will disappear. In the other variety of telangiectasis, in which we have a patch composed of dilated blood-vessels, the vessels are to be destroyed in the same way as will be later described under rosacea. If we have what is commonly called a "birth mark" or a "port-wine mark" or "claret stain" to remove, it may be attacked in one of two ways. A No. 5 broach attached to the negative pole may be passed under the nævus just beneath the skin, and an endeavor made to destroy the vascular supply; or, which is the better way, the point of a fine cambric needle attached to the negative pole may be passed at a slight angle into the skin, making a series of punctures not too close to each other and in parallel lines across the patch. The current is to be made and broken in the same way as in the removal of hair, and the needle should go through into the subcutaneous tissues or lower part of the corium. Before beginning to work, it is well to make a series of dots with pen and ink at the places into which you propose to pass the needle. If this is not done, the field of vision is soon obscured by the reaction in the skin. By operating on the patch over and over in this way, you will gradually lessen the redness. Care must be taken not to substitute a prominent white scar for the red patch. What we strive for is the production of a pinkish patch. The only objection to this method of destroying nævi is that it is slow in working a cure. Deforming scars will not result, as will sometimes be the case when we use acids. If care is had to pass the needle down through the whole thickness of the skin and slightly on the slant, perseverance in repeating the operation will result in the removal of the nævus. If one has practised electrolytic destruction of hair, he will have acquired the requisite patience for this operation.

Cavernous nævus is another form of vascular nævus that can be cured by electrolysis. If the tumor is of very large size and rapidly growing larger, surgical procedures of another kind are demanded. I have cured several nævi of this variety, as large as three-quarters of an inch in diameter, and prominently raised above the surface of the skin. In this operation a No. 3 broach or a cambric needle is to be passed through and beneath the growth, and a current of two to five milliampères used. Several tracts are to be made parallel to each other; or the needle may be partially withdrawn and again passed through the nævus in several directions, radiating from the point of puncture. The latter method is perhaps the better. No hemorrhage will be caused. At the time of operation the tumor will appear blanched over the course of the needle. If you are successful in striking the blood-vessels of the growth at the first sitting, a rapid cure will result. In most cases several sittings will be necessary. After each sitting the tumor will become smaller and contraction will continue for some time, even without further operation. At last nothing will remain but a soft, pliable, and hardly noticeable

scar. By some it is recommended to use two needles, a gold or platinum one attached to the positive pole and a steel one attached to the negative pole, passing both needles into the growth at the same time. I have no experience with this method. If the patient is a baby, it can readily be held during the operation, that takes but a few minutes. In older children an anæsthetic must be given. Of course this will be unnecessary in an adult.

Pigmentary nævi may be destroyed in the same way as vascular nævi. As they are usually small, so-called moles, they may be destroyed by passing a No. 5 broach under them and through the upper layers of the skin, and using a current of one and one-half to two milliampères. In this way several tracks can be made. As the pigment is deposited in the lower part of the mucous layer of the skin, we should take care to wound the true skin as little as possible. It is quite possible to remove pigmentary moles without leaving a scar. The little knife, of which I have already spoken, has proved itself of value in my hands. Passing it flat under the upper layers of the epidermis and turning on the current, you can, by exercising very slight pressure on the needle holder, slice the nævus off. As electrolytic action is all the time taking place, when the slight wound is healed there will be no return of the pigmentation, nor will there be an easily perceptible scar. In cases in which we have not gone too deep there will be no scar.

In nævus pilosus it is necessary to destroy the hair before we try to destroy the pigmentary patch. The same method is employed in doing this as in destroying superfluous hair, only now, instead of using the fine broach and trying to produce as slight a mark as possible, I am in the habit of using a fine cambric sewing needle, with the purpose of destroying not only the hairs but also the skin about them. It is possible in this way to destroy not only the hair but the mole at the same time. If pigmentation is left after the hairs have been destroyed, it will be broken up in dots, so that all that is needful for us to do is to destroy these dots by passing into them perpendicularly the point of the cambric needle and letting the current run.

Fibrous nævi are readily removed by electrolysis, but as the method of doing so is the same as in fibromata, I will speak of them together later.

The dilated vessels of *rosacea* are best destroyed by passing a steel broach into the lumen of the vessels at an angle or perpendicularly to the vessel. When you strike the vessel right you will see coursing through the vessels in the neighborhood little bubbles of gas that bear a strong resemblance to the blood globules in the circulation of a frog's foot, as seen under the microscope. If the vessels are large and tortuous, it is advisable to puncture them several times in their course. In hypertrophic rosacea we can cause the lobulated masses, if not of too great size, to flatten out by making multiple punctures with the cambric-needle electrode. If the masses are large, they should be removed by the knife. A current strength of three to five milliampères should be used for the destruction of the lobules, while one and one-half to two milliampères are sufficient to destroy the vessels.

The electrolytic current is very efficient for the destruction of all sorts of *small tumors* about the face, where we desire to leave as little scar as possible. By it I have destroyed fibromata, warts, and fibrous nævi, and there is nothing better than it to destroy xanthomata. In *fibromata*, warts, and fibrous nævi, my little knife does the work beautifully. Attached to the negative pole of the battery, it is passed flat under the growth, and a current of two or three milliampères turned on. I usually pass under the middle of the growth. The tissues melt away, as it were, with much bubbling of gas. Gentle pressure on the knife will cause it slowly to work its way, not cut its way out, and one side of the growth is detached. Now the current is broken, to be again completed when the knife blade is turned in the opposite direction and the other half of the growth is detached. The advantages of electrolysis over the plain knife in the destruction of these growths are that the pain is slight, there is not the slightest drop of blood shed, and no subsequent dressings are needed, that are more or less unsightly; all that is necessary in the way of a dressing being carbolated vaseline or some such antiseptic for a few days. The result of this operation is usually good. A red disc is left that slowly becomes white and continues to contract, so that after a time it is hard to say where the growth had been. If unevenness of the skin should remain, it can be removed by electrolysis. Inasmuch as *warts* often can be made to disappear by more superficial caustics than electrolysis, the latter should be kept as a last resort.

It has chanced that since I have had my little knife I have not had a *xanthoma* to remove; but they are removable by means of electrolysis. To do this, a No. 5 or No. 7 broach must be used, passing it carefully under the growth, using a current of about two milliampères, breaking the current and removing the needle. Several passes are to be made at one sitting, depending upon the size of the growth.

Lupus, whether of the erythematous or the tuberculous variety, is always obstinate. We can scarcely hope to cure it without leaving scars; indeed, it of itself almost always leaves scars. In the treatment of *lupus erythematosus* I have never used electrolysis, but multiple puncture with it is well spoken of by Hardaway and others, and might be employed. In *lupus vulgaris* I have seen good results from its use. There are two ways of using it in this form of lupus. One is by a cambric needle. This is best adapted to those cases in which there are a number of the characteristic small brownish tubercles in and about the cicatrix. If a current of four to six milliampères is allowed to pass for a minute through each tubercle, the needle being entered perpendicularly, destruction of it will result. The same thing has been attempted by using a needle dipped in an acid or caustic alkali. It is usually the case that the acid or alkali, or at least a good part of it, is rubbed off at the surface of the skin, and that but a small portion of it is carried to a sufficient depth to do much good. On the contrary, in electrolysis the destructive action is most active at the point of the needle, so that we are able to destroy the tubercles through their entire depth. The other method of using electrolysis in lupus is by the button electrode, such as I now show you. You see that it is

Fig. 2.—Metal Button Electrode.

a round zinc plate, half an inch in diameter, set in a rubber bulb that is made to screw on to the usual handle of a sponge electrode. This can be used to destroy patches of lupus. It is to be placed over the patch and a current of five to seven milliampères passed through it for six or seven minutes. When the electrode is removed, it will be noticed that the patch is blanched, but soon little swellings and then drops of moisture appear at the sites of the tubercles. Crusts form over the places operated on, and fall in a week or so. The patch will then be seen to be flatter. After a few sittings the thickening will be so reduced that we will have only individual tubercles to deal with, and then it is best to use the needle. In extensive cases other methods are better than this, as

they act with more rapidity, and the patient is content to give up his time to the treatment. But in small patches it is a good method, as the patient is in no wise interfered with in his business, and has no operation to dread, and but little and passing pain to endure.

I have put down *milium* and *molluscum* as diseases that are amenable to electrolysis. And so they are, as either can be readily destroyed by it. But the usual methods of treating these diseases are so simple and leave so little to be desired that I do not specially recommend electrolysis in their treatment. *Keloids* of small size have been benefited by electrolysis, high currents being used. Small *epitheliomas* can be destroyed, but I prefer other means that are more radical.

For the removal of *powder stains* electrolysis is probably the best means we have. Of course if the patient is seen immediately after the accident has occurred that has driven into his face a lot of powder, we should try and pick out all the grains we can. Soon the powder disintegrates and the skin is stained just as it is stained by India ink in tattooing. If each black or blue dot is entered with the steel broach and the current passed just as in the destruction of superfluous hair, we will succeed in course of time in destroying all the powder marks, and substituting for them minute white cicatrices that are very much less noticeable than are the powder stains. If tattoo marks are also in dots, they can be destroyed in the same way. The absolute controllability of electrolytic action makes it pre-eminently more fit than any other destructive agent for the removal of these deforming stains.

14 East Thirty-First Street.

NEW AND ORIGINAL[1] METHOD OF OSTEOPLASTIC RESECTION OF THE SKULL.

By J. J. BUCHANAN, M.D.,

SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

A satisfactory method of osteoplastic resection of the skull has long been desired. It is believed that the procedure here described will be found to have advantages over those hitherto employed. Among these may be named the following:

1. It causes very little injury to the bone.
2. It is not attended by jarring or other possible injury to the brain.
3. It is free from danger to the dura mater.
4. It is precise in its results and the flap is capable of any required variation of shape.
5. The bone flap, when returned to place, fits exactly and has no tendency whatever to displacement.
6. It is easy and comparatively rapid of execution, causing no fatigue to the operator.
7. The instruments are simple, inexpensive, not liable to break or get out of order, and are not dependent on a motor of any kind.

The elements of the method are: (1) The selection of a flap suitable to the requirements of the case, usually in the form of a quadrangle, pentagon, or hexagon; (2) incision to the bone on all sides except at the base of the flap; (3) perforation of the cranium at each angle of the incision with a small mastoid trephine; (4) separation of the dura mater from the cranium between the points of perforation; (5) sawing the bone between the perforations with a Gigli-Haertel wire saw, passed between the bone and dura mater from one perforation to the next; and (6) lifting the flap of scalp and bone from the dura mater.

The instruments required are:

1. Shapes most generally useful for outlining the flaps. These are pentagons or hexagons, usually with sides 5 cm. long. These shapes are of aluminium or double-faced rubber cloth, either material being capable of sterilization without injury.
2. A slightly conical trephine 6 mm. in diameter.
3. A dural separator 3 mm. wide, blunt extremity slightly wider and thicker, grooved upper surface, very slightly curved from end to end, turning rather abruptly upward at each extremity. The shape is important. The length between the curves at the extremities is 5 cm.
4. Gigli-Haertel wire saws, 30 cm. long. This is the instrument the use of which distinguishes this procedure from those hitherto proposed.
5. Small blunt hook to lift the loop of the saw from the trephine opening.
6. Two bone elevators.

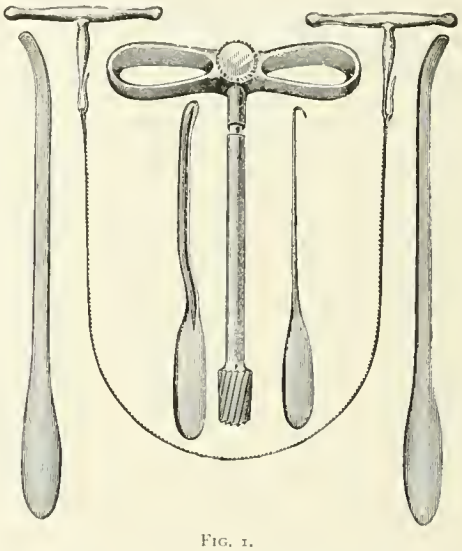

Fig. 1.

The Operation.—In selecting the shape and direction of the flap, regard should be had for the area it is desired to uncover and the location of the vessels of the scalp entering its base. A distance of 5 cm. between openings will usually be found most convenient, although longer intervals may be separated and sawn without trouble. Impromptu and atypical outlines may be used, but ordinarily a set figure, selected beforehand, will be most satisfactory. The pentagon shown in the figure may be made to form several different flaps by using different sides for the base and by reversing the figure.

An incision having been made to the bone along all the sides of the figure laid out except its base, trephine openings are made at each angle in the usual manner. The small size of the trephine renders this a very easy matter.

The dural separator is now passed into one of the openings and, by gentle lateral movements, made to separate the dura mater from the skull till its extremity can be seen at the bottom of the adjoining opening.

In case the skull is thick, it may be necessary to chip away, with a chisel, the perpendicular edge of the trephine hole into which the separator enters at that part of its circumference which is opposite the

[1] When this article was prepared, the writer had no knowledge of any previous work of the kind. It was in the hands of the editor of the Medical Record on December 12th, but its publication was delayed by misplacement of the cuts. In the *Philadelphia Medical Journal* of January 1, 1898, Professor Keen reported a case operated on by the method here set forth, and stated that he had read a description of it in the *Centralblatt für Chirurgie*, August 14, 1897, in an article by Professor Obalinski. The present belated paper, having lost its claim to priority, may serve to call attention to the value of the operative procedure.

opening toward which it is directed. This allows the separator to enter obliquely to the surface and easily follow the surface of the dura mater. In thin skulls this will be found unnecessary.

When the end of the separator appears at the bottom of the adjoining opening, a wire saw is passed

Fig. 2.

along its groove till the looped extremity of the saw appears at the bottom of the trephine opening, through which it is drawn with the blunt hook. The handles of the wire saw are then attached and the separator is held in place by an assistant, who at the same time steadies the head. The saw is then made to cut its way out, which it does with surprising ease. Any possible injury to the dura is obviated by retaining the separator in place during the sawing; but no injury has been observed even when the dura has been left unprotected. During the sawing the hands should be kept well apart, for the saw is apt to break if used at an acute angle.

This proceeding is to be repeated with all sides of the flap except the base, which can be sawed nearly through without injury to the overlying scalp.

The elevators are used to pry the flap up, and very

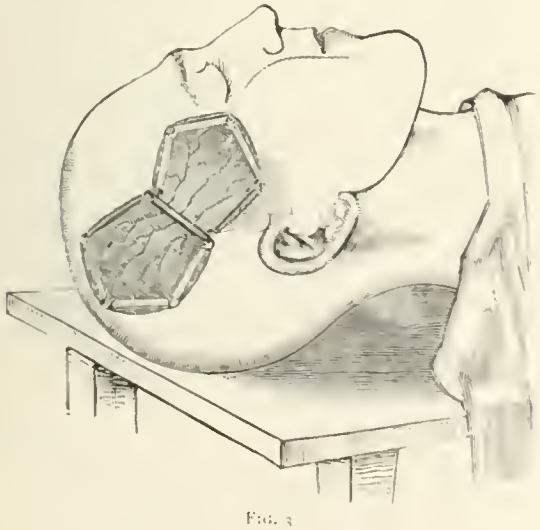

Fig. 3.

little force is required to break the unsawed portion at the base.

When the flap is returned, it fits precisely and cannot possibly be displaced. The only loss of bone is at the trephine openings, while between the sawed surfaces a sheet of paper cannot be passed.

It is hoped that an extended clinical trial may prove this method as satisfactory as it has been in numerous experiments on the cadaver.

The simple instruments required (with the exception of the saws) have been made in a satisfactory manner by Messrs. Feick Brothers, of this city.

VICARIOUS MENSTRUATION, WITH REPORT OF CASES.*

By ROBERT F. COUGHLIN, M.D.,

[illegible]

Assistant Physician to the Norwegian Hospital, [illegible]

A certain writer, in an article on "Vicarious Menstruation," began the same in the following manner: "It is quite generally stated, at the beginning of reports or papers on medical topics, that the subject is an unusually important one. In the present instance the beaten track must be left, for the subject is not of very great importance, though I trust it may be of sufficient interest to warrant brief consideration." In beginning my paper, I feel that I shall have to differ from this writer, and follow along the same old "beaten track." The subject appears to me to be of great importance, as well as interest, and before finishing I hope to be able to explain to you why the subject is so important. The number of cases to be reported is small, but sufficient, I believe, for the purpose. The definition of vicarious menstruation, as given by Billings in his dictionary, is: "A term applied to a bloody discharge from the rectum, nose, or other part of the body, or from an ulcer, occurring in the female at the menstrual period."

The majority of the profession have no doubt as to there being such a condition as vicarious menstruation. A number, however, believe that this condition never occurs.

Although the British Gynæcological Society gave this subject considerable attention, I have failed to find very much literature in regard to the same. Dr. Robert Barnes,[1] in 1886, published a review of the subject, in which he relates many of the explanations advanced to account for these phenomena, such as plethora, the surplus of blood being discharged at the point of least resistance; a weakened condition of the tissues, due to hereditary disease or other causes; abnormal structure of the vessels in the locality from which the blood is effused; a deprivation of the natural tegument of the organs from wounds, ulcers, etc.; the hemorrhagic diathesis; nervous influences; a supplementary relation of the various organs of the body, etc. In his treatment of vicarious menstruation, he directs attention to the removal of mechanical obstructions, the correction of constitutional derangements which give rise to the nervous influences bearing directly on the disorder, the treatment of diseased conditions at the seat of hemorrhage, and the application of such measures as bleeding from the foot and leeching of the vulva. Hot water and iodine should be used to stimulate the uterus, the useful drugs being hamamelis, gossypium, digitalis, ergot, iodine, mercury, and arsenic. Purgatives, diuretics, and faradization are often of use.

Although the condition is generally considered harmless, Holmes[2] reports one case in which the cause of death was intestinal hemorrhage.

Kobern,[3] in 1896, reported a case of acute tuberculosis concealed by vicarious bleeding taking place through the lungs. He therefore states that the prog-

* Read before the Norwegian Hospital Alumni Society, January [illegible], 1898.

nosis should be guarded when there is bleeding from the lungs. Personally I believe that tuberculosis should be looked for in all cases of vicarious menstruation, as out of five cases I have to report two patients (forty per cent.) who became victims of acute tuberculosis. One other patient is still under observation, with the probability that she too will later develop the disease. All the cases to be reported have come under my personal observation within the last four years.

Case I.—Freda E——; birthplace, Sweden; age, twenty-one years; condition, unmarried. Family history: Patient is one of seven children, all of whom are living and healthy. One sister suffered for a while with amenorrhœa, but finally recovered entirely. Patient's father is alive and enjoys very good health. Mother of patient did not menstruate until she was past seventeen years of age. In her case before menstruation began she was troubled a great deal with anæmia and nose-bleeding attacks. Patient does not know whether these nose-bleeding attacks occurred at regular intervals or not, nor does she know whether they continued after her mother menstruated. There is no family history of insanity or lung diseases. Patient claims that she is the only one in the family who is at all nervous or of a nervous temperament.

Previous history: Patient has always been a healthy person, though more or less nervous. She says that she never has menstruated normally. When fifteen years of age she first noticed that her nose would bleed at regular intervals, the attacks occurring regularly every twenty-eight days, and lasting three days. This peculiar condition continued until she came to this country (about one year ago), when the attacks of vicarious bleeding became somewhat irregular. During these vicarious hemorrhages patient says that she becomes very nervous, worries a great deal, and is depressed generally; trivial affairs, which would not trouble her at any other time, irritate her—in fact, the slightest thing causes her to become very angry, and, as she expresses it, "quite beside herself." Physicians in her own country have treated her for her trouble by the use of medicines, but she has never undergone an examination. During first visit to my office a vaginal examination was refused. I gave a mixture containing iron, aloes, myrrh, cantharides, and guaiac.

February 12, 1893, patient returned, reporting no improvement. Upon inquiry she expressed her willingness to undergo an examination for her trouble.

Examination: A healthy appearing, well-developed young woman. Heart and lungs normal. Breasts moderately large. External genitals well developed and normal in every particular. Hymen intact. By using care the speculum was introduced without much pain or discomfort, and it was then found that the internal genitals were infantile. Cervix pink in color and very small. Os externum about the size of a pinhead. Vaginal walls pink in color and normal. Uterus, ovaries, and tubes could not be made out, probably because of their small size.

Treatment: Dilated cervix slowly and passed sound to the depth of two inches. Used application of iodine to uterine walls by means of applicator. Continued with emmenagogue mixture and gave pills containing quinine and strychnine.

February 19, 1893, patient returned, reporting improvement. Says she feels strong and well in every respect. Has had one attack of epistaxis since last visit (one week ago). Dilated cervical canal again, and used iodine as before. Complained of constipation, for which she was given pills consisting of aloes and myrrh. Stopped emmenagogue mixture and gave a pill containing iron, nux vomica, quinine, and conium.

March 14, 1893, reports further improvement in general health, but has not as yet menstruated. Has had two attacks of epistaxis since last visit. Used iodine application to uterine walls and continued with internal treatment.

March 22, 1893, continued improvement in general health and spirits; still there is no sign of menstruation. One attack of epistaxis since last visit. Applied iodine to uterus as before. Continued with tonic pills, and aloes and myrrh as a laxative.

April 5th, patient is improved markedly. She says she has no more pains or aches, and no longer worries at all. Nervous symptoms have entirely disappeared. Appetite is good. Sleeps well. Is very well nourished. One slight nose-bleeding attack since last visit. Continued local and internal treatment.

April 19th, no attack of epistaxis since last visit. Patient in very good condition. Continued treatment as before, and directed her to return in a month's time.

May 17th, patient continues to be in very good health. One slight attack of nose-bleed since last visit, which was one month ago. There has been no normal menstruation. Health perfect. Did not use local treatment during this visit, but gave orders to keep up constitutional treatment. Requested patient to return one month from to-day. She failed to return and I saw her no more.

The subsequent history of the patient shows that two years after she remained away from my office she suddenly developed insanity, was removed to an asylum, where she later died of phthisis pulmonalis. The form of insanity was said to be melancholia.

There are several facts to be considered in reviewing this case:

1st. The possible hereditary history, the mother of the patient having failed to menstruate until she was seventeen years of age. She too was subject to nose-bleeding attacks.

2d. The regularity of the vicarious bleeding before she came to this country, viz., occurring every twenty-eight days and lasting three days.

3d. As her nervous symptoms began to clear up and her general condition improve, the attacks of epistaxis became less frequent and finally discontinued when her health became perfect.

4th. The fact that she was a well-developed young woman in every respect, with the exception of her genital organs.

5th. That notwithstanding the persistent local applications of iodine and the internal treatment, there was no sign of the catamenia.

6th. The fact that she developed pulmonary phthisis after becoming suddenly insane.

Case II.—Mrs. M——; birthplace, United States; age, forty-six years; occupation, housewife. Family history: Patient's father was a very strong, healthy man, and lived to be seventy-six years old. Her mother was always a very delicate, frail woman, and at the age of forty-five years developed consumption and died. A brother also died of the same disease at the age of forty. A sister still lives at the age of fifty years. She is healthy and well, but is inclined to be neurotic. The grandparents of patient lived to be very old. None of patient's family so far as she knows ever had any vicarious bleeding.

Previous history: Patient has given birth to nine children, three of which are living. Five years ago she was operated upon for laceration of the cervix. Since the time of operation she has been fairly well. Throughout her menstrual life she has had more or less trouble at the menstrual periods, this trouble consisting in slight attacks of raising of blood, which has always been of a bright red color. Her physicians have told her never to mind these affairs, as they were perfectly natural, and, in fact, did her more good than harm. At the time of menstruation she as a rule has a great deal of pain, is nervous, depressed, and given

to crying spells. The menstrual flow for a number of years was very free at these times, often lasting eight or nine days, but of late it has been quite scanty. On the contrary, the raising or spitting up of blood has been more frequent and the amount of blood larger. Of late the patient fears that there may be some disease of her lungs.

Present condition: A large-framed, fairly healthy appearing woman, of middle age. Complains of the coughing up of blood during the menstrual periods. Says this never occurs at any other time. On yesterday menstruation began, and this morning she was seized with a very severe attack of hæmoptysis. Claims the amount of blood she lost was fully a quart, but of course she exaggerated in this regard. A physical examination of the chest showed a few bubbling or moist râles at the apices. No dulness on percussion. Vocal fremitus normal.

Treatment: Ergot and hamamelis for hemorrhage, combined with rest in bed and a nourishing diet. Subsequently antituberculous treatment was instituted, but in spite of all means to combat the disease she gradually lost flesh and strength, night sweats set in, cough became distressing, and, to make a long story short, she took on all the signs and symptoms of acute tuberculosis, from which she is now dying.

In this case certainly the vicarious bleeding from the lungs was a predisposing cause of the tuberculous disease.

Case III.—K. M——; birthplace, Ireland; age, twenty-four; occupation, servant; condition, unmarried.

Family history: Parents, brothers, and sisters healthy. No hereditary taint.

Previous history: At thirteen patient began to menstruate, and soon after this time she noticed a slight "sore" on her lower lip. At times this sore would bleed, the bleeding generally occurring at the menstrual epoch. Patient claims that the sore never troubles her between the "periods," as healing takes place promptly after the bleeding attacks, only to break out again at a subsequent mentrual period.

Present condition: A strong, healthy appearing young woman. Appetite good. Bowels regular. Sleep normal. General health good.

Complaint is made of condition of lower lip. Examination shows the same to present a vesicular purpuric eruption, situated near the median line on the mucous membrane of the lower lip. At the present time patient is menstruating. During this menstruation there has been no bleeding from sore on lip, but this she says is exceptional. Anæmia is present to some extent. No signs of tuberculosis discovered in this case.

Treatment: Constitutional for anæmia. Glyceride of tannin for local use.

This case was seen but once.

Case IV.—Mrs. D——; birthplace, Ireland; age, forty-six; occupation, housewife.

Family history: No hereditary taint.

Present condition: Was called in to see this patient because of an obstinate attack of epistaxis. Inquiry reveals the fact that these nose-bleeding attacks are very apt to occur at the menstrual periods. The present attack appears to be worse than usual. The commencement of this trouble dates back a number of years.

Physical examination: Patient very anæmic and much debilitated. No signs of tuberculosis present, though her general appearance is tuberculous.

Treatment: Ergot and hamamelis were given for hemorrhage, and later constitutional treatment was instituted with some degree of success.

Case V.—Miss A——; age, twenty-four; birthplace, United States; condition, unmarried; occupation, bookkeeper. Patient began to menstruate at fourteen. When about twenty years old she noticed a small rose-colored spot just under the left eye. This spot remains all the time, but during the menstrual period it becomes very bright, with slight swelling and redness surrounding. Nothing was advised in regard to treatment. There never had been any vicarious hemorrhage in this case.

Case VI.—Miss S——; birthplace, Germany; condition, unmarried; age, twenty-two; occupation, seamstress. Hereditary taint absent.

Previous history: Patient began to menstruate at sixteen. Was well and healthy up to six months ago, when she began to have vomiting-spells, which finally resulted in attacks of hæmatemesis. These bleedings are always worse during the menstrual periods.

Present condition: Patient is a delicate appearing young woman. Skin very pale, membranes anæmic. Lungs and heart normal. Patient seems very nervous and trembles during this examination. No tumor found in the epigastric region. Slight tenderness over region of stomach. Pain is always present after eating and is relieved after vomiting or as soon as the stomach is empty.

Treatment: Milk diet, rest, pepsin, bismuth, opium, and ergot.

Subsequent history: This patient was seen by me only once. I was enabled, however, to learn later that she improved after the time I saw her, but subsequently developed all the symptoms of melancholia, on account of which she was removed to an institution for the treatment of mental diseases.

Conclusions.—1st. There can be no doubt as to the actuality of vicarious menstruation.

2d. It is not an uncommon condition.

3d. It should not be lightly regarded, especially when there is any bleeding from the lungs.

4th. There is a close relationship between vicarious menstruation and pulmonary tuberculosis.

5th. The association of vicarious menstruation and nervous conditions.

6th. While Case V. was not a case of vicarious menstruation, strictly speaking, it presented a phenomenon similar to it.

7th. In Case VI. there was a possibility of the same being gastric ulcer; but as the bleedings were generally worse during the menstrual epoch, and as a rule occurred most frequently at these times, it is fair to assume that the nature of the affection partook of vicarious hemorrhage.

8th. The possible relationship between vicarious menstruation and certain forms of insanity, particularly depressed conditions, as, for example, melancholia.

A Mechanical Device for Separation of Urine in the Bladder.—An ingenious and simple device for separately catching the urine from the female ureters is one described by A. Neumann (*Deutsche medicinische Wochenschrift*, 1897, No. 43). It consists of a tube containing within it a distensible screen; after introduction of the tube into the bladder, this screen is pushed forward in such a manner as to divide the bladder sagittally into two parts, this artificial wall being held in place by its pressure on the anterior and posterior bladder walls. The finger in the vagina guides the screen so that it is central and between the openings of the two ureters. The author has diagnosed with this instrument a one-sided pyelo-nephritis. The method is simple, safe, and easy of execution.

REPORT OF A CASE OF REMOVAL OF THE APPENDIX; CŒLIOTOMY FOR SECONDARY PELVIC ABSCESS, FOLLOWED BY FÆCAL FISTULA; INTESTINAL RESECTION (WITH THE USE OF THE MURPHY BUTTON) IN THE SAME PATIENT.[1]

By RICHARD P. FRANCIS, A.B., M.D.,

SURGEON TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.; MEMBER OF THE NEW YORK ACADEMY OF MEDICINE; OF THE AMERICAN MEDICAL ASSOCIATION, AND OF THE ORANGE MOUNTAIN MEDICAL SOCIETY.

In this eminently surgical age, when asepsis and skilful technique have made many operations, once most formidable and rare, matters of every-day occurrence, one hesitates to ask the attention of his professional brethren to the account of a single case, lest what seems most noteworthy and exceptional to him may to others be but another repetition of a tale too often told.

There are few who make any pretence to surgery who have not removed the appendix: secondary abscess, necessitating a second operation, has often been reported; and, since Murphy introduced his button in 1892, the ingenious and time-saving device has been used scores of times.

Yet, in spite of all this, it is believed that the following case has points of interest that are worthy of being placed on record. It certainly gives weighty proof of the necessity of immediate operation in certain kinds of appendicitis; it illustrates the fact that fæcal fistulæ should be kept under observation until closed; and, more than all, shows how a strong and healthy constitution, backed by that intangible, all-important factor, the *vis medicatrix naturæ*, will help the surgeon more than knowledge, skill, dexterity, and patience. The history of the case is as follows:

The patient, W. F——, was a boy, fourteen years old, who had always been in good health except for frequent attacks of indigestion. In the spring of 1897 one of these attacks kept him in the house for three or four days. At this time the possibility of there being some inflammatory action in or about the appendix was considered, but not seriously entertained. Since then he had been in apparently perfect health up to the time of his present illness.

On October 18, 1897, he was taken sick with general abdominal pain and nausea. When he was seen he next afternoon by the writer, there were pain and tenderness all over the lower half of the abdomen, more marked in both iliac fossæ; there were no dulness on percussion and no tumor; the temperature was 99° F. The next morning pain was rather more marked in the left iliac fossa, and the other signs were unchanged. In spite of the lack of grave symptoms, the patient's face had the appearance of one suffering from severe septic trouble. The diagnosis of perforative appendicitis with probable septic peritonitis was made, and was concurred in by Dr. T. W. Harvey, of Orange, who saw the patient in consultation about 11 A.M., and agreed that immediate operation was indicated.

Accordingly the patient was taken to the Mountainside Hospital, and at half-past three the operation was begun by the writer, assisted by Dr. Harvey. The appendix was found lying free, with the tip just over the brim of the pelvis. It was of the size of the little finger, red and angry looking, with two small spots of gangrene at the tip (after its removal it was found to contain an enterolith). There was general purulent pelvic peritonitis, but there were no adhesions. The appendix was removed, the abdominal cavity flushed with normal salt solution, and packed with sterile gauze. The operation lasted an hour, and there was very little shock. The next day there was a free discharge of clear serum from the wound, and everything was looking well. During the next week the general condition was good, except for a profuse mucous diarrhœa that was finally relieved by a dose of castor oil.

For the next three or four days there were nausea and pain across the abdomen, which became much distended and tympanitic; considerable flatus was passed without relief. The wound healed steadily and firmly by granulation. An examination made November 4th, two weeks after the operation, showed a distinct, symmetrical, rounded swelling, dull on percussion, to the left of the median line, three inches below the level of the umbilicus. Digital examination showed marked bulging of the anterior wall of the rectum. The diagnosis of secondary pelvic abscess was made, and, with the assistance of Dr. Harvey, the patient being under ether, an incision four inches long was made on the left side midway between the umbilicus and the anterior superior spine of the ilium. The small intestines presented at the wound and were found matted together, and on one coil two spots of gangrene, about two inches apart, were seen. With difficulty the adhesions were separated, until at a depth of some two inches the abscess was found, and from it was evacuated at least a pint of thin foul-smelling pus. The next day there was a free discharge of pus and fæcal matter from the wound.

A few days after this operation it was found that the gangrenous spots seen in the bowel at that time had broken down, and that there were two openings, each the size of a nickel, through which fæcal matter was discharged through the wound—the general abdominal cavity having been walled off by adhesions. Neither flatus nor fæces had passed by rectum, and though liquid nourishment was well taken and nutritive enemata were retained, the patient seemed to be losing flesh and strength, and it was feared that the openings were so high up in the bowel that he would starve to death if some radical measures were not taken. Meantime the abscess had been discharging freely.

Dr. McBurney, being called in consultation, advised against operation, thinking that, owing to the weak condition of the patient and in the presence of so large an amount of pus, it would be extra hazardous, and feeling convinced that sufficient nourishment could be assimilated. His advice was to keep the abscess well drained, and, for a while at least, allow the natural healing processes to take their course; if necessary, an operation for closing the fæcal fistula, or possibly a resection of the bowel, could be performed at a later date.

The subsequent progress proved the wisdom of this course. The next day there was an evacuation of fæcal matter through the rectum, the first for nearly two weeks, and the general condition began to improve forthwith. The abscess cavity contracted slowly, and finally ceased discharging.

From this time progress was uneventful and uninterrupted, except for a chill and rise of temperature to 104.5° F. on November 29th. No cause was found for this, and the next day and subsequently the temperature and pulse were normal.

The patient left the hospital December 17th. At this time the external wound had contracted to the size of the little finger; a probe could be readily passed into the two openings in the bowel; the sinus could be plugged with cotton, so that only three or four dressings were needed in the twenty-four hours; there were daily evacuations of the bowel through the rectum. In a week or ten days the patient could take short walks out of doors, and was in excellent general condition. The fistula contracted rapidly, and by January 1st was

[1] Presented at a meeting of the surgical section of the New York Academy of Medicine, held February 14, 1898, and at a meeting of the Orange Mountain Medical Society, held February 4, 1898.

of the size of a lead pencil. The hope was entertained that there was a good chance that no further operative interference would be needed.

On January 6th there was a sudden attack of vomiting, accompanied by moderate abdominal pain. Through the next day nausea and pain continued, necessitating an injection of morphine in the evening; an enema produced a large normal fæcal movement. The next day pain continued, and there was vomiting of abundant clear, odorless fluid, tinged with bile; there were two normal stools following enemata, and about noon a discharge from the rectum of nearly a pint of shreddy mucus. This was followed by relief of pain for two or three hours. During the next day, the fourth from the beginning of symptoms, vomiting continued and the paroxysms of pain were very severe and frequent. There had been no rise of temperature, and the pulse remained about 80. It should be noted that there had been no discharge through the fistula since the beginning of the attack. A probe could be passed for about an inch into the fistula and there stopped. It seemed probable that the lumen of the bowel had been obliterated, and that an operation was a matter of necessity.

Accordingly on the next day, January 10th, the patient was again taken to the Mountainside Hospital, and the operation was performed by the writer, assisted by Dr. Harvey. As there was some doubt about the site of the obstruction, a median incision was first made, and through this it was seen that the colon was collapsed and empty, while coils of the small bowel were much dilated and reddened. Exploration showed no cause for obstruction, other than what might be at the fistula. In order to make this exploration in a satisfactory manner, the incision was extended in both directions nearly from the umbilicus to the pubes. Attention was now turned to the fistula, which, at the beginning of the operation, had been packed with iodoform gauze. Two elliptical incisions, joining at either end so as to include the scar and fistula between them, were made. As was expected, the knuckle of bowel containing the two openings was adherent here, and, pressing upon it and constricting it, were three or four other knuckles of bowel, adherent to the abdominal wall and to each other. With much difficulty and the consumption of valuable time these adhesions were all separated, but, in spite of care, a rent an inch long was made through the bowel wall at one point. This was closed with a Lembert suture of fine silk.

It was now possible to lift from the abdominal cavity the knuckle of bowel that was adherent to the fistula. The two openings in it were about as large as when they were first seen months before, showing that the obstruction had not been due to cicatricial contraction. This piece of bowel, some three or four inches long, was excised, and an end-to-end anastomosis made by means of a Murphy button. In doing this a V-shaped piece was excised from the mesentery, which had been previously tied off with catgut. The joined bowel was then dropped back, the abdominal cavity was freely flushed with hot decinormal salt solution, and both wounds were closed with silkworm-gut sutures, without drainage.

Owing to several difficulties encountered—much bloody oozing, particularly near the scar, the separation of the intestinal adhesions, the repair of the rent in the bowel, etc.—the operation lasted nearly three hours. The patient had been freely stimulated with strychnine and whiskey, and by two or three enemata of hot salt solution (and also by the salt solution put in the abdominal cavity), but at the close of the operation he was in a state of profound shock. The pulse was 195 and barely perceptible at the wrist; the respirations were shallow and rapid; the skin was cold and clammy. Stimulants, external and internal, were freely used, and with their aid, but more with the aid of the extraordinary vitality and recuperative power which had been shown throughout the illness from its beginning in October, the patient rallied, and in twelve hours the pulse had dropped to 160 and the general condition correspondingly improved. For the next two days there was naturally much anxiety felt whether all probable complications had been safely avoided. Within four or five hours after the insertion of the button there was a large liquid fæcal movement *per vias naturales*—this showing that all obstruction had been removed and that the joint was tight, temporarily at least. From this time forward the functions of the bowel were performed naturally and without disturbance. There was some inflammatory action in and about the wounds, due undoubtedly to skin infection, which is not surprising when it is remembered that a fæcal fistula had been discharging for two months. The wound, however, healed practically by first intention.

Two days after the operation the temperature rose to 102° F., and for the remainder of the week was between 100° and 101° F.; after this it was normal. The pulse continued over 100 for a week. The diet consisted exclusively of liquids, not including milk, until the button was passed, after which it was gradually increased. On the eleventh day the button could be felt in the rectum with the tip of the finger; as it was not passed after a copious enema, it was readily removed by the finger the next day.

Three weeks from the day of the operation the patient was discharged from the hospital, well. Since then he has gained rapidly in flesh and strength, and now seems perfectly sound.

Progress of Medical Science.

Acute Partial Enterocele.—Dr. Frank A. Stahl, *Journal of the American Medical Association*, October 2, 1897, closes a long and quite exhaustive article on the subject of acute partial entrocele with the following: "1st. Acute partial entrocele does occur. 2d. The symptoms of an acute partial enterocele are of a milder type than those of a complete enterocele; if this enterocele is strangulated the vomiting is not stercoraceous, constipation is not absolute. Exceptionally, the reaction is so slight that the condition continues unrecognized. 3d. Because of the mildness of symptoms, smallness of size, and its tendency to disappear, it requires most careful differentiation. 4th. Acute partial enterocele is to be especially differentiated in its early form from enlarged inguinal gland; in its later or inflammatory form from an adenitis suppurativa. 5th. The acute form of partial enterocele, if not relieved, either induces the usual reactionary changes of an acute hernia or it is converted gradually into the chronic form of partial enterocele. 6th. Its treatment is reduction, by taxis or herniotomy."

Motor and Sensory Channels in the Cord.—The generally quoted conclusions from experiments are that motor channels cross at the bulb, sensory channels in the cord. Both statements must be qualified, and we may say at once that, whereas precision will be added to the first statement, reservations to the second must be made amounting almost to contradiction. With regard to motor channels, while their major part cross at the decussation of the pyramids, a minor part (in man) cross in the spinal cord, and we shall see that these parts are picked out by degeneration, as well as recognizable by their tardy development, as the crossed and direct pyramidal tracts. But with regard to sensory channels, the evidence is far more uncertain and unfinished. Clinical evidence shows that the sensory

tract crosses somewhere, but not where; until recently the statement was repeated unchallenged, and by mere force of repetition acquired perhaps undue credit, to the effect that sensory channels cross in the cord. Now, however, there is an increasing disposition to abandon this view; the recent experiments of Gotch and Horsley, and those of Mott, have yielded evidence in opposition. The electrical token of centripetal impulses has been found most pronounced on the same side of the cord as excitation; monkeys after hemisection have been found with the less sensitive leg on the same side as the lesion, as was originally stated by Galen seventeen hundred years ago, presumably from experiments on monkeys. To such opposition evidence must also be added the indirect testimony of degeneration—ascending degenerations above a hemisection are most marked on the same side of the cord, and degenerations between the bulbar nuclei and the cerebral cortex cross the middle line at the decussation of the fillet. We seem, in fact, to be approaching the conclusion that sensory as well as motor channels have their major decussation in the bulb, their minor decussation in the cord: in which case we must admit that sensory impulses from each side of the body can pass up both sides of the cord, but that most pass on the same side.—Dr. Augustus Waller, "An Introduction to Human Physiology," page 481.

Treatment of Gonorrhœa in Children.—Dr. Jules Janet, in his article on gonorrhœa, in the *Revue de Thérapeutique Médico-Chirurgicale*, December 15, 1897, says that this affection is especially frequent in little girls, although it may be encountered quite as often in small boys. Dr. Viger has cured a gonorrhea in a boy of two years by means of permanganate washings, twelve to twenty-five centigrams to the thousand. Dr Janet had no experience of this kind, and he gives no rules for its treatment, but he has quite frequently cared for little girls. In these cases the localizations of the gonococci are less numerous than in the woman, because the urethro-vulvar glands are less developed. The most frequent site is the vulva and the vagina, more rarely the urethra and the rectum, and very exceptionally the uterus and adnexa. The diagnosis of vulvo-vaginal infection presents no difficulty. That of urethral infection is made in the following manner: Wash the vulva and vagina with borated water; then introduce by the vaginal orifice an olivary explorer of appropriate calibre and slight resistance, and by means of this the urethra is pressed forward and one obtains a urethral drop if there is infection. This exploration should be made at least two hours after the last micturition. Diagnosis of ano-rectal gonorrhea presents no difficulties, but the uterine variety can be diagnosticated only with an endoscope. This is difficult and necessitates a special outfit, so that it is not necessary to go into details. The treatment of these different localizations of the affection is similar to that of homologous foci in women, but necessitates a small instrument. The author prefers a short fine Nélaton sound (five centimetres in length, 9 Charrière in calibre) pierced only at the extremity. After the vulva has been carefully washed with tampons of cotton steeped in permanganate of potassium (fifty centigrams to one thousand) the syringe is filled with the same solution. The beak is armed with the little sound anointed with glycerin, and this is introduced into the vagina, which is then copiously irrigated. In the beginning this treatment should be repeated twice daily, a little later once. It can be done by the nurse. Later one abandons the irrigations, but the child should be kept under observation, so that any relapse may be treated early. In other cases the treatment is more difficult and must be carried out by the physican himself. There are sometimes mucous para-urethral diverticula which are so deep that they need especial irrigation with a small syringe armed with a fine metallic cannula. If the urethra is infected, after the vulva and vagina have been washed, a new Nélaton sound like that used in irrigation of the vagina is introduced into the urethra; the urine is evacuated and a permanganate solution (twenty-five centigrams to one thousand) is injected with the syringe. The urethral orifice is well opened and the child is made to expel the permanganate introduced into the bladder. It is prudent not to repeat this operation oftener than once a day, and to stop as soon as the urethra seems to be disinfected, for this disinfection takes place more frequently than that of the vulva and vagina, and it is not so liable to reinfect itself, especially if one is careful to continue washing the vulva with permanganate solutions several times daily. This last precaution is useful in all cases, even in simple vulvo-vaginitis. The treatment of ano-rectal gonorrhea consists in washing the anus with cotton tampons steaped in permanganate of potassium (fifty centigrams to the thousand), then injecting into the rectum with a large short Nélaton sound fifty grams of the same solution, which the child will evacuate immediately afterward. The treatment should be repeated once daily.

Vaginal Irrigations.—Irrigations of hot water at 104° to 122° F. act by the heat, which increases the circulation of the pelvic viscera. At a temperature of from 104° to 112° F. they have vasodilating action, while at a temperature of 112° to 122° F. they cause constriction of the vessels. The latter temperatures are indicated in certain forms of metritis, especially the atrophic type when due to prolonged lactation or to early menopause in stout subjects. In these cases the hot vaginal douche will regulate the uterine functions and the menses. Hot irrigations are of considerable value in chronic metritis, with a hard uterus, due to venous stasis, and by their use the symptoms disappear, menstruation becomes more abundant, and the mucosa takes on its normal rose color. In metritis of puerperal subinvolution they cause a retraction of the enlarged organ, as well as the mucous transformation of the bloody lochia. In the abovementioned conditions it is often well to increase the effect of the irrigation by the addition of slightly irritating substances, such as the chloride or carbonate of sodium; but what is still better is a teaspoonful or two of the plain tincture of iodine to every quart of water. But under no circumstances should we use antiseptic substances, properly speaking, because they cause changes to occur in the epithelium and bring about absorption by the mucosa, whose power of absorbing is greatly increased by heat. Hot injections of 112° to 122° F. act remarkably well in cases of chronic peri-uterine inflammation, as well as in peri- and para-uterine exudations. Combined with rest, these exudations may become absorbed, and many patients are cured who at first might have appeared to be only suitable subjects for surgical interference. In such conditions the irrigations must be used in large quantities, at least two quarts morning and night. If the patient is not sick enough to be confined to bed, she should be instructed to remain on a sofa for two hours after each injection. It sometimes happens that the irrigation will make the pain worse, a fact which indicates that there is a recent, non-encapsulated pelvic exudation, often containing very virulent bacteria, and if this is present the irrigations must be immediately stopped for a certain lapse of time. The same applies when the pain increases in cases of pelvic abscess of peri-uterine origin with an acute or febrile evolution.—*Annals of Gynecology and Pediatry*, September.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 4, 1898.

THE THYROID.

THERE was a time when the scientist was inclined to accept the dicta of his co-workers, and when he quietly digested the results of some new discoveries without the fear of having them discredited before they had barely been swallowed. But times have changed, and the *fin-de-siècle* atmosphere has penetrated the laboratories of the chemist, the physiologist, and the pathologist. At the present time refutation and disputation follow closely on the heels of the announcement.

Perhaps in no field of experimental medicine have the reports of the past half of the decade been so discordant and difficult to bring into correlation as those bearing upon the physiological activity of the thyroid gland and its kindred structures. While there have been published excellent *résumés* of small fields of this discussion, the ground as a whole has not been thoroughly covered, so that the excellent and extensive discussion by Dr. R. H. Cunningham, "Experimental Thyroidism," *Journal of Experimental Medicine*, vol. iii., 1898, page 147, is especially opportune.

In this is presented a complete and well-rounded contribution, treating of all the important work that has gone before, with an extended series of experiments which have been conducted by the writer, with the view of bringing the many discordant views into some sort of harmony. As a result of his studies the writer draws the following conclusions:

1. Absolutely fresh thyroid gland is not poisonous, in the usual sense of the term, when absorbed through the alimentary canal.

2. The symptoms of induced thyroidism are manifestations of an intoxication resulting from the ingestion of decomposed thyroid material, a conclusion that agrees in part with the previously related observations of Lanz.

3. The so-called experimental thyroidism is not specific for the thyroid alone, for the ingestion of many substances derived from animal tissues other than the thyroid gland may produce an intoxication strikingly similar in every respect to that of experimental thyroidism.

4. Most, if not all, animal tissues yield substances which, if injected in large quantities directly into the circulation or beneath the skin, will produce an intoxication often very similar to that produced by injections of various substances derived from the fresh thyroid tissue.

5. The effects resulting from the intravascular or subcutaneous injections of aqueous extracts, decoctions, and concentrated extractives of the thyroid tissue, of the thymus, of muscle, etc., are by no means necessarily indicative of the function and the action of the hypothetical internal secretions of the same tissues during life.

6. The utilization of the fact that ingestion of decomposed thyroid material produces on certain occasions an intoxication with certain symptoms similar to those of Graves' disease is not justifiable for the furtherance of the theory that the symptoms of exophthalmic goitre result from an overproduction of the thyroid secretion.

7. Our results lead us to conclude with Drechsel that the fresh thyroid tissue yields at least probably two substances that are capable of palliating the symptoms of the acute cachexia in totally thyroidless dogs.

8. The thymus tissue also yields one and probably two substances that are equally as capable as the thyroid extractives of palliating the acute cachexia of totally thyroidless dogs.

9. Neither of the above substances is an enzyme, nor does either contain iodine.

10. Neither the feeding of minced raw thyroid glands, nor the injection of aqueous thyroid extracts, decoctions, and concentrated solutions of the extracted palliative thyroid principles is capable of keeping totally thyroidless young dogs alive longer than a few weeks (possibly three weeks). Still less capable are the thyroid preparations containing decomposition products.

11. The presence of one, or usually several, small accessory thyroid bodies, which gradually hypertrophy and wholly or partially assume the functions of the excised thyroid lobes, accounts for the occasionally long survival of thyroidectomized, thyroid-fed young dogs.

12. Totally thyroidless young dogs are so quickly overwhelmed by the cachexia, and the intervals between the thyroidectomy and the onset of the severe dyspnœic attacks, and subsequent deaths differ so slightly, no matter which of the usual varieties of fresh food is employed, that kinds of fresh food cannot be unquestionably affirmed to influence the onset of the cachexia in any especially definite manner. Animal foods, in which constituents poisonous to rabbits have developed, probably hasten slightly the onset of the severer symptoms, and the vaunted remarkable modifying influence of a diet of ordinary milk, such as Breisacher observed, does not exist in the case of the totally thyroidless dog.

13. Monkeys whose general metabolism is disturbed in consequence of the removal of a greater portion of the thyroid gland, evidently become more susceptible to those constituents of meat that are poisonous to rabbits, and sufficient clinical evidence exists for concluding that probably a like susceptibility to animal foods containing such constituents also exists in men

when the function of the thyroid gland is sufficiently disturbed.

14. And, finally, as regards the thyroid factor in the pathology of exophthalmic goitre, the writer agrees with Gley, that the majority of the symptoms in many patients with that disease can apparently, from an experimental standpoint, be as plausibly explained by the hypothesis of partially deficient thyroid activity as by the hypothesis of augmentation of thyroid function.

UNSANITARY CONDITIONS OF CUBA.

It has been computed that during our civil war one man in every thirteen died of disease, or proportionately five times as many as were killed in action. The proportion of deaths resulting from disease and wounds within the past three years has been infinitely higher than this rate among the Spanish troops stationed in Cuba. By some statisticians, it is asserted that no less a number than fifty per cent. have succumbed, the vast majority of whom have died from disease. That this is not an exaggerated statement seems probable from the report for 1896 of Dr. Angel de Larro Cerego, surgeon-general of the Spanish army in Cuba, which has just been published in Madrid, and, considering the source from which it emanates, may be taken as a fairly correct account. From it we gather that of the 200,000 Spanish troops landed in Cuba during that year, fifty per cent. were invalided in the first two months of their arrival by endemic diseases and exhaustive marches. Of the patients admitted to hospital during 1895, there were 7,034 suffering from yellow fever, the admissions from which reached 23,580 in 1896 and 4,636 in the first six months of 1897, making a total of 35,250 cases of yellow fever, of which 11,347 were fatal. The fact, too, must be borne in mind that this awful death rate takes no count of the mortuary records of this fever occurring outside the military hospitals in the towns and villages throughout the island. From June 30, 1896, to June 30, 1897, there were 79,552 cases of malaria of such severity as to necessitate the patients being sent to hospital. The island of Cuba, as is well known, has for long rested under the imputation of being one of the most unhealthy portions of the globe; the deadly palmetto swamps lying on either side of the trocha are from May to October hotbeds of malaria, in addition to the prevailing climatic fevers. In regard to the mortality among the Spanish soldiery, much of the excessively high death rate must certainly be ascribed to the lack of efficient sanitary measures and to improper food and clothing. It is stated that the rank and file of the army are attired in linen, in the dripping and feverous swamps in the rainy season, when the whole air is impregnated with fever germs. Yet, although there can be no doubt that the troops of this country will be looked after with far greater regard for their health than the unfortunate soldiers of Spain, still the fact must be faced that the dangers from disease will be very great, even though every precaution be taken. We drew attention some few weeks ago, in the Medical Record, to the absolute necessity of having sterilized water for the use of troops on active service, and then recommended the adoption of an efficient portable filter. Especial point is given to these remarks by a report published in the London *Lancet* of May 14th, which runs as follows: "Enteric fever is now very rare in Alexandria, where Berkefeld filters have been provided for about two years. The disease also is much less common in Cairo than it was before the introduction of efficient filters."

SOME REMARKS ON MALARIA.

In connection with the forthcoming invasion of Cuba, a paper read by Surgeon-Captain Rogers, at the meeting of the Epidemiological Society, held in London on February 18th, upon the influence of the movements of the ground water upon the incidence of malaria in India, may be commended as worthy of the attention of the military medical authorities of this country. This is especially the case in respect to some remarks made by *The Lancet* when commenting on this paper. These are as follows: "It is too commonly assumed that in malarial countries the disease is associated only, or at least chiefly, with swampy and with low-lying districts. Its endemic occurrence on the table-land of the Deccan, of which Chota Nagur (the district in which Dr. Rogers made his observations) forms a mountainous portion, is a sufficient refutation of this supposition." It certainly is true that we possess no very exact knowledge of malaria, despite the fact that it is probably the most widely spread and one of the most fatal to human life of any disease. Nevertheless, until some further and more convincing proofs are to hand to the contrary, the majority of persons will still cling to the old belief that it is more general as well as more virulent in low-lying swampy districts than in the higher lands. However, Dr. Rogers' observations upon the influence of the ground water upon the incidence of malaria were of a most interesting nature, the more so that he had the opportunity of studying the subject under exceptionally favorable conditions. He was in charge of four hundred soldiers. The ground-water level was taken twice a week in three wells contiguous to the camp, and the mean of these three levels was taken to represent the level of the ground water. As invariably occurs in those districts where malaria prevails, all but a very few of the cases happened in the rainy season. Dr. Rogers' investigations, however revealed the fact that the fever did not begin with the rain, but commenced to increase only when the rains had raised the ground-water level from twenty-five to sixteen and one-half feet from the surface, thus demonstrating that the heavier the rainfall the more prevalent the fever. *The Lancet* argues from this coincidence that Dr. Rogers appears to have established the fact that there is a causative relationship between certain movements and levels of the ground water and the incidence of malaria. This view seems to be a reasonable one to take, and, if justified by further investigations, will go far toward clearing up the question as to the incidence of malaria.

News of the Week.

Conference of State and Provincial Boards of Health of North America.—The thirteenth annual meeting of the conference of State and provincial boards of health of North America will be held in Detroit, Mich., August 9, 10, and 11, 1898. The "Quarter-Centennial Celebration of the Establishment of the Michigan State Board of Health" will be in progress at the time. After the meeting it is expected that the sanitarians from outside of Michigan will be given free transportation to various summer resorts. Therefore, it is hoped that all will come prepared to spend at least a week in Michigan. The first day, August 9th, will be given to meeting with the Michigan quarter-centennial celebration in effecting organization and hearing reports of committees. The second day will be given to answers to the following questions: "What are the principal lines of work of your board? How is each accomplished? What modification, if any, does the experience in your State suggest?" The third day, August 11th, will be given to discussion of "The Restriction and Prevention of Tuberculosis."

Use of a Brooklyn Hospital Offered to the Government.—The use of St. Catharine's Hospital in Brooklyn, with its mother superior, forty-five nuns, the entire hospital staff, and all the attendants, has been offered to the government. The institution is conducted by the sisters of St. Dominic.

The Western Ophthalmologic and Otolaryngologic Association.—The third annual meeting of this society was held in Chicago, April 7 and 8, 1898. The address of welcome was made by Dr. F. Henrotin, president of the Chicago Medical Society. Dr. A. Alt, of St. Louis, Mo., responded for the association. The annual address was then read by the president, Dr. B. E. Fryer, of Kansas City, Mo. After the usual routine business had been concluded, a scientific communication was read by Dr. Herman Knapp, of New York City. The ophthalmologic and otolaryngologic sections each held five separate and two joint sessions, many articles of interest being read and discussed. The last joint session was occupied with the exhibition of clinical cases. The following officers were elected for the ensuing year: *President*, Dr. J. Elliott Colburn, of Chicago; *First Vice-President*, Dr. W. Scheppegrell, of New Orleans; *Second Vice-President*, Dr. Casey A. Wood, of Chicago; *Third Vice-President*, Dr. H. Gifford, of Omaha, Neb.; *Treasurer*, Dr. W. L. Dayton, of Lincoln, Neb.; *Secretary*, Dr. F. M. Rumbold, of St. Louis. New Orleans was unanimously selected for the next meeting, which will take place just before the Mardi Gras of 1899, thus allowing the members to conclude their scientific session with the gayeties of the carnival season.

The Hospital Ship "Relief," now being fitted up here, will have accommodations for one hundred and fifty patients. All the staterooms on the main deck will be removed, giving space for large airy wards. The frames of the bunks, which will be in two tiers, are to be of gas pipe, and each cot will have a woven-wire and cotton mattress. On each side a wire screen will be attached to prevent the patient falling out with the rolling of the ship. Attached to the rear of each cot will be a wire crate to contain bandages, dressings, and medicines. The cots will be arranged in rows, the space between rows being wide enough to permit the easy passage of a litter and its bearers. On the port and starboard rails davits will be fixed, to which will be fastened cradles, to be raised and lowered by a steam windlass, by means of which the sick or wounded can be expeditiously raised to the deck from the transport barge alongside the ship. The cradle will then be run along a track to the ward, or to a bath-room if the patient's condition will allow of a bath. There is a disinfecting apparatus for the purification of the patient's clothes and of the mattresses and bed clothing after a cot has been vacated. There will be separate bath and toilet rooms for convalescing patients, for the officers and medical staff, and the nurses. There will also be an isolating-ward on the upper deck. The ship will also be provided with electric fans, an *x*-ray plant, a refrigerating plant, an ice-making machine, and a distilling plant. As quickly as possible the patients taken aboard the ship will be transferred to the nearest shore hospital. Dr. L. H. Williamson, of St. Louis, and Dr. R. M. Myers, of Washington, have been appointed to service on the *Relief*.

Measles is prevalent among the soldiers in camp at Hempstead, San Francisco, and elsewhere.

Trained Nurses for the Army and Navy.—A bill has been introduced in the house of representatives by Mr. Cummings, of New York, authorizing the secretaries of war and navy to enlist one hundred female nurses for service in hospitals and hospital ships during the war with Spain. The nurses must be graduates of training-schools, and will have the same pay as hospital stewards.

The Early Diagnosis of Measles.—Dr. F. P. Atkinson, of Surbiton, writes in *The Lancet* that he has carefully observed a number of children who had been exposed to the contagion of measles, and has noted that for a fortnight at least prior to the appearance of the influenza symptoms, although they seemed to be perfectly well and had a good appetite, the temperature persistently remained at 97° F., but it at once commenced to rise directly the running of the nose and eyes commenced. He thinks that in cases of doubt whether children have taken the infection or not, this may be of service in helping to a correct decision.

Mount Sinai Hospital.—Dr. Carl Koller has been appointed adjunct ophthalmic surgeon to the above institution.

The German Hospital of San Francisco has opened its doors to the Red Cross Society for the care of sick soldiers. The San Francisco branch of the Red Cross has raised over $30,000.

Dr. Anita McGee has been appointed to the duty of selecting nurses for the army. She is one of the vice-presidents-general of the Daughters of the Revolution, and wife of Dr. W. J. McGee.

Dr. Mavrogenis, of Athens, is said to be the last survivor of the Greek war of independence. He was born in 1798, and was one of the first to rise against the Turks in 1821.

Control of Tuberculosis in Denmark.—A committee of the Danish Medical Association has caused to be distributed throughout that country placards and pamphlets giving careful instructions for the prevention of tuberculosis. The placards are hung up in railway carriages and stations, schools, and factories, and the pamphlets are distributed gratis in public places. A movement is on foot also for the establishment in many parts of the country of sanatoria for consumptives. The disease has been increasing at an alarming rate in Denmark, and it is hoped that these measures will be successful in restricting its spread.

Contract Medical Practice.—The Connecticut State Medical Society, at the annual meeting recently held, passed a resolution discountenancing the making of contracts for medical service at a fixed annual rate with lodges, mutual-benefit societies, and medical clubs.

Dentists for the Army.—Representative Otey, of Virginia, has introduced a bill into congress providing for the appointment of a brigade dentist for each brigade, with the rank of major, and for each regiment, with the rank of captain.

A Convalescent Hospital is being fitted up at Fort Myer, Va., for the reception of all soldiers recovering from the effects of wounds or operations. They will be sent there from the other hospitals as soon as they are in condition to be transported without injury, and will be kept there until discharged cured.

Slander of a Physician.—The court of appeals of this State has recently handed down a decision of general interest, as showing that a medical man has some rights which an offended patient is bound to respect. A physician who was called in to attend a neighbor's daughter, prescribed belladonna for her. Within a few days she began to lose her eyesight, and became almost totally blind. When this loss of vision was first discovered, the attending physician and another who was called in consultation attributed it to the action of the belladonna, but later they came to the conclusion that it was not due to this cause. The doctor was obliged to sue for the payment of his bill, the defence being that the blindness was caused by the belladonna administered. The jury disagreed, but the man later paid the bill, or a portion of it. Afterward he published an article, asserting that the physician through his carelessness and ignorance in prescribing belladonna was directly responsible for the patient's loss of vision. The doctor then brought an action against the writer of the article for slander and libel. The expert witnesses all testified that belladonna could not have caused the blindness, but the court nevertheless acquitted the defendant. This decision has now been reversed by the court of appeals, the judge holding that the justification sought to be established by the defendant had failed, and that the verdict was against the weight of evidence.

The American Medical Temperance Association.—The annual meeting of this association will be held in this city at Prohibition Park, Borough of Richmond, on July 5th and 6th. Papers have been promised by Drs. T. H. Manley, D. H. Mann, J. J. Morisy, and Ira Van Gieson, of New York; W. Van R. Blighton, of Buffalo; M. H. Hunt, of Boston; F. Horner, of Marshall, Va.; Norman Kerr and Sims Woodhead, of London; and Sagrund, of Paris. The following are the officers of the association: *President*, N. S. Davis, Chicago, Ill.; *Vice-Presidents*, J. B. Whiting, Janesville, Wis., F. E. Yoakum, Shreveport, La., J. Taft, Cincinnati, Ohio; *Secretary*, T. D. Crothers, Hartford, Conn.; *Corresponding Secretary*, J. H. Kellogg, Battle Creek, Mich.; *Treasurer*, G. W. Webster, Chicago, Ill. The late Dr. Quimby, of Jersey City, was a vice-president of the society at the time of his death.

Hispano-Portuguese Surgical Congress.—The first meeting of this congress, which it has been arranged to hold every year in Spain and in Portugal alternately, was held in Madrid from April 18th to the 23d, under the presidency of Dr. Calvo y Martin. The list of communications included about ninety papers. The proceedings seem to have been somewhat hurried, or the orators and readers of papers were allowed a more liberal time limit than is customary elsewhere, inasmuch as of twenty-two communications on the programme of the first day only ten could be dealt with. Portugal was not represented at the congress.—*British Medical Journal.*

An Experiment in Government.—The San Diego (Cal.) Medical Society has turned over a new leaf and elected the women members to fill the offices instead of men. Dr. Magee, who has been secretary for ten years, stepped out and made room for Mrs. Dr. Nelson. During the present year the society will have a lady president, a lady vice-president, and a lady secretary. —*Kansas Medical Journal.*

"The Journal of Tropical Medicine" is the name of a new monthly journal to be published in London by John Bale, Sons & Danielsson, under the editorial management of Mr. James Cantlie and Dr. W. J. Simpson. As its name implies, the new periodical will be devoted to the publication of papers on tropical diseases and to the discussion of subjects, scientific and practical, affecting the interests of medical men in tropical and subtropical climates.

The California State Medical Society.—The twenty-eighth annual meeting of this society, recently held at Fresno, was marked by unseemly quarrelling, which culminated in a personal encounter between two of the members. The meeting was largely attended and the programme gave promise of much useful scientific discussion, but the politicians succeeded in creating a scandalous disturbance and bringing the medical profession of the State into disrepute.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twentieth Annual Meeting, Held in Brooklyn, N. Y., May 16, 17, and 18, 1898.

Monday, May 16th—First Day.

President's Address.—Dr. Thomas R. French, of Brooklyn, welcomed the members to Brooklyn. The history of the association was presented by Dr. Delavan in 1894, and the speaker would therefore confine his remarks to the progress in laryngology and rhinology in the past twenty years. Twenty years ago those who confined their work to one line were few; now their number was legion, and the tendency toward the selection of a special field for practice was growing stronger each year. In no department of medicine had the workers increased so fast as in laryngology. Years of practice together with natural aptitude were absolutely necessary in order to acquire skill in the surgical treatment of diseases of the larynx, but much less practice was required to permit intranasal surgical work to be done; this fact was unquestionably accountable for the large amount of indifferent or mischievous nasal surgery. The advice of Sir Morell Mackenzie ten years ago, that a man should practise medicine and surgery during the first ten years of his career, should be considered of greater value to-day than ever before. Despite the evils that were growing out of specialism, the fact that men were centring their thoughts on special lines of work more than ever would result in the largest amount of good to mankind. The advance of civilization was dependent upon the subdivision of labor. It therefore behooved us, individually and collectively, to think well on these things, that we might determine how best to secure for specialism the minimum of harm and the maximum of good. While the methods of treatment for laryngeal tuberculosis employed to-day gave better results than heretofore, we could scarcely look for signal success in dealing with this disease until the nature of tuberculosis was better understood. The speaker said that a corresponding fellow of the society, Dr. John Mackintyre, had succeeded in obtaining by the use of the *x*-ray an image of the septum, the roots of the teeth, and other hard structures in the neighborhood. He had also demonstrated the process of ossification in the thyroid cartilage. In a letter to the reader of the paper, dated January 6, 1898, Dr. Mackintyre had said that it was possible to get shadows of the larynx, but they were not so sharply defined as in the photographs of hard bone or foreign bodies.

The Laryngo-Tracheal Neoplasms of Tuberculosis.—Dr. J. N. Mackenzie, of Baltimore, read a paper with this title. He said the larynx and the trachea were the seat of various forms of neoplasms, which could be separated into three groups. In the first group was granular hyperplasia (ordinary granuloma). The second variety of growth might be termed papilloma; this was less common than the preceding, and was found in any part of the larynx, especially in the posterior wall. The speaker had found only one reference in literature giving the microscopical appearances of these growths, and in this instance the neoplasm was proved to consist of papillomatous tissue. In view of the fact that the essential nature of these neoplasms was as yet undetermined, he wished briefly to give the history of the following case. A man had tuberculosis of the lungs with consolidation at the right apex. The posterior part of the larynx was filled with a mass resembling pieces of coral. On the right vocal cord, on inspection, was seen a growth which extended under the cord, apparently springing from its free border. On phonation the growth passed beneath the cord on the opposite side. Several pieces were removed for examination. The microscopical report showed papillomatous nodules cut across and epithelium partly necrotic; also dense round cells, with a few giant cells. In the submucous layers the normal tissue was replaced by new tissue. The case fairly represented a type of laryngeal neoplasm found in tuberculosis. Microscopically it showed papillomatous tissue infected with tuberculous disease. The third variety was a true tuberculous tumor. In 1882 the speaker first called attention to this variety of tuberculosis occurring in the windpipe, and claimed that he was the first to give a description of this condition. By tuberculous tumor he meant an isolated, well-defined growth, occurring independently of ulceration or tuberculous infiltration, and covered by normal mucous membrane, with little or no tendency to ulcerate. These tumors were very rare, and he himself had seen but three cases. These cases should be clearly differentiated from ordinary infiltration, first by their gross appearances: histologically tuberculous tissue was found in the deeper parts of the growth, whereas in the ordinary infiltration the tuberculous mass was found under the epithelium. In regard to diagnosis, the growth might be confounded with malignant neoplasms, and the only certain way to differentiate was by the microscope. The color, situation, presence of tuberculosis in the body, etc., were of value in diagnosis, but the only crucial test was examination by the microscope. A great responsibility was imposed when a question of operation arose: we should not use the knife recklessly. As had been shown, these growths pursued a slow course with little tendency to ulceration, and unless serious interference with function was threatened, it was better to leave them alone; on a man in the last stages of tuberculosis it would be worse than useless to operate. In regard to the after-treatment, it had been advised to apply lactic acid or the galvano-cautery. In cases in which the joint was involved and the entire larynx seemed to be more or less affected, the question of extirpation would come up.

Dr. Delavan agreed with the reader of the paper in thinking that interference with these growths was liable to do harm. He thought the hypodermic or submucous injection of lactic acid better than any other form of treatment.

Dr. Rice, of New York, related the history of a case that he had seen one and one-half years ago, in which was found characteristic granulation tissue between the arytenoid cartilages. A few weeks ago this growth was seen to be slightly broken down and superficial ulceration existed. The growth was grayish in color, touching both vocal bands, and filled the posterior part of the larynx; it had not been examined microscopically.

Dr. H. L. Swain, of New Haven, said that one of the largest growths of the interarytenoid space that he ever had seen occurred in a tuberculous patient. The microscope showed evidences of papillary hypertrophy. In appearance it resembled papilloma. The patient was sent to the Adirondacks, where she remained a year and a half, when she returned home nearly cured and free from symptoms. She later developed tuberculosis of the wrist-joint.

Climatic Treatment of Laryngeal Tuberculosis.—Dr. W. F. Chappell, of New York, spoke of the climatic conditions and the general surroundings of Liberty, N. Y., and described the method of treatment, both local and general, in use at the Loomis Sanatorium.

Dr. Emil Mayer, of New York, said that in the treatment of these cases he had reached practically the same conclusion as Dr. Swain, that the patients, when sent to sanatoria, should be kept there for a much longer time than they were desirous of remaining. He thought small buildings or cabins to be used for sleeping advisable. The question as to where patients were to be sent was one of the utmost importance, whether to a clear, cold climate, to a dry climate, or to a warm one. In all these cases it should be borne in mind that the supervision of a competent physician was requisite.

Dr. James E. Newcomb, of New York, thought that in this country we were extremely lax in our care for this class of patients. Many felt that a case of tuberculosis was to be kept as short a time as possible, and then sent on to some one else. In sanatoria, patients became impressed with the fact that tuberculosis was a contagious disease, and it made them stronger allies of the physician in his efforts to have the sputa properly cared for, especially in the patient's home.

Dr. Thomas R. French, of Brooklyn, was favorably impressed with Dr. Mayer's cottage plan, and there was no question in his mind that all sanatoria should have but one or two rooms in each building.

Bernay's Sponge in the Nose and Nasopharynx as a Hæmostatic.—Dr. W. K. Simpson, of New York, demonstrated the use of the Bernay sponge, which, he said, consisted of cotton fibre subjected to many hundred pounds of pressure and compressed to a disc one-sixtieth of an inch in thickness. The sponge would swell to fifteen times its size and absorb twelve times its weight of liquids. Its efficacy in general surgery depended upon the absorbing power, which enabled it to be used as a cleansing agent and subsequently to pack the wound. Through this power of absorption and increase in size it exerted pressure, which was limited only by the size of the cavity in which it was packed. In tamponing the anterior or posterior nares these sponges had proved far more efficient than cotton or gauze, which had to be frequently reinserted; this inconvenience was not found with the Bernay sponge. Then the slow absorbing power of cotton or gauze was no guarantee against hemorrhage. In case of epistaxis, the sponge should be cut in semicircular form and introduced into the nostrils with the convexity upward. A string could be fastened to the sponge to assist in its removal. In tamponade of the posterior nares a disc could be used without shaping. As to the other uses, the speaker said he had found these sponges an excellent splint in the later stages of an Asch's operation for deflected septum. They were also of use in fracture. They could be covered with gutta percha and introduced into the nares to prevent adhesions forming after operations. They were useful as intranasal dressings by reason of their power of absorbing discharges. As a means of conveying medicament to various parts of the nose, they were also very useful. As in the case of all nasal tampons, hemorrhage might occur on their removal; this could be avoided by the application of some antiseptic ointment to the sponge before its introduction.

Dr. Mackenzie asked if the sudden expansion did not give rise to pain.

Dr. Swain asked if the sponge would contract so that it could be removed with ease.

Dr. Simpson, in answering Dr. Mackenzie's question, said that he had not noticed that it caused severe pain: that the expansion would be in proportion to the amount of hemorrhage. The cavity of the nose was soon filled by the sponge, with but little pain. The sponges were particularly applicable in those cases in which it was absolutely necessary that no hemorrhage should occur after operation. In answer to Dr. Swain, he said that the sponges did not contract; they continued to expand and were subject to the same rules as applied to any other packing.

Kirstein's Autoscope.—Dr. J. W. Gleitsmann, of New York, showed this instrument. It was for use in cases in which the laryngeal mirror did not disclose the posterior laryngeal wall. This autoscope should be used when one was satisfied that the whole larynx could not be seen. In the German Dispensary it was noticed that the patients on whom this instrument was used did not return. He thought there might have been a lack of dexterity in its employment. He had used it himself in Kirstein's clinic, and found that it could not be used satisfactorily without anæsthetizing the patient. The instrument could not be left *in situ* sufficiently long to obtain a good view of the larynx.

Enlargement of the Lingual Tonsils a Cause of a Cough.—Dr. Beverley Robinson, of New York, read a paper on this subject. For many years past, he said, it has been recognized that enlargement of the lingual tonsil is a cause of cough, although few appreciated the fact. Its beginning was insidious, especially in young adults. If the cough lasted for only a few hours the general practitioner usually examined the chest and then examined the throat; this examination being negative, he concluded that it was a stomach or a reflex cough. The speaker emphasized the point that impaired condition of general health and a continuance of a catarrhal relaxation were predisposing causes. Anæmia, constipation, and habitually irregular habits as regards food and rest were responsible for this condition. Overfeeding and indulgence in cake in children caused congestion of the lingual tonsil. Rheumatic dyscrasiæ, frequently found in adults, were causative factors which must be attended to. The symptoms of acute congestion of the lingual tonsil were mainly those of an irritative cough, and there was little to be learned on inspection. At first there was some expectoration, later it became thick muco-pus, and later still there was found blood, which came from an inflamed lingual tonsil. All the symptoms were worse at night. Sometimes the patient went to bed and slept from one to three hours, when he was aroused by a cough which anodynes failed to relieve, except for a short time. The speaker had noticed that the tonsil appeared red and swollen, and in his observation the left side was more frequently enlarged than the right. He had found the fossa completely filled by a swollen gland, which overlapped the border of the glottis. It should first be determined if any underlying dyscrasia was present, and if it was this should be treated. Gout and rheumatism should always be considered. Swollen lingual tonsils were unaffected by cough mixtures. External medication could not be relied upon. The compound tincture of iodine, with an equal amount of glycerin and water, applied every day, might reduce the size and generally acted well. Change of air was a very essential thing in the treatment. If there was marked renal deficiency, spirits of Mindererus was useful. If there was a malarial element, the use of Warburg's tincture was of benefit. For hypertrophy of the tonsil the speaker recommended, first, the electro-cautery; second, the snare; and third, ablation by means of the tonsillotome.

Dr. James E. Newcomb recommended the use of boroglyceride locally and oxalate of cerium internally, the latter drug being given so that one drachm was taken in the twenty-four hours.

Dr. Clarence C. Rice said that the lingual tonsil did not enlarge in early life. As regarded acute inflammations, physicians often overlooked these acute attacks of inflammation, which were put down as glossitis. The speaker did not believe that children had localized attacks of inflammation of the lingual tonsil

which were not secondary to inflammations in the neighborhood.

Dr. H. L. Swain, of New Haven, said he was interested in the subject of lingual tonsil, and that in 1885 he had given the *résumé* of sixty-six cases observed, in which he went into the histological condition of the tonsillar growth and its development. At birth there was no adenoid tissue to be observed at the base of the tongue. After zymotic diseases in children there resulted a congestion and an enlargement of the adenoid tissue at the vault of the pharynx, and accompanying these there was an enlargement of the lingual tonsil.

Dr. John O. Roe, of Rochester, said that the lingual tonsil was composed of the same structure as the faucial and pharyngeal tonsil, and that when there was an enlargement of one tonsil there was an enlargement of the other. A few years ago he invented a tonsillotome for the removal of the lingual tonsil, made somewhat on the same plan as the one of Dr. Mackenzie. In adults the instrument worked beautifully. He spoke of the varicose condition found at the base of the tongue. Sometimes a nodular mass was seen which had to be removed piecemeal, and here the growth should be snared with a stiff wire. This operation caused but little pain, especially when cocaine was used.

Dr. J. W. Gleitsmann, of New York, related the case of a woman who had an obstinate cough which was relieved after the removal of her tonsil. Later the cough returned, and another examination revealed a small hidden growth, the removal of which cured her. Cases occurring in children, in which cough was produced by an enlargement of the lingual tonsil, he had not had the opportunity to see.

Fracture and Depression of the Anterior Wall of the Maxillary Antrum, with Restoration of the Depressed Wall.—Dr. John O. Roe, of Rochester, reported this case. On the 15th of last February a woman, aged thirty-five years, got into an altercation with a man and received a severe blow with the fist, breaking in the anterior wall of the antrum like an eggshell. The speaker did not see the patient until three days after the accident. The face then presented a one-sided appearance, on account of the cavity which was situated in the cheek. An operation was performed. The upper lip was raised, the dissection being carried high; by keeping close to the bone there was but little hemorrhage. A hole was drilled through the antrum, entering the cavity through the canine fossa. By means of a curved sound the crushed wall of the antrum was raised into the right position. On the sixth day the dressings were removed. The antrum was cleansed until the hole existed no longer. There appeared no evidence of trouble, and the contour of the face was entirely normal.

The Treatment of Fractures of the Nose.—Dr. John O. Roe read another paper, with this title. He said these fractures were infrequent, on account of the yielding character of the cartilaginous septum. Fractures of the nose were the consequences of forces applied from without, and usually were the accompaniments of fracture of the superior maxilla. Such injuries were usually attended with severe hemorrhages. Fractures of the nose were usually bilateral. These fractures were classified as simple, compound, and comminuted. Injuries to the lacrymal apparatus affected the resonance of the voice, and one should therefore be careful in examining these parts. In the treatment, replacement of the parts should be done as speedily as possible after the receipt of the injury. Much swelling could be prevented by antiseptic measures. If the fracture was a compound one, the parts should be rendered aseptic and the wound brought together with sutures. In replacing the fragments the sound and little finger should be used conjointly. The smooth-bladed forceps was useful, but too much force should not be applied. If the septum was fractured, it should be replaced at the same time. These parts should be held in place by means of splints. The external one should be of aluminium or copper, and it could be shaped to the normal contour of the nose, and should be large enough to cover the entire nose. The edges of this splint should be fastened by a piece of adhesive plaster, while another piece strapped the whole thing to the side of the face. For the internal splint, the speaker had made two arms, one of which went on the floor of the nose and the other exerted general pressure from the outside. These two arms were so arranged that they could be regulated by means of a screw; by means of this sufficient pressure could be brought to bear to bring the parts to their normal position.

Dr. Casselberry, of Chicago, said the apparatus he used was made of plaster-of-Paris bandage, and was perfectly satisfactory. The parts should first be properly adjusted; elevation from within and support from without should be aimed at. Inside the nostril he used iodoform gauze, which was retained very well without much inflammatory reaction. The plaster-of-Paris bandage was first moistened and then passed across the nose, spreading it out over the cheek: this was moulded in place, and, by means of pieces of tape attached to the upper and lower angles, it was held in place. After it had become fixed and additional pressure was desired, pieces of cotton might be used. This dressing was extremely simple and very convenient, the only disadvantage being that it disfigured the patient for two or three weeks.

Dr. J. Payson Clark, of Boston, referred to the splint devised by Cobb, which, he said, consisted of a head band moulded to the head in the same way that one's hat was shaped to it. From the front of this two straight bands came down, and one could exert pressure on the parts which needed it.

Dr. George A. Leland, of Boston, mentioned the case of a patient who had been thrown out of a carriage and kicked by the horse, and had sustained a fracture of the nose. The superior maxilla was driven backward into the antrum. In these cases the interior of the nose bulged forward and so left plenty of room for the use of the finger in replacing the fragments. In these cases he advised the use of the finger rather than of the other instruments. He wished to emphasize the importance of intranasal rather than extranasal replacement of the fragments; also splints in the interior rather than upon the exterior of the nose.

Early Diagnosis of Whooping-Cough.—Dr. Henry L. Wagner, of San Francisco, read a paper with this title. In many cases one could shorten the duration and prevent the spread of this disease by adopting proper measures. This was especially interesting to the general practitioner, but particularly to the rhinologist and ophthalmologist, who so often saw this disease in its very beginning. The diagnosis could be made at once by bacteriological examination of the secretions. The nose was the primary place of infection. The secretions from a normal mucous membrane contained but very few bacteria, and in whooping-cough there was a large number of bacteria, especially of one kind. These bacteria were characteristic. The bacterium, when full grown, was two or three times as long as it was broad; it was rounded and somewhat thickened at the ends, and was divided apparently in the middle. It was surrounded by a capsule, not unlike Friedländer's pneumococcus. The method of staining was by using a one-per-cent. acetic-acid solution and then Loeffler's solution—fuchsin, 1; carbolic acid, 5; glycerin, 50; water, 100. The

speaker used plain aniline dyes. Argonin solution could also be used; this stained the bacteria blue and the cells red.

Dr. Swain asked if the speaker was successful in finding the bacteria in every case of whooping-cough; also how long before the patients began to cough.

Dr. Wagner answered that he had found them in every case. He considered the bacteria as really the cause and the primary cause; they might be found in the pharynx, but the most usual site for them was in the nose, and they could always be found before the whooping-cough set in

Leprous Ulcer of the Lip.—Dr. Henry L. Wagner, of San Francisco, reported a case of leprous ulcer of the lip. This had been considered to be rare, only one case having ever been reported. At the international congress it was held that the primary seat of this contagious disease was the mucous membrane of the upper respiratory tract. The disease could be communicated by contact. The case he reported occurred in a middle-aged white man who had lived in China. He consulted the speaker for a broken-down ulcer with small nodules on the lower lip. This had existed for many months, with little pain. The speaker suspected that it was syphilitic. The patient's nose and throat showed nothing abnormal. He scraped away some of the ulcer and submitted it to examination, which examination revealed a large number of lepra bacilli and innumerable suppurative bacilli. The lepra bacilli were lying about among the staphylococci and streptococci of suppuration. These bacilli were lying partly in and partly without the cells. The patient went away and unfortunately did not return.

The Use of Schleich's Solutions for Anæsthesia in Nose and Throat Operations.—Dr. Emil Mayer, of New York, read this paper. In 1895 Schleich presented his results from experiments with this new mixture. In its use, in the speaker's experience, there was no stage of excitement or any asphyxia or cyanosis. Bronchitis or broncho-pneumonia did not occur. It was rarely associated with vomiting and the patients became conscious in an incredibly short space of time. The speaker had used this method of anæsthetizing in twenty-three cases. Solution No. 1 being evanescent, it had not been used in twenty-one cases, but he was now better impressed with the use of No. 1, which he would use more in the future. There was no excitement; the tension of the pulse was markedly increased; the breathing was quiet, and in from three to five minutes after inhalation was discontinued there was complete consciousness. An average of six drachms was used. The youngest patient operated upon was two years of age. Schleich had used this method in more than one thousand cases without complications. He thought this rapid return to consciousness must be especially alluring. The speaker made the following deductions: Schleich's theory of adaptability of the boiling-point of the anæsthetic to the temperature of the body was amply proven; these mixtures were safe for short operations; there was no stage of excitement; the tension of the pulse was increased; the patient became rapidly conscious.

Dr. Delavan, of New York, thought well of this method. He referred to the plan of Mr. Bennett, of London, who, he said, used nitrous-oxide gas as a preliminary. It seemed to the speaker a satisfactory and safe method. The rapid return to consciousness he did not think was always desirable in throat work.

Dr. W. K. Simpson, of New York, thought that the rapidity with which the patients went under the anæsthetic and the rapidity with which they recovered from it were two great points in favor of this new compound.

Tuesday, May 17th—Second Day.

The Hoarseness of Singers.—Dr. S. W. Langmaid, of Boston, read this paper. In this condition the nasal mucous membrane, he said, was swollen, the turbinates were enlarged, and the larynx was congested. Occasionally there was absence of catarrhal affection, but there was a disability resulting from impaired muscular power of the glottis. Laryngitis was usually present. The acute catarrhal condition might be superimposed upon long-existing infection of the cavity by catarrh of the nose. The speaker then referred to the predisposing factors of this condition, such as neuroses, constitutional defects, anæmia, rheumatism, atmospheric conditions, etc. In these cases weakness of the intrinsic muscles—the tensors, the adductors, and sphincters—always existed. He briefly referred to the various conditions noted, such as the bending inward of one or both cords, the divergence of the posterior portion of the cords, and, what was more constant, deflection of one or both cords, more often only one. For some years he had noticed that when one cord was deflected it was the left, but of late years he had found the reverse true. He emphasized the importance of removing any inflammatory conditions, as but little good could be done while such conditions remained. First, treatment should be directed to the mucous membrane. If stenosis existed, it should be removed. The swellings should be reduced. If there was a septal spur or a deflected septum, it should be attended to. The glands in the posterior larnygeal space often interfered with singing in young persons. In the dry and painful state of the throat, steam inhalations were to be recommended. In the case of muscular weakness, strychnine was of benefit. Complete rest of voice was desirable.

Spasm of the Tensors of the Vocal Cords.—Dr. J. Edwin Rhodes, of Chicago, read a paper with this title. He said that dysphonia spastica was a very rare affection, Mackenzie having seen only thirteen cases. The condition was produced by an abnormal use of the voice; possibly there was also some neurotic condition not yet understood. It was an occupation neurosis, the same as writer's cramp. It was usually connected with some nasal affection. The symptoms appeared upon attempted phonation. The voice was a jerking one when it was made to pass from a low to a high tone, and there was difficulty in getting started. There was an involuntary breaking in the speech. Disturbances of reflexes and hysteria were other elements in its etiology. The prognosis was very unfavorable. In the treatment local applications, strychnine, sprays, etc., were of no benefit. The best possible treatment was long rest of the voice, general tonics, such as iron, arsenic, iodide of potassium, electrical treatment, etc. Astringent applications were sometimes of value. The use of cocaine in the nose relieved the spasm for some time, but of course this could not be recommended. One should not hope for any cure in any fixed line of treatment.

Dr. Simpson, of New York, said it was very pathetic to have singers, who had become hoarse, appeal for relief in order that they might go on with their occupation to gain a living. He had come to the conclusion that the fundamental cause of singers' hoarseness was to be found in the fact that the human larynx was never intended to be used for constant singing; this was not natural. The human larynx was intended to be used for conversation. This was shown to be true in amateurs as well as in professionals; even the de Reszkes must occasionally stop the use of their voice. The fundamental cause of this condition was overuse of the voice. The speaker referred to the baritone voice, in which a man had a natural baritone voice with limitation to high or low tones; when a baritone

made an effort to accentuate high or low tones, it produced a condition called stretching the vocal cords. When was the proper time to begin the use of the voice? In reply the speaker referred to the case of a young girl who began singing when very young; after three or four years she was absolutely unable to sing. In this case there was a lack of tension of the vocal cords. She had overstrained and was worked out. He also related the history of a case showing the other extreme. An elderly woman, aged fifty-five, had musical aspirations and thought she would take singing-lessons. She was put through the same drilling as others; she soon became hoarse and had marked swellings of both arytenoid cartilages.

Dr. Mackenzie, of Baltimore, reported a case occurring in a boy, aged sixteen. Ever since puberty he had been troubled with his voice changing into the falsetto. He had been under treatment since that period, about two years, when the speaker first saw him. He found that he had an obstruction from a nasal spur, which caused him some difficulty in breathing. The boy's larynx was pushed up over one and one-half inches, and the speaker thought the muscles of the larynx had contracted too much. He then placed one finger over the Adam's apple and the other he introduced into the boy's mouth, and pushed the larynx into its proper position. He then had the boy talk, which he began to do with as good a voice as he ever had. The boy went home then and in two weeks he had a magnificent chest voice. He thought that the future treatment of all these cases should be muscular training. In his clinic he had one woman whose duty it was to teach muscular movements.

Dr. Delavan, of New York, thought that another factor in the production of this condition was that which caused a relaxation of the system in general and the vocal organs in particular. He expressed himself as extremely opposed to the use of cocaine, on account of the alluring nature of the remedy and the ease by which one might become attached to it.

Lipoma of the Larynx.—Dr. F. W. Hinkel, of Buffalo, reported the case of a man, aged fifty-five, who in 1895 was in excellent general health. In 1883 the patient was conscious of a swelling at the back of his tongue, and consulted Dr. Roswell Park, who removed a tumor, which was about one and three-fourths inches long and one-half inch in diameter. After some years there was a gradual return of the symptoms, and in February, 1893, Dr. Park again removed a tumor, which was one-third of an inch in diameter. Again, in 1894 he removed a tumor similar to that removed the year previous. The patient consulted the reader of the paper, in 1895, for a cough and difficulty in swallowing. There were no other symptoms. He stated that his father had died of cancer of the face. Upon the left epiglottis a pinkish body was found, which was soft or doughy in consistence, and there were varicosities at the root of the tongue. On March 9, 1898, the patient again consulted him for discomfort, and upon examination a tumor was found at the free margin of the epiglottis and bending toward the right. The left aryepiglottic fold was thickened. There was no involvement of the ventricular band. With forceps and scissors the growth was readily removed. It was three-fourths of an inch in length. The epiglottis presented a curious appearance. The epiglottic fossa was filled with a tissue similar to the tissue removed. The persistent recurrence of the tumor led the speaker to send a specimen to Dr. Wright for examination, who, from the microscopical appearances, reported the case to be one of lipoma of the larynx.

Dr. Hinkle also reported a case in which death followed immediately an operation for nasopharyngeal adenoids under chloroform anæsthesia, and made some remarks on anæsthetics in this operation.

Recurrence of Adenoids after Excision.—Dr. Arthur Ames Bliss, of Philadelphia, reported three cases, in which recurrences had appeared. To prevent the return of the tumors he advised a very thorough removal; the incomplete removal of these adenoids would, as a rule, result in their recurrence.

Operative Treatment of Pharyngeal Adenoids.—Dr. D. Bryson Delavan, of New York, said that he would especially refer to the surgical means used for the removal of these growths. It was twenty-one years since attention was called to this subject. The two grand principles which should be kept in view, and without the recognition of which success could not be obtained, were thoroughness and humanity. One should aim at a minimum of discomfort. Thoroughness meant complete removal, because any tissue left behind was certainly unhealthy tissue. In regard to the humanitarian side, certain methods gave less pain, shock, and injury. The statement had been made that the operation was not painful; but for many years he had carefully questioned his patients, and invariably the answer was that the removal of the adenoid was accompanied by sharp pain. In operating upon these growths four classes of instruments were used, which were, 1st, the curette; 2d, the forceps (Gottstein); 3d, the adenotome with plain edges; 4th, the wire loop or snare. Another instrument of great use was the finger nail. The sharp spoon should not be used, on account of the danger of hemorrhage. The Gottstein knife was very popular. The advantages of the various instruments were treated of, as well as their disadvantages. It was best for the patient to be in a state of complete anæsthesia; the skilful and thorough removal with a blunt pair of forceps was desirable, when through reason of age or superior strength of the patient or some other special indications general anæsthesia was desirable.

Dr. J. W. Gleitsmann, of New York, said that three or four per cent. of the operations were followed by recurrences. He had used ethyl bromide very extensively, and was well satisfied with it.

Dr. Casselberry, of Chicago, said he had used ether exclusively for many years when a prolonged operation was necessary. In brief operations he thought bromide of ethyl might be good.

Dr. Wagner, of San Francisco, said that he had given up the usual method of operating, on account of recurrences in some cases. He now had a hook with which he pulled the growth down; then with a special set of instruments which he had had made he dissected everything out. He had never seen recurrences following this operation, and there were no bleeding whatsoever and no pain in its performance.

Dr. A. B. Thrasher, of Cincinnati, thought that fatalities from the use of chloroform were due more to the method of administering it than to the drug itself.

Dr. J. E. Logan, of Kansas City, spoke of the preparation of the patient before giving these anæsthetics. He thought that in young children only a general anæsthetic was to be considered. In operations upon adults, he never gave a general anæsthetic. In adults he used forceps almost entirely; in children, the curette with the additional use of the finger nail properly cleansed. In operating about the origin of the Eustachian tube, he advised the use of the finger nail in removing any growths, and so obviating any danger of injury to these orifices.

Wednesday, May 18th—Third Day.

The discussion on the last three papers read at Tuesday's meeting, on the subject of adenoids, was continued.

Dr. Swain advocated the use of chloroform, operating in the primary stage of anæsthesia. There had been no bad effects from its use in his hands, and, in

spite of what had been said, he would go on giving chloroform.

Dr. Bryan, of Washington, thought it was very desirable that the patient should not be so completely under the influence of the anæsthetic that he would be unable to expel foreign matter; in other words, the reflexes should not be abolished. Unless the growth was thoroughly removed it would recur. He stated that it was his observation that in adenoid cases the obstruction often came from the mechanical effect of the secretions. The removal of the adenoids and the turbinates did away with many of the symptoms, but in many cases, in which it was stated that there had been a recurrence of the trouble, he had made an examination and found the throat and pharynx free; no adenoids were to be found, but there were present an acute rhinitis and an engorgement of the inferior turbinate. In regard to the instruments, he did not think there was any one instrument that would remove the growth entirely in all cases; hence he used the curette and the forceps. He had had one made with an anatomical curve: a cast of this region in many children was made, from which pattern a curette was formed.

The Upper Respiratory Organs and the General Health.—Dr. J. C. Mulhall, of St. Louis, read a paper with this title. The general health of every child that had a rhinitis was at fault, and this fault was often due to bad hygiene. Diseases of the upper air passages might produce disturbances of the general health, and disturbances of the general health might produce diseases of the upper air passages. Dr. Bulkley, of New York, had claimed to have cured an acute attack of rhinitis with large doses of sodium bicarbonate: he agreed with Dr. Bulkley as to this agent, and he considered it to be especially efficacious in those who were suffering from a uric-acid diathesis. This drug was good, too, in those cases in which there was a constant desire to hawk. Another factor in these diseases was an auto-intoxication from the intestinal tract. People eat hot bread and rolls for breakfast, cereals and sugar, and much candy, and so laid up a large supply of carbohydrates that were not worked off. The surgeon always had the intestinal tract cleared out before operations, in order to prevent infection from within; this was as important as the prevention of infection from without. It had been noted that a cut in the skin would heal much more rapidly if the intestinal canal was cleaned out by a calomel purge. Opera singers were acquainted with the fact that careful dieting and an abundance of outdoor exercise were productive of better voices. A patient, for instance, had nasal symptoms, and upon examination a nasal spur was found; there were also present symptoms referred to another part of the body; the removal of the spur was followed by removal of all the symptoms. Another patient referred to him was relieved by sawing wood; he lost thirty pounds in three weeks. Pugilists were frequent subjects of pharyngeal catarrh, produced by their wild living and bad habits; but as soon as they trained down for a fight, all these symptoms disappeared; all the bad things in the body were then eliminated. In the purulent catarrh of adolescence, unless the patient was taken away from books and the piano and placed on iron, outdoor exercise, and good food, no progress would be made toward the cure of the disease, no matter what local methods were used. Prophylaxis should begin in childhood. The nearer we approached the outdoor life, the better was it for our health. The head covering should be that which allowed air to touch the scalp. One should eat but three meals a day, and candy only after meals, if at all. Rubber shoes and mufflers were a mistake. The diet was most important. The speaker's motto was, "Long live the general health; away with the spray."

Dr. Mayer, of New York, said he had a practical suggestion to offer: in those patients suffering from grippe, with enlarged turbinates, and who suffered intensely, and for whose relief something must be done, he had found the tincture of gelsemium in small doses frequently repeated of marked benefit: or one could follow the advice of Dr. Delavan—puncture the engorged turbinates and then spray with menthol solution, following this with the tincture of gelsemium.

Natural Immunity.—Dr. Henry L. Wagner, of San Francisco, read a paper upon this subject. Two kinds of immunity were to be considered—the natural and the acquired. Natural immunity existed not only in the body, but also in the upper air passages. Microorganisms were constantly carried to all parts of the body by active respiration without causing infection of the body, which fact alone proved this immunity. The bactericidal power of the nasal mucus was referred to, as well as the active phagocytosis occurring in the mouth. Mucin was antagonistic to bacteria. It had been said that the physical function of mucin was to prevent mechanically the invasion of bacteria, but he had found that the immunity caused by mucin was produced by the development of a ferment like pepsin or trypsin.

Operative Treatment of Inflammation of the Frontal Sinus.—Dr. J. H. Bryan, of Washington, reported two cases, one of chronic suppurative sinusitis with caries of the frontal cells and a fistulous opening into the orbit. An incision was made along the eyebrow, just along the supra-orbital notch. The orbital plate was opened, and it was found that it communicated with the frontal sinus. The cavity was filled with granulation tissue. The sinus was freely curetted, and an attempt was made to pass a probe through the nasal duct: this could not be done until a trocar had been passed through into the nose. One week later the patient was discharged from the hospital. Ten days afterward the drainage tube was removed and the patient made an uneventful recovery. The scar of the incision was concealed by the hair on the eyebrow.

The second case was one of chronic frontal sinusitis, with suppurative caries of the frontal cells. An external operation was advised, and many of the carious ethmoid cells were removed by means of the curette. After the operation the patient grew worse; later purulent secretions were blown from the right nostril. Her headaches increased in severity. A radical operation was then advised and accepted. An incision was made through the eyebrow at a point just within the supra-orbital notch. A flap was raised and the bone just above the superciliary ridge removed by means of a trephine. The cavity was found to be filled with thick fetid pus. The vertical septum was broken down and the ethmoid cells were found to be in a state of caries. The septum was completely removed and all the diseased bone also. The parts were irrigated with a solution of chloride of zinc and the cavity was packed with gauze and irrigated daily with a bichloride solution.

Disease of the Accessory Sinuses.—Dr. J. W. Farlow, of Boston, reported a case of this nature, which was interesting from the fact of its following scarlet fever. There was, too, a thickening of the superior maxilla. Particularly to be noted was the absence of discharge from the nose. The eye was pushed outward, downward, and forward, and possibly the antrum was involved secondarily.

Acute Inflammatory Conditions of the Upper Air Passages Accompanied by Laryngeal Œdema.—Dr. Clarence C. Rice, of New York, explained that his reason for bringing this subject before the association was that he had found it had been so little discussed by the members. In the classification of this disease he wished to have it understood that laryngeal œdemas

due to diphtheritic infection were to be carefully excluded, which had not been done in many of the cases published. He thought it was also well to leave out of consideration cases of non-inflammatory œdema, or so-called "passive œdema," which was only a symptom of general disturbance and due to cardiac, renal, and hepatic disease. Another line of cases which should be properly excluded was those which might well be termed "chronic" œdema of the larynx, in which the swelling was occasioned by a chronic local disease, such as tuberculosis, syphilis, and malignant disease of the larynx. The paper therefore dealt with acute œdemas only. He included in his cases the œdemas due to traumatism and external irritants of all kinds. He found that while many authors made separate chapters in their text-books of œdematous laryngitis and erysipelas of the larynx, others combined the two under one consideration, and there were some observers who thought erysipelas was very frequently the cause of primary idiopathic œdematous laryngitis, and pathologically identical with it. Semon, of London, who had written a most interesting article on this subject, had stated his belief that erysipelas of the larynx, phlegmonous laryngitis, Ludwig's angina, were pathologically identical, differing only in virulence and locality of attack. He had tabulated fourteen cases. Sestier had used a classification which was perhaps as fortunate as any, calling the case typical when it originated in the larynx, contiguous when it proceeded from the pharynx or other parts, and consecutive when it occurred as a sequel to a previous disease of the larynx. He found that in one hundred and ninety acute cases it was primary sixty-eight times, and secondary one hundred and twenty-two. The late Sir Morell Mackenzie had stated that in nearly all the instances of so-called idiopathic œdematous laryngitis the disease was due to blood poisoning, and that he had met with it among hospital physicians, medical students, and nurses. He stated also that in every case that had come under his notice ample opportunity for acquiring septicæmia had been present. The paper referred to an epidemic of cases occurring in St. Louis in 1886 and presented to the society by Dr. Glasgow. Nearly all these cases began as pharyngeal trouble, the laryngeal œdema being secondary, and Dr. Glasgow felt that they were constitutional in their cause and showed rheumatic tendency. The author of the paper expressed himself as having grave doubts as to the pathological identity of acute primary laryngitis and erysipelas of the larynx. He had never been able to demonstrate this to his satisfaction, and thought it unwise to make the diagnosis without a corresponding erysipelatous condition of the skin. He quoted Mackenzie as saying that in the large majority of cases erysipelas of the pharynx and larynx occurred as an extension of a similar attack on the face. Mackenzie had seen but four cases, and in none was the diagnosis made until the disease extended to the skin. In fifty per cent. of Semon's cases the laryngeal œdema seemed to be secondary to cellular inflammation about the tonsils. Dr. Rice had tabulated for his paper forty-one cases reported by journals from the year 1887 to date, exclusive of the fourteen cases by Semon. He found that but four or five cases were reported annually, and that the prevalence of grippe since 1890 had not materially increased the number of reported cases. In about fifty per cent. of all the cases the cause was put down as "catarrhal," *i.e.*, due to exposure to cold. The author cited three cases of moderate laryngeal œdema of his own following peritonsillar inflammation; two cases of œdema of the larynx due to traumatism—*i.e.*, one following the use of the galvano-cautery applied to the lateral wall of the pharynx, and the other due to a foreign body which had lodged in the pyriform sinus; and two cases of œdema due to constitutional causes. These two cases seemed both to be preceded by inflammation at the base of the tongue, possibly due to inflammation of the lingual tonsil. There was no indication of diphtheritic exudation. Exactly what the infection was in these cases it was difficult to determine, but in neither case had there been pre-existing inflammation of the respiratory tract, except possibly inflammation of the tongue. The author thought the cases very rare in which there was an acute primary œdematous laryngitis which existed without relationship to any other inflammation in this location. He thought the possible existence of diphtheritic poisoning in many of these cases should be more carefully considered; and it was likely that some which were put down as primary and acute were really secondary to renal disease. Extraordinary exposure to cold, together with the effects of alcohol and tobacco, were potent factors.

The Use of Aqueous Extract of Suprarenal Glands, Locally, in the Upper Air Passages.—Dr. Henry L. Swain, of New Haven, read a paper with this title, of which the following were the conclusions: (1) The aqueous extract of suprarenal glands was a powerful, local, vasoconstrictor agent, and a contractor of erectile tissue, which it was safe to use in very considerable amounts without dangerous or deleterious effects locally or to the general constitution of the individual. (2) These local effects could be reproduced in the same individual, apparently any number of times, without entailing any vicious habit to either the tissue or the individual. (3) The use of the extract seemed rather to heighten the effects which might be expected from any given drug used locally after it. (4) In acute congestions it had its widest application and greatest opportunity for good, but in certain chronic conditions of the hay-fever type, when redundant tissue seemed prone to develop, it could be relied upon as one of the most helpful adjuvants at command.

Officers.—The annual election of officers resulted as follows: *President*, William E. Casselberry, of Chicago; *First Vice-President*, John W. Gleitsmann, of New York; *Second Vice-President*, F. Whitehill Hinkel, of Buffalo; *Secretary and Treasurer*, Henry L. Swain, of New Haven; *Librarian*, Jonathan Wright, of Brooklyn: *Delegate to the Council*, Thomas R. French, of Brooklyn: *Representative to the Congress of Physicians and Surgeons*, W. K. Simpson, of New York; *Members of the Council*, Thomas R. French, of Brooklyn; John O. Roe, of Rochester; W. H. Daly, of Pittsburg; Charles H. Knight, of New York.

Chicago was chosen as the next place of meeting.

AMERICAN GYNÆCOLOGICAL SOCIETY.

Twenty-Third Annual Meeting, Held in Boston, May 24, 25, and 26, 1898.

Paul F. Mundé, M.D., President.

First Day—Tuesday, May 24th.

The meeting was called to order by the president in the hall of the Boston Society of Natural History.

Address of Welcome.—Dr. A. C. Sinclair, of Boston, delivered the address of welcome. He referred to the fact that twenty-two years ago Dr. James R. Chadwick, of Boston, took the first step toward the organization of this society, which began with a membership of thirty-nine.

Congenital Pelvic Kidneys Obstructing the Parturient Canal; Report of a Case of Vaginal Nephrectomy.—Dr. Edwin B. Cragin, of New York, read this paper. He said that although this condition was a rare anomaly, it occurred with sufficient frequency to be worthy the attention of the obstetrician and gynæcolo

gist. In round numbers it might be said to occur about once in a thousand cases. In by far the larger number, the left kidney was the one presenting this anomaly, and the condition was usually unilateral. He had been able to find recorded only five cases in which dystocia had resulted from this unusual position of the kidney, and to this list he could now add another. His case presented the following history: The patient was a Cuban, twenty-five years of age, whom he had first seen on May 8, 1897. She had had two preivous confinements, both of them requiring interference to effect delivery. Behind the cervix was a tumor which reduced the internal conjugate diameter of the pelvis to about seven centimetres. The other pelvic measurements were normal. As the tumor was situated quite low in the pelvis, it was decided to attack it by the vaginal route. It proved to be the left kidney. Vaginal nephrectomy was performed by first clamping the vessels and ureter at the hilus of the kidney, and after the removal of the organ applying ligatures and packing gauze firmly against the pedicle. Twelve hours after the operation labor began, and after about five hours a living child was easily delivered. From the ease with which the delivery was effected and the previous difficult labors, there was little doubt that the kidney was the cause of the previous dystocia. As the kidney in this case formed a cyst, it was the unanimous opinion of those who saw the case that the induction of premature labor would not have accomplished the desired result. The question of the possibility of Cæsarean section and replacement of the kidney had been considered, but in view of the low origin of the renal vessels, the shortness of the ureter, and the fixity of the kidney, it had been decided not to adopt this plan of treatment. The absence of the right kidney had been excluded by the abundance of normal urine excreted and the existence of hydronephrosis in the displaced kidney. From this experience Dr. Cragin drew the following conclusions: (1) A kidney, displaced into the pelvis, might cause dystocia; (2) the induction of premature labor, timed according to the amount of obstruction, was the procedure indicated; and (3) in rare cases, in which the pelvic kidney was in a condition of hydronephrosis, vaginal nephrectomy might be proper. He had failed to find in the literature a report of such a case of vaginal nephrectomy.

Dr. Howard A. Kelly, of Baltimore, said that he had seen three cases in which the kidney had been displaced in this way. In one of these the left kidney was in the pelvis, and in the other two the right kidney was displaced.

Dr. Hunter Robb, of Cleveland, said that one of the cases seen by Dr. Kelly had been in his practice. It was a case of double tubo-ovarian disease in which the kidney presented just above the brim of the pelvis. The mass was thought to be an adherent tube and ovary until the operation. Nothing was done with the kidney, as there were no symptoms referable to it.

Dr. S. C. Gordon, of Portland, and Dr. E. C. Dudley, of Chicago, each reported one case in which the kidney of a male was found at or below the brim of the pelvis.

Dr. Philander A. Harris, of Paterson, reported having operated upon a woman whose left kidney was located in the true pelvis.

Dr. Robb said that, as he had proved it was not necessary in dogs to strip off the capsule and peritoneum from the kidney, he would like to ask if Dr. Cragin had done so in his case.

Dr. J. Wesley Bovée, of Washington, D. C., remarked that nephrectomy seemed to be an unnecessarily severe measure in these cases.

Dr. J. Clifton Edgar, of New York, asked if Dr. Cragin had attempted to dislodge the kidney upward by postural treatment—a method which was wonderfully successful in cases of prolapsed funis.

Dr. Charles P. Noble, of Philadelphia, reported one case of congenital displacement of the kidney, in which the organ was found near the sacro-iliac junction. He expressed the opinion that a Cæsarean section was no graver than a nephrectomy, and that consequently, if in a case of dystocia due to displacement of the kidney the organ was not diseased, Cæsarean section would seem to be a desirable method of treatment.

Dr. Paul F. Mundé said that he had met with two cases of intrapelvic and evidently congenitally displaced kidney.

Dr. Cragin, in closing the discussion, said that he had stripped back the peritoneum, but not the capsule. Owing to the shortness of the ureter and renal vessels, the kidney could not be pushed up.

Pregnancy Following Ventrofixation with Improvements in Technique.—Dr. A. Lapthorn Smith, of Montreal, presented the results of a collective investigation on this subject. The following conclusions were based upon about twenty-five hundred cases, by forty-one operators, including one hundred and eleven cases of his own: (1) For the cure of retrodisplacements and also prolapse of the uterus, ventrofixation, with two buried silk stitches passed through the peritoneum and fascia, gave the most reliable results. (2) Ventrofixation should be reserved for cases in which abdominal section was necessary for other reasons, and in which pregnancy was not expected to occur. (3) Although pregnancy followed in only one hundred and forty-eight of the cases, in thirty-six of these there was pain, miscarriage, or difficult labor. (4) When suspensio uteri was performed—*i.e.*, attachment of the uterus to the peritoneum—only a few relapses occurred, and subsequent pregnancy and labor were much less complicated. (5) In the intra-abdominal method of shortening the round ligaments, the latter were able to develop as pregnancy advanced; and hence the serious accidents following ventrofixation were avoided. (6) Complications were more frequent when there was much anteversion of the uterus; hence the anterior surface of the fundus should be attached to the abdominal wall. (7) As large a surface as possible should be made to adhere by scarifying both the anterior surface of the fundus and the corresponding surface of the abdominal peritoneum. (8) As a number of his correspondents had stated that they knew of many cases in which pregnancy and labor had not been unfavorably influenced by Alexander's operation, this should be preferred whenever the uterus and appendages were free from adhesions. (9) The results of Alexander's operation were so good that even when there were adhesions it might be well to free the adhesions by a very small median incision before shortening the round ligaments, after which the abdomen should be closed. This would not add more than five per cent. to the mortality, which in Alexander's operation was *nil*.

Treatment through the Posterior Vaginal Cul-de-Sac of Adherent Uteri.—Dr. William Pryor, of New York, read a paper with this title. He said that the posterior cul-de-sac operation, because of the position of the incision, enabled the operator to apply conservatism in a class of cases in which he would not otherwise dare to attempt it. That operations between the bladder and vagina, such as Mackenrodt's, were not desirable, had been well shown in the statistics collected by Dr. G. M. Edebohls. The hernia service at the Hospital for Ruptured and Crippled bore evidence to the frequency with which hernia followed Alexander's operation, even in the hands of the most skilful. After thorough preparation the uterus was curetted, and the posterior cul-de-sac entered with

the fingers. With the patient in the Trendelenburg posture, it was easy to deal with the pathological conditions encountered. The cervix was forced upward and the upper part of the vagina was packed with gauze. A catheter was left in the bladder for two days, after which the gauze was removed. The dressings were continued until the cul-de-sac had closed. Hernia could not occur through the scar, because it was thicker than the normal vagina and under the protection of the sacral promontory. The cervix being high and the body free, there was no tendency to abortion. The after-treatment was undoubtedly troublesome and exacting.

Dr. H. A. Kelly opened the discussion on the two preceding papers. He said that the suggestion made by Dr. Pryor, to act on the posterior pole of the uterus, was a most rational one from a mechanical point of view, but it involved certain difficulties of technique. Personally, he had preferred suspension of the uterus —not fixation—and had done this operation one hundred and ten times. There had been at least eighteen pregnancies following the operation, and in only one case—one of his earlier ones in which a faulty technique had led to suppuration and extensive adhesions —had there been anything unusual about them. Statistics on this subject should give an analysis of the difficult labors based upon the particular method of operating, for he had found that there were at least forty-five different methods. If the round ligaments had been intended to support the uterus, they would not appear lax and bent when the abdominal cavity was open. In one of these patients, upon whom he had subsequently performed laparotomy, the ligament was so thin and stretched that it measured nineteen centimetres in length and 1.5 millimetres in diameter.

Dr. A. Palmer Dudley, of New York, said that after having observed the intense suffering of three of his patients during pregnancy after ventral fixation, he had determined to avoid this operation in future. He was opposed to the Alexander operation, but he believed the internal shortening of the round ligaments would prove effective and satisfactory. If the ligaments were properly scarified and doubled upon themselves within the abdomen, and sewed together in two directions, they should hold securely, and they certainly gave no opportunity for the formation of intestinal adhesions. His objections to Dr. Pryor's operation were: (1) It was necessary that the pelvic floor should be movable; and (2) the resulting scar tissue in the vagina would cause tenderness and discomfort during sexual intercourse.

Dr. C. P. Noble said that he had seen no occasion to change his opinion that fixation of the uterus was a bad operation for all women during the child-bearing period, and that the best operation was that of suspensio uteri, as done by Dr. Kelly. In two out of seventy-five cases in which he had done Alexander's operation, the round ligaments had stretched within a few months, and this was true of the work of other operators. In the few instances in which he had used the method of intraperitoneal shortening of the round ligaments the results had so far been very satisfactory.

Dr. H. J. Boldt said that Alexander's operation gave the least trouble if done in properly selected cases, *i.e.*, those in which the uterus was freely movable, and in women in whom the adnexa could be carefully mapped out, so that disease of these organs could be excluded.

Dr. Edward Reynolds, of Boston, said that he had seen three out of the five cases referred to by Dr. Pryor as having the uterine body adherent to the posterior peritoneum. In the first case the diagnosis had been confirmed by laparotomy, and he had then performed vaginal fixation. A few hours afterward the patient had been seized with severe paroxysms of pain, and these had recurred at short intervals for about two weeks. She eventually recovered. The same thing was observed in the other cases, and the only explanation he could suggest was that the utero-sacral plexus which had been involved in the adhesions had been injured.

Dr. Matthew D. Mann, of Buffalo, said that he did not think it was sufficient to hold up the cervix alone, and hence he preferred to shorten the round ligaments at the same time. He had done about one hundred Alexander operations in the past three years, and in only two had hernia developed. The extensive opening up of the intercolumnar fascia and ring he believed to be entirely unnecessary, and a fertile cause of hernia. When there was extensive disease of the appendages, he favored intraperitoneal shortening of the round ligaments at the same time that the abdomen was opened for the treatment of the adnexa. If both tubes and ovaries were removed, ventral fixation might be allowable. He believed it to be a great mistake to employ non-absorbable sutures for these operations.

Dr. Gordon said that in an Alexander operation, unless the peritoneum was stripped entirely from the round ligament up to the internal opening, a glove-shaped fold of peritoneum would be carried down, and, by enlarging the internal opening, would favor the occurrence of hernia.

Dr. Horace T. Hanks, of New York, said that he thought the reason the cases operated upon by Dr. Kelly's suspension method were so free from reflex disturbances was that the uterus was not fixed too firmly. He had operated forty-six times by this method, making the incision through the rectus muscle and fastening it with two or three silkworm-gut sutures.

Dr. R. Stansbury Sutton, of Pittsburg, said that in suspending the uterus he followed a peculiar method, by which the abdominal cavity was not opened at all. The patient was placed in the Trendelenburg posture, a large staff was inserted into the uterus, the fundus of this organ brought against the abdominal wall, and a cut made down to the peritoneum; then with a running catgut suture the fundus was sewed to the abdominal wall.

Dr. E. C. Dudley said that if the uterus was so diseased that the normal mobility at the angle of reflexion was impaired, and the uterus remained straight, then the uterus was apt to go back after any operation for shortening the round ligaments, unless the cervix could be fixed back in the hollow of the sacrum. To obtain permanent results after suspension operations it was necessary to stitch to the abdominal wall the posterior wall of the uterine body at a point a little back of the summit of the fundus. For this purpose he greatly preferred catgut.

Dr. Hunter Robb said that many patients were needlessly subjected to these operations, for he had seen many of them entirely recover without any operative procedure. These patients often seemed to be relieved shortly after operation, but in the course of a year or two they would frequently complain as bitterly as before. It had seemed to him that the mere separation of adhesions would often relieve all the subjective symptoms.

Dr. James R. Chadwick, of Boston, said that he had done at least two hundred Alexander operations, and had followed most of the cases, yet he had never known hernia to succeed one of these operations, and he saw no reason for its occurrence if a proper method of operating was adopted.

Dr. Andrew F. Currier, of New York, said that as many of the persons seeking relief by these operations were young unmarried women, it was not desirable to use a pessary, and disfigurement should be

avoided as far as possible. He, therefore, preferred internal shortening of the round ligaments.

Dr. J. Riddle Goffe, of New York, said that for the past two years he had been shortening the round ligaments through a vaginal incision, and regretted that so far others had not seen fit to give the method a trial, as it had proved satisfactory to his patients and himself.

Dr. A. J. C. Skene, of Brooklyn, said he was sure more trouble followed from scar tissue in the vagina than from the wounds of abdominal section. He found a field for all of the operations that had been discussed, but the comparatively frequent absence of the round ligament served greatly to limit the usefulness of the Alexander operation.

Dr. Bovée spoke of the advantages in certain cases of shortening the utero-sacral and the broad ligaments. The harm done by a too short or abnormally attached anterior vaginal wall should also be borne in mind.

Dr. A. Lapthorn Smith said that hernia was impossible after Alexander operations, if they were done as he was accustomed to do them. Lest he should be tempted to use the knife too much, he introduced the forceps into the ring and closed his eyes while feeling for and pulling out the ligament.

Dr. Pryor, in closing the discussion, said that hernia was known to follow operations done by the most skilful surgeons and by various methods. He recommended his operation only in certain cases of adhesion; it was not intended at all to take the place of Dr. Kelly's operation of suspension.

Discussion: Has Electricity Ceased to be a Useful Therapeutic Agent in Gynæcology?—Dr. Henry J. Garrigues, of New York, opened the discussion, by touching upon the chief uses of the different forms of the electric current. Speaking of faradization, he said that the current from the short, thick wire coil was useful in subinvolution, infantile uterus, amenorrhœa, sterility, and uterine hemorrhage. The high tension current, obtained from the long, fine wire coil, was chiefly of value for its analgesic action. The galvanic current had a wider field of usefulness. While it was much less used at present in extra-uterine pregnancy than formerly, he would prefer, in the case of a patient personally dear to him, to give it a trial, provided the pregnancy had not advanced more than a few weeks. In many cases of uterine fibroids the symptoms were markedly relieved, and the patient's general condition was improved by the use of the galvanic current. In only one such case, however, had he observed a total disappearance of the tumor under this treatment.

Dr. Egbert H. Grandin, of New York, said that in taking the affirmative regarding the question propounded, it should be stated that he did so only after having given electricity a prolonged trial in gynæcological practice, and after having been at one time a more or less enthusiastic advocate of it for the treatment of certain conditions. He described in detail how he had abandoned the electrical treatment in one condition after another, always after having abundantly tested it by the touchstone of clinical experience. Thus he had tried the electrical treatment in about fifty cases of uterine fibroids, and, while he had been able to control the discharges in about thirty per cent. of the cases, he had never seen the tumor disappear, except when the menopause had supervened, and he had soon learned that the painful cases were unsuitable for the treatment, because the condition was chiefly due to disease of the appendages. He had treated by electricity five or six cases, supposed to be ectopic gestation, and all the patients had recovered. One of the patients lay in collapse for hours, and subsequently had a suppurating hæmatocele. About eighteen months later he again saw her in collapse with symptoms of extra-uterine pregnancy, and he subjected her to laparotomy. With her recovery from this operation he had recovered from the effects of an erroneous belief in the efficacy of electricity in the management of these cases. Since then he had operated in fourteen cases of ectopic gestation, and the only death was one from fatty heart. In none of these operative cases could electricity have been of any avail, except perhaps to precipitate a fatal termination.

Dr. George Engelmann, of Boston, said that electricity must still be considered a potent agent in the treatment of certain gynæcological cases. In uterine fibroids electricity was used to relieve certain symptoms, chiefly those dependent upon congestion. It at least had the merit of being perfectly safe; it did not confine the patient to bed, and very often gave speedy relief.

Dr. H. J. Boldt said that, while cervical stenosis could be relieved symptomatically by the galvanic current, it resulted after a year or two in a worse stenosis than before. In a recent case of ectopic gestation, in which he had applied a current of fifty milliamperes, the embryo had not been destroyed and the patient had nearly died from the subsequent rupture and hemorrhage.

Dr. A. Palmer Dudley said that he had given Apostoli's method of treating uterine fibroids a careful trial for two years, using the most approved apparatus, but had come to the conclusion that it was a very uncertain and unsatisfactory method.

Dr. A. Lapthorn Smith said that he had used electricity quite extensively in gynæcology for the past ten years, and had permanently restored to health about forty women suffering with uterine fibroids. He had followed Apostoli's method in these cases, using an average current strength of one hundred and twenty-five milliamperes and an average of thirty-five or forty applications. He had absolute proof of cure in two cases, and in the others the patients had been symptomatically cured.

Dr. Florian Krug, of New York, heartily indorsed the position taken by Dr. Grandin. He attributed the success of electricity entirely to poor diagnoses and ill-observed cases.

Dr. R. Stansbury Sutton, of Pittsburg, said that he had given the electrical treatment of uterine fibroids his very best attention for five years, and then, finding that it had resulted in no cures, he had discarded it. True, it would control the hemorrhage, but so would the curette, and galvano-puncture was certainly dangerous.

The Porro Operation versus Total Hysterectomy.—Dr. Henry J. Boldt, of New York, read a paper with this title. He strongly advocated total hysterectomy in preference to supravaginal amputation, with extra-peritoneal treatment of the pedicle. With the present technique, he said, total hysterectomy could be performed nearly as quickly as the Porro operation. In all cases giving the absolute indications for Cæsarean section, complete extirpation of the uterus was to be preferred. The following were appropriate cases for total hysterectomy: (1) Women who had a living child in the uterus, at or near term, and in whom the pelvic diameters would not admit of the delivery of a living child by the natural passages; (2) when the child was dead *in utero*, and the organ had been infected through this cause; (3) when there was sufficient cicatricial contraction of the vagina to prevent delivery in the usual manner; (4) cases in which there was rupture of the uterus, demanding abdominal section, and in which closure of the uterine wound was unsafe; and (5) some cases of atony of the uterus following Cæsarean section. In cases of advanced cancer of the cervix the Porro operation should be given the preference. There was only a difference of a few minutes in the time re-

quired for the performance of a Porro operation and an ideal total hysterectomy. The advantages of total hysterectomy were: (1) Less danger of infection; (2) practically no danger of secondary hemorrhage; (3) less danger of intestinal obstruction; (4) shorter convalescence; and (5) less danger of ventral hernia.

Dr. E. P. Davis, of Philadelphia, heartily indorsed the position taken by Dr. Boldt, and emphasized the fact that at the present time the choice of the method of delivery could not be based absolutely on the pelvic measurements, but must depend upon a careful weighing of all the factors entering into this most difficult problem. An experience with nine hysterectomies in which the stump had been treated intraperitoneally, had convinced him of the superiority of this method.

Dr. Philander A. Harris reported two cases upon which he had operated during the past year for the absolute indication.

Dr. Robb cited a case showing the advantages of the intraperitoneal treatment of the pedicle.

Dr. A. Palmer Dudley remarked that for years he had advocated the intrapelvic method of performing hysterectomy, but in the future he proposed to do complete hysterectomy in the manner described by Dr. Boldt.

Dr. Joseph Taber Johnson, of Washington, D. C., referred to a case which seemed to prove that the removal of the whole uterus was not necessarily the best procedure in every case.

Dr. Boldt, in closing the discussion, said that in the true Porro operation the pedicle was treated extraperitoneally, and he considered it inferior to complete hysterectomy.

Second Day—Wednesday, May 25th.

Observations in Regard to General Anæsthesia, Especially by the Schleich Mixtures.—Dr. Henry J. Garrigues, of New York, in a paper with this title, detailed his experience with the Schleich method in one hundred cases. He said that his clinical experience had not entirely borne out the theory of Schleich regarding the relation between the boiling-point of the anæsthetic and the body temperature. The general effect of the anæsthetic, both during and after operation, had been satisfactory. In speed, it ranged between chloroform and the A.C.E. mixture: it greatly promoted the patient's comfort, and its administration was simplicity itself. The average duration of the anæsthesia had been fifty-two minutes, but in some cases it had been as long as two or three hours. He preferred to use the ordinary Allis ether inhaler, leaving the top open until consciousness had been nearly lost. He had used the No. 1 mixture almost exclusively, and, on an average, 1.5 c.c. had been administered every half-minute. The average quantity necessary to produce anæsthesia had been 17.5 c.c., and the average quantity necessary for the entire period of anæsthesia—fifty-two minutes—had been 51 c.c. The average time necessary to anæsthetize the patient had been six minutes. There had been much less accumulation of mucus in the mouth and throat than with ether, and less of that slight cyanosis so commonly associated with the use of the Trendelenburg position.

In seventy-one per cent. of the cases there had been no vomiting at all, and in the remainder it had been slight or moderate. The respirations had been invariably increased, and in three instances the breathing had been temporarily arrested. Deep respiration and slight superficial breathing should indicate the necessity for an immediate interruption of the anæsthetic. In nearly all the cases the pupils were contracted. The return to consciousness was very rapid, the average period having been nine minutes and the minimum one minute. In conclusion, Dr. Garrigues recommended the Schleich mixtures for general use, and especially to the gynæcologist.

Dr. W. R. Pryor remarked that the petroleum ether used in the Schleich mixtures was pure benzin, and should not be confounded with rhigolene. The only manufacturer of it in this country was Cooper. He said that he used the No. 1 mixture exclusively with the Esmarch inhaler, and had found that it must be administered almost continuously, like chloroform. A more profound narcosis was obtained with less of the anæsthetic, and the return to consciousness was quite rapid.

Dr. Boldt said that in three cases he had observed such deep cyanosis that a change had been made to another anæsthetic, but in these cases Dr. Garrigues had not supervised the administration of the anæsthetic. At present he preferred ether to the Schleich mixtures.

Dr. H. T. Hanks said that in a trial of the Schleich mixtures at the Woman's Hospital, cyanosis, nausea, and severe vomiting had been observed, with no corresponding advantages.

Dr. Malcolm McLean, of New York, said that caution was necessary in the use of the Schleich mixtures near an open flame, for with atmospheric air they formed violent explosive mixtures.

Dr. Kelly remarked that ether was usually given so wretchedly in this country that it could not fairly be compared with the other anæsthetics.

Dr. Chadwick said that in the home of etherization—Boston—ether was considered so safe that it was quite common to intrust its administration to a nurse.

Dr. M. D. Mann, of Buffalo, said that he had always been an advocate of ether for anæsthesia, but having, during the past year, lost four patients from uræmia after etherization, he had been led to investigate more carefully its effects upon the kidneys, and had found in upward of thirty cases that albumin, with granular and blood casts, made its appearance in the urine shortly after etherization in about fifty per cent. of the cases. This condition usually lasted about one week. In not one of his fatal cases had albumin been found in the urine just prior to etherization.

Dr. Noble remarked that some years ago Dr. Kelly and he had independently investigated this subject, and had arrived at about the same results.

Dr. A. Palmer Dudley said that he had had three deaths after laparotomy from acute suppression of urine. He now insisted on giving his patients plenty of air during the operation, so as to avoid overtaxing the kidneys, and when there was reason for suspecting the integrity of the kidneys he ordered a large wet pack of infusion of digitalis to be placed over the region of the kidneys immediately after operation.

Operation for the Relief of Incarcerated Pregnant Uterus.—Dr. Matthew D. Mann, of Buffalo, presented this paper. He said that up to the present time the alternatives had been restoring the uterus to its proper position or emptying it of its contents. If the uterus was large, efforts made through the vagina to liberate it would fail, because the atmospheric pressure caused a prompt return of the organ to its faulty position. If, therefore, the usual measures failed, he would advocate opening the abdomen and pulling the uterus up as preferable to emptying the uterus. Another indication for operation was the uterus bound down in this backward position by adhesions. Two illustrative cases were reported.

Dr. Henry D. Fry, of Washington, D. C., said that he had had one of these cases in 1895, and had opened the abdomen, liberated the uterus, and performed ventral suspension to prevent a recurrence of the incarceration. The woman had passed through her pregnancy and confinement without incident. Operative measures were, however, not justifiable until an effort

had been made to liberate the uterus, with the patient anæsthetized.

Dr. P. A. Harris reported a case in which he had endeavored by pessaries and by manipulations under anæsthesia to relieve the condition, but without success. A few days later, to his surprise, the uterus spontaneously assumed its proper position.

Dr. Malcolm McLean described a remarkable case in which nature, in her effort to liberate the uterus, had caused a distortion of the organ resembling a double uterus. After the abdomen was opened and the uterus released, it at once assumed its customary globular shape.

Dr. Mann, in closing, said that he had taken it for granted that a case would not be considered irreducible until an effort to release the uterus had been made under anæsthesia.

Bacteria of the Vagina and their Significance, Based upon the Examination of the Vaginal Secretion of One Hundred Pregnant Women.—Dr. J. Whiteridge Williams, of Baltimore, read a paper with this title. After reviewing the many investigations of this kind that had been made, and noting the conflicting opinions, he detailed his own results. In his cases he did not find a single streptococcus or staphylococcus aureus. The different results obtained by various investigators, he said, were entirely explicable by differences in technique. Those who had obtained positive results had introduced a large speculum and taken the secretion with a platinum needle, but the introduction of such a large object carried past the hymen the organisms lying at the ostium vaginæ. To obviate this, he had used a small scoop, and, in introducing it, had spread the hymen and labia widely apart so as to avoid contact. Consequently organisms were not introduced from without and no pathogenic germs were introduced into the vagina. The author, therefore, concluded: (1) As the vagina did not contain pathogenic germs, autoinfection with these germs was impossible: (2) if the vagina contained streptococci frequently, a vaginal examination with the sterile finger would be very dangerous, which it was not: (3) the vagina might occasionally contain bacteria which might give rise to sapræmia by auto-infection, but this was usually quite mild: and (4) death from puerperal infection was due to infection from without, and usually to neglect of aseptic precautions on the part of the physician or midwife.

Dr. Robb said that his own work had proved the correctness of this view regarding the different results obtained, for in some experiments, on taking cultures from a drainage track, it had been proved that a minute portion of bichloride solution, used to sterilize the outer parts, had been carried along into the deeper portions, giving negative results. The same mistake had been made by some observers in their bacteriological examinations of the vagina.

Dr. Edward Reynolds said that while he did not doubt the correctness of the investigation just reported, he did not think that practical surgeons should allow a laboratory demonstration of the innocuousness of the vaginal secretion to guide their actions until this view had received abundant clinical confirmation. He believed that it would be unsafe to discard antiseptic cleansing of the parts before labor.

Dr. Charles Jewett, of Brooklyn, said that he had made it a practice for some time past to refrain from both ante-partum and post-partum douches, even in operative cases, provided the vagina was healthy.

Dr. Henry D. Fry said that he had recently had bacteriological examinations made of the vaginal secretion of about fifty women who had had slight elevations of temperature following parturition. In not a single case had the streptococcus or the staphylococcus aureus been present.

Dr. R. L. Dickinson, of Brooklyn, expressed the hope that some simple and effective method would be discovered of sterilizing the external genitalia in parturient women.

Dr. Philander A. Harris said that he firmly believed that the practice of entirely refraining from making vaginal examinations in obstetric cases would not cause any more deaths than are now produced by septic infection.

Dr. Howard A. Kelly said that it was probable that this investigation of Dr. Williams would have the effect of stopping a good deal of meddlesome and hurtful practice. As cases had been reported in which serious and even fatal puerperal sepsis had had its source in some small ulcer or sore on the patient's body, it was within the province of the obstetrician to attend to all of these small details and to warn the patient of the possible risks of inserting her finger into the vagina, even if only to relieve a slight pruritus.

Dr. Williams, in closing the discussion, said that a vaginal examination must be dangerous in all obstetric cases, because it was impossible in such practice properly to cleanse the external genitals. Douches were contraindicated both theoretically and practically. It had been shown that the normal vaginal secretions possessed a marked bactericidal action, and that, no matter what antiseptic douche was employed, it diminished the protective action of these secretions. Moreover, it had been found in lying-in institutions that the results were not so good when ante-partum douches were given. Personally he did not make an internal examination in more than one-third of his cases of labor; the only two conditions which could not be determined by an external examination, and which were made evident by a vaginal examination, were the degree of cervical dilatation and prolapse of the cord.

President's Address: Puerperal Sepsis.—Dr. Paul F. Mundé, of New York, delivered this address. He said that at the present time it was customary to distinguish three varieties of puerperal sepsis, viz.: (1) Sapræmia, or that variety in which the septic focus remained localized; (2) septicæmia, in which the streptococci found their way into the general system; and (3) pyæmia. While in the first form the products were usually putrid, in the second there was commonly no offensive odor or peculiar pathological discharge. Owing to more enlightened methods of treatment, the pyæmic variety was at present quite rare. In the majority of cases in private practice the infection came from the fingers or instruments of the physician or nurse, and sometimes from the clothing. He believed that at times pathogenic germs were sucked into the vagina by a change in the position of the patient. He had seen one instance in which there seemed to be little doubt that the infection of the parturient canal came from a discharging felon on the patient's hand, as she admitted having used one finger of that hand to relieve a vaginal pruritus. Another source of trouble was the retention of the discharges by flexion of the uterus. It was sometimes the custom in private practice to refrain from making any vaginal examination, trusting entirely to the external examination. This was perhaps wise if the attendant had reason to doubt the aseptic condition of his hands, but with the usual precautions taken before an abdominal section it should be possible to clean the fingers sufficiently to admit of carrying out the old-fashioned method of making a vaginal examination. Every effort should be made to secure thorough evacuation of the placenta and clots from the uterus after delivery, and to keep the uterus well and firmly contracted. The symptoms of puerperal septicæmia were usually those characterizing septic infection elsewhere. The prognosis was grave in those cases in which the virulence of the infection was indicated only by elevation of temperature and

rapid pulse. To make a correct diagnosis it was absolutely essential that the genital organs be carefully examined. A speculum examination might show a yellow or brownish discoloration of the cervix and vagina. The first indication for treatment was to remove all foreign substances from the endometrium, either with the fingers or with the blunt curette. The uterine cavity should then be irrigated with potassium permanganate, a dilute solution of chloride of zinc, or peroxide-of-hydrogen solution, diluted one-half. In very bad cases of septic endometritis he was in favor of using a curette, either dull or sharp, but he used the latter on the puerperal endometrium only when the dull curette failed to remove the decidua. It was much better to apply a strong solution of chloride of zinc, tincture of iodine, or a solution of phenol, washing out the cavity and packing it with iodoform gauze afterward, than it was to indulge too freely in curettage. When the uterine cavity was empty and clean, there could be no advantage in keeping up intrauterine irrigations; if the temperature remained elevated, it was evident that the condition was one of general and not local infection. If the patient could be kept alive by the administration of alcoholic stimulants, and by the use of strychnine, caffeine, and nourishing food until nature could throw off the invading germs, the physician would gain the victory. Dr. Mundé said that he had no faith in quinine as an agent for reducing the temperature in cases of puerperal fever or for favorably influencing the infection, but he did not hesitate to give phenacetin, in doses of from three to five grains, combined with caffeine, when the high temperature seemed to warrant it. The ice bag or cold coil to the abdomen was a potent means of reducing the temperature. His experience with serum therapy in puerperal sepsis was limited to three cases, but all of these were apparently desperate and had resisted all of the usual measures. The patients were given from three to six hypodermic injections of ten cubic centimetres of the serum, at intervals of from four to twelve hours, and all three recovered. He felt that in a severe case of puerperal sepsis, in which the streptococci had evidently passed beyond the genital organs, and in which the usual measures proved impotent, the serum treatment should be tried. He would treat general puerperal purulent peritonitis by a combination of the vaginal and abdominal operations. He favored treating pelvic exudates, first, by cold, and afterward by heat and blisters, until it was evident that suppuration had begun; for he had seen many instances of complete restoration of the organs to their normal function, even when he had felt almost sure suppuration would occur. If the source of infection was in the uterus and appendages, and could not be removed in any other way, complete hysterectomy was perfectly justifiable, but it was not easy to decide when this indication was present. The remainder of the address was devoted to several minor topics, of more or less general interest.

Choice of Methods in Hysterectomy.—Dr. E. W. Cushing, of Boston, read this paper. He said that while the extraperitoneal method of treating the stump had practically been abandoned, it was well to remember that it was a precious resource when, by reason of extreme shock or hemorrhage, it was advisable to terminate an operation immediately. Regarding the question of leaving part of the cervix, he said that the burden of proof seemed to rest with the advocates of total hysterectomy, for the operation was prolonged nearly half an hour. As the cervix was the seat of sexual sensation to a considerable degree, it was desirable, when possible, to retain it. Of course in malignant disease the hysterectomy should be total. When the whole cervix had been removed, the operator might leave the vagina wide open, or he might close the peritoneum, or both peritoneum and vagina might be closed. In his opinion, the method of election was that of closing the vaginal opening with a continuous catgut suture, and afterward uniting the peritoneum with another continuous suture of catgut. This left no raw surface in the peritoneal cavity, avoided drainage, and gave an especially smooth and painless convalescence. In septic cases it was well to pack the uterine cavity with gauze, and even stitch up the cervix. The so-called "combined operation," he said, really belonged to a transition stage in the development of hysterectomy. The separation of the vagina by the thermo-cautery was not applicable to a hysterectomy for fibroids, as it prevented primary union: it should be done only when there was a positive indication for drainage or for leaving the vagina open. He was of the opinion that the abdominal route would always possess certain important surgical advantages. The present indications for the vaginal operation were: (1) Inflammatory conditions associated with large collections of pus, in a greatly debilitated subject; (2) when the patient was very old, the abdominal walls were very thick, and the vagina was capacious; (3) in cases of cancer of the cervix, when it was undesirable to close the opening in the pelvic floor and the abdominal operation was liable to cause sepsis.

Treatment of Myomatous Uteri.—Dr. Howard A. Kelly, of Baltimore, presented a paper on this subject. He took the stand that myomectomy was the operation of election in the treatment of uterine fibroids in women under forty years of age, except in cases in which the tumors were interstitial and larger than a six-months' pregnancy, or when there was extensive lateral inflammatory disease. Hystero-myomectomy was to be preferred to myomectomy, after the fortieth year, except when myomectomy was the simpler operation, as in pedicle tumors. It was necessary to exercise extreme care in controlling hemorrhage. The introduction of a sound prior to operation would determine the level of the tumor and its relation to the uterine canal.

Dr. A. Lapthorn Smith opened the discussion on the two preceding papers. He said that he had recently removed a fibroid tumor from the uterus of a woman who was about four months pregnant, without interfering with the course of pregnancy. The woman was out of bed in two weeks, and out of the house five weeks after the operation.

Dr. C. P. Noble said that, having done twenty-five myomectomies without a fatality, he felt it was an operation which should be generally adopted in the case of young and child-bearing women. Two of his patients had since been delivered of children.

Dr. W. H. Baker, of Boston, also indorsed myomectomy, as a result of six years' experience in this line.

Dr. S. C. Gordon said he had misgivings about doing this operation, because, as the "soil" was unchanged, it seemed to him that there was a liability of a return of the fibroids. Regarding Dr. Cushing's paper, he said that, as a general rule, he thought the abdominal route would be found the preferable one.

Dr. Cushing objected to myomectomy on the same grounds, for, he said, in cases of multiple fibroids one usually found the uterus filled with tiny myomata, which would probably grow if not removed.

Dr. Robb said he could add ten cases to Dr. Kelly's list. In one case pregnancy occurred a few months after the removal of four fibroid tumors.

Dr. Skene said he had long practised myomectomy, and favored it more as his experience with it increased.

Dr. Kelly, in closing, said that there had been no pregnancies in his list. Of the thirty-two women in his list who had previously been pregnant, seventeen had had difficult labors. There were three recurrences in his ninety-seven cases. We should not interfere

during pregnancy simply because a myoma was discovered attached to the uterus.

Thyroid Extract in the Treatment of Fibroid Tumors.—Dr. William E. Mosely, of Baltimore, presented a communication on this subject. His experience in five hospital cases could be summarized as follows: (1) The tolerance of the extract varied greatly in different individuals; (2) in cases of bleeding fibroids it had a marked influence in controlling the hemorrhage, and in certain cases caused a diminution in the tumor; (3) in doses of nine to fifteen grains a day it improved the general health; (4) the average duration of the treatment was about nine weeks.

Extract of Mammary Gland in the Treatment of Fibroids.—Dr. John B. Shober, of Philadelphia, in a brief communication on this subject, gave his experience with the remedy in four cases. Regarding the dose, he said that one should not administer for any length of time a reliable extract in doses of more than from three to six grains a day. When employed in doses of fifteen to twenty grains a day of the desiccated powder it was found to be a powerful depressant to the heart. In these cases of fibroids, under the influence of this extract metrorrhagia and menorrhagia ceased, the general health improved, and, in some instances, the tumor became smaller. It seemed to act on the tumor very much as ergot did.

Dr. M. D. Mann said he had tried the thyroid extract in about a dozen cases, and felt greatly encouraged with the results. In about ten of the cases of small fibroids there had been decided benefit. As a rule, the hemorrhages decreased, and sometimes the tumors became smaller.

Dr. E. L. Duer said he had tried the thyroid extract in thirteen cases, but only six of them had been sufficiently long under observation to warrant any deductions. He could not say that he had secured better results than from other medical treatment, except in one case of subserous fibroid. In this one the tumor at the beginning of the treatment reached up to six inches above the pubes. Early in February the patient was put upon five-grain doses of the thyroid extract. On April 4th it was noted that the tumor extended only two and one-half inches above the pubes, and on May 14th the tumor was scarcely discernible on the most careful examination.

Dr. Malcolm McLean said that he had been using the thyroid extract in cases of fibroids since last October. In at least three of the eight cases the hemorrhage had been absolutely controlled and in two the size of the tumor had been markedly reduced.

Dr. Fry said that he had treated four cases in this way, two of them being in young women. In the latter the tumors were hemorrhagic, and the extract had controlled the bleeding. In the other two, systematic measurements showed a steady decrease in the size of the tumors.

Discussion: Should Non-Absorbable Ligatures be Discarded in Gynæcological Surgery?—Dr. Seth C. Gordon, of Portland, opened the discussion. His conclusions were: (1) All suture material which was unabsorbed must necessarily have more or less exudate about it; (2) such exudate was of lower vitality than normal repair tissue when the tissues were just approximated and not strangulated; (3) a few days only were necessary when there was no infection, and hence when there was no great strain absorbable sutures only were needed; (4) when continued strain on the parts was unavoidable, non-absorbable sutures should be used for at least two weeks, but should be so placed as to be removable; (5) for such sutures the silkworm gut seemed to be the best; (6) for all other purposes catgut was sufficient; (7) inflammation was always destructive to complete repair; (8) inflammation was always due to infection; (9) sterile catgut or kangaroo tendon should therefore meet all the indications for suture or ligature material, with the exceptions named.

Dr. R. S. Sutton continued the discussion. He said that he had abandoned the use of silver wire except in operations for vesico-vaginal and recto-vaginal fistula. He had also abandoned the use of silkworm gut in all operations except Tait's perineal operation, and he had almost discarded the use of silk, except for intestinal surgery and occasionally for tying the pedicle. After having given up the use of catgut, on three different occasions, he was induced to procure a quantity of catgut known as "O" and "OO." This was put for forty-eight hours in sulphuric ether and the bottle agitated occasionally. It was then placed between the folds of a towel for a short time, after which it was transferred to a five-per-cent. formalin solution. It remained in this for twenty-four hours, and after having been again placed for a short time in a dry towel it was put in a bath of one pint of alcohol, forty minims of formalin, and half an ounce of resin. He had made up an enormous quantity of this catgut two years ago, and when the last was exhausted about sixteen months later, bacteriological examinations showed it still to be sterile. Formerly on closing the abdominal wound with silkworm gut he had had frequent stitch abscesses. Now he closed the wound with catgut in planes, the upper layer being under the skin, and these wounds did not suppurate.

Dr. Charles P. Noble said that he was using catgut more and more, yet he had had good results with non-absorbable sutures, and he doubted if for the occasional operator the absorbable ligatures and sutures presented any advantages over the non-absorbable ones. Out of four hundred and seventy-two cases in which he had used the latter, suppuration occurred in only ten, or about two per cent., and in only two had hernia developed. He was now employing catgut sterilized according to the cumol method, and while it was rather expensive and its preparation tedious it had stood the test of bacteriological examination.

Dr. Howard A. Kelly said that catgut did not bear tension well, and in surface work it was liable to become infected. Since he had used catgut prepared according to the cumol method he had never met with any infection from the catgut, although he had used on an average fifty strands of catgut daily for the past two years.

Conservative Operations upon the Uterine Appendages.—Dr. A. Palmer Dudley, of New York, read this paper. He said that he had done one hundred and three conservative operations on the uterine appendages without a death, and with inflammation in one case. He had not had the courage until recently to attempt such work when there was reason to believe that gonorrhœa existed, but recently he had met with an accidental success in this direction, and would follow up this clew in the future. Two cases in which the specific nature of the infection was proved by microscopical examination, and in which he had done conservative work, were then given in detail.

A Method of Searing the Pedicle with the Electro-Cautery.—Dr. A. J. C. Skene, of Brooklyn, demonstrated the method. The broad ligament was seized with a hæmostatic forceps which was in electrical connection with a galvanic battery. The current was allowed to flow about half a minute for arteries of about the size of the radial, and a longer time for larger masses. The object was to desiccate but not to cauterize, and the current could be gauged by a milliamperemeter, or roughly in practice by the heat of the instrument when touched with the finger. This method not only reduced the pedicle to the smallest size, but it was thoroughly aseptic, and would completely close the lumen of a Fallopian tube or of the appendix.

TUBERCULOSIS OF THE BLADDER—DISTRIBUTION OF THE LEPROSY BACILLUS—TUBERCULOSIS OF THE TONSILS—CLINICAL EXHIBITION—ROYAL SOCIETY—THE PRINCE'S FUND—MR. HORSLEY AND THE NEW PRESIDENT OF THE COUNCIL—THE VACCINATION BILL—SIR WILLIAM STOKES—AMERICAN LADY DEFIES HER AMBASSADOR—THE NEW PHARMACOPŒIA—"PHOSSY JAW"—COLLINS COMMITTED ON CHARGE OF MURDER—WILL OF SIR R. QUAIN.

LONDON, May 15, 1898.

THE Medical Society held its last scientific meeting for the season on Monday last, when Mr. Moullin read a paper on tuberculous disease of the bladder. He advocated direct treatment after suprapubic cystotomy—the operation, according to him, not being attended with much risk and if undertaken early enough affording a chance of removing the disease. Thus early diagnosis would, as in so many other cases, be of the utmost importance—a point Mr. Moullin did not fail to enforce. He remarked that irritability of the bladder and hæmaturia occurred from the commencement of the disease, and that the cystoscope would reveal any ulcer, while the bacillus is easy to detect. The number of cases of primary tuberculosis seems to be on the increase, but this is probably due to more careful observation. Secondary cases are mostly from pyelitis, and the infection may be carried by the vessels and lymphatics. Concomitant infection of the ureter is consequently not necessary. When it is, the disease is most likely to be found at or near the orifice of the ureter; so in this locality it suggests tuberculous pyelitis. In three cases in which he had operated, two were satisfactory and the third was too recent to judge.

Dr. Freyer could not admit that the risk of suprapubic cystotomy was so slight. Out of the forty or fifty cases recorded by Barling as operated on for stone in children, the deaths numbered twenty. He had operated in six or seven cases, and in only one had he had reason to regret it. Still his opinion was rather against operation in this disease.

The differential diagnosis from stone was not easy, but he observed that the micturition in tuberculous disease of the bladder was as frequent by night as by day, while in stone was frequent only in the day.

Mr. Battle had operated in six cases, in none of which had there been any evidence of tuberculous disease elsewhere. He had seen serious results from operation only when the wound had been closed too early.

Dr. Clifford Beale observed that in post-mortem examinations the disease was not found to be associated with pulmonary tuberculosis.

The Pathological Society has had before it the question of the distribution of the leprosy bacillus in the tissues. Unna's view that the parasite inhabits the lymphatics and not the cells, in opposition to what was previously believed, has been confirmed by Bergengruen, Gerich, Herman, and Dohl. Dr. Kanthack, at the last meeting, gave an abstract of a paper of Bergengruen's, in which, though he does not deny that the bacillus may occasionally be found in the cells, declares that Unna's view is correct. Bergengruen has the merit of establishing this (for Unna cannot be said to have done so satisfactorily); his specimens show that the giant cells in leprosy of the larynx are due to endothelial proliferation around bacillary thrombi. The latter appear to be engulfed by the giant cells, but as a matter of fact they remain in the lumen of the lymphatic vessel, the endothelium of which grows around and into the thrombus and so destroys it. The thrombus acts as a foreign body, irritating the contiguous endothelium at some parts where the cells proliferate and form a plasmodial mass.

The president (Dr. Payne) remarked that, although he once thought the bacilli intracellular, he now doubted it, for in a case under his care sections of cutaneous lesions showed the organisms diffusely scattered through the tissues, the globes or clumps being practically absent.

Dr. Hebb had noticed in longitudinal sections of leprous nerves that the bacilli were distributed in long irregular lines corresponding with the clefts of the tissue, and did not regard the location as that of the cells.

Dr. Andrewes suggested that the location might differ in external lesions and internal organs. He had seen the bacilli in the spleen look as if they were in the cells.

Dr. Kanthack said that the greatest difficulty of determining the question was in the spleen, as a zoöglœa adhering to a cell would closely simulate a location within it. Serial sections of the individual cells would alone suffice for the determination.

Dr. Hugh Walsham then brought forward the results of an inquiry into tuberculosis of the tonsils, which he had undertaken in consequence of a suggestion made by Dr. Sims Woodhead that these bodies were probably the frequent site of infection. Dr. Walsham found histological signs of tuberculosis in twenty-one out of thirty-four cases of "enlarged tonsils." As in many cases there had been nothing to direct attention to the throat during life, he termed them "latent;" but there was nothing to show whether the tuberculosis was primary or secondary, and probably the explanation must be sought in the passing of expectoration over the parts. Of course in acute miliary tuberculosis the tonsils, like other tissues, might be invaded through the blood stream.

There were some interesting exhibits before the Clinical Society. Mr. Eve showed three cases of transplantation—or, as Mr. Jackson Clarke proposes to call it, reimplantation—of tendon for infantile paralysis.

Dr. Pasteur showed a woman with atrophy of the thyroid and certain symptoms of myxœdema following Graves' disease, and said the pulse had fallen to 40 and 50. This symptom was, however, variable, for during the excitement of the examination it rose to 70 and 90. Thyroid extract had been given, but seemed to aggravate the symptoms.

Dr. Garrod showed a child with a typical Mongol cast of features, associated with cyanosis and a loud systolic murmur and a thrill. He had observed this cast of features to be frequent when idiocy is associated with heart disease.

Among others exhibited were a woman who had undergone gastro-duodenostomy; another from whom portions of five ribs had been removed; a man of thirty who had become hemiplegic on the twenty-fourth day of an attack of typhoid, and it was remarked that only eight similar cases are recorded by English physicians; a woman of fifty-two with osteitis deformans affecting all four extremities, in whom the disease began twelve years ago.

The Royal Society had a brilliant assembly at a *conversazione* on Wednesday. Many interesting exhibits attracted attention. So-called "wireless telegraphy" was carried on between the library and secretary's room. Photographs of the solar eclipse were shown; also some colored photographs, one scene having been taken in both spring and autumn. There was also a green oyster on view. The majority of such creatures derive their color from copper, but it is

said that Marennes oysters owe it to an animal pigment. As to typhoid, which has been said to be conveyed by oysters, it is now asserted that the bacillus found in these and other shellfish resembles that of typhoid, but is not the same. The differentiation deserves attention, but even if made out the danger of sewage in oyster beds would still remain.

Fears are being freely expressed that the Prince of Wales' fund will not be the boon it was hoped to prove to the London hospitals. It is no longer doubted that many who have given a lump sum to the fund feel that they have discharged all their duties in the matter, and some have withdrawn annual subscriptions. The few large hospitals which have received considerable sums may feel satisfied, but the much larger number consider themselves losers by the prince's fund. It will be a disappointment to the prince if his scheme should prove a failure, and there is no longer any doubt that there is danger that such may be the result of the jubilee effort to place the hospitals on a secure footing.

Mr. Victor Horsley has issued a fourth report to his constituents, from which it appears that the new president of the General Medical Council has instructed the registrar to refuse him access to the documents of the council, unless he first obtains the permission of the executive committee or of the council. This extraordinary assumption of authority to refuse a member of the council access to its archives is, I fancy, unprecedented in public bodies of this kind. Mr. Horsley naturally wrote to the president to ask by what authority he sought to debar him from his natural rights in the matter, and in his report says that the president has complicated his extraordinary action by refusing in uncivil terms to answer either of the three questions he put. Mr. Horsley says the medical acts and standing orders confer no such power on the president, and he is taking steps to clear away this novel and foolish hindrance to his work. I am astonished that a man of Sir W. Turner's judgment should assume such an unconstitutional attitude, and await the development of the conflict with interest, for it promises lively times.

The vaccination bill has been read a second time, and the details are exciting more interest. Dr. Bond, in a letter to *The Times*, makes some suggestions, among which I notice is the payment out of public funds even when the operation is performed by a private practitioner. Some economists are startled at this, but it is not unprecedented. I remember that many years ago a certain board of guardians offered to pay every private practitioner in the parish who filled up the usual certificate. The result was satisfactory, for even busy and well-to-do doctors preferred to vaccinate their own cases and had no objection to fill up the certificates for the very trifling fee, rather than have their patients troubled by others.

The presentation to Sir William Stokes took place in the College of Surgeons of Dublin on Saturday. It commemorates his twenty-five years' professorship at the college, and consists of handsome pieces of plate. In the evening a dinner was given him in the college by a large number of his brethren and former pupils. Sir William has written a life of his distinguished father, the late Dr. William Stokes, the great Dublin physician, which is just about to appear in the "Masters of Medicine" series.

A young American lady was lately released from an asylum on the representation of Colonel Hay, who undertook that she should at once be sent home; but, having been duly discharged, she defies the ambassador and positively refuses to leave England. Being told that unless she promptly sailed for the States she would be again sent to an asylum, she called at the embassy and said she had seen the English authorities and was informed that her discharge was permanent. It is a curious problem for the embassy.

The new Pharmacopœia is now on sale. The price is fixed at 10*s* 6*d*, and dear enough many think for an official publication, the purchase of which is compulsory on so many. It ought to be sold at the same rate as are parliamentary papers. Of course the cost of producing it has been enormous, but that is because of the extravagant methods of the council.

Phosphorus disease has been mentioned in Parliament in consequence of recent cases, and the home secretary stated yesterday that there had been systematic neglect of the factory regulations as to reporting "phossy jaw," and in one case he had ordered a prosecution—so there may be further revelations as to the value of hygienic laws.

Dr. Collins was yesterday committed for trial on the charge of murder by producing abortion on Mrs. Uzzielli.

The will of Sir Richard Quain has been proved. The personal property is over £118,000.

Mysterious Disease in Africa.—While the bubonic plague seems to be spreading in India and threatens almost to equal in fatality the epidemic of a year ago, the French physicians in Algeria have discovered a disease in Africa which, if the meagre reports which have been received prove true, is none the less fatal. It is a mysterious disease, and no satisfactory diagnosis has yet been made of it. It first shows itself by the patient having an inordinate desire to sleep. Its symptoms resemble those manifested in laudanum poisoning. If the patient be not at once aroused, he soon falls into a stupor which is succeeded by death. From its symptoms it has been called, by the correspondents of French medical journals in Algeria, *la maladie du sommeil* (the sleeping-sickness). Europeans are not susceptible to it, Arabs only slightly, but the negro falls a ready victim. Two doctors of the University of Coimbe have a theory that the disease is microbic. With some bacilli in serum obtained from the blood of a young negro who had died from the disease, they inoculated half a dozen rabbits. The little animals became drowsy, and soon died, betraying all the symptoms of the disease.—*Scientific American.*

Health Reports.—The following statistics concerning cholera, plague, and small-pox have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending May 28, 1898:

CHOLERA.

		Cases.	Deaths.
India, Madras	April 16th to 22d	1	2

PLAGUE.

India, Bombay	April 19th to 26th		442

SMALL-POX—UNITED STATES.

Louisiana, New Orleans	May 14th to 21st	1	
New York, New York	May 14th to 21st	1	
Ohio, Carroll	May 11th	6	

SMALL-POX—FOREIGN.

Belgium, Antwerp	May 1st to 7th	2	
Bohemia, Prague	May 1st to 7th	3	
Canada, Halifax	May 14th to 21st	3	
Ceylon, Colombo	April 8th to 23d	1	1
China, Hong Kong	March 26th to April 2d	7	7
Engand, Newcastle-on-Tyne	May 1st to 7th	2	
Germany, Bremen	April 13th to 30th	1	
India, Bombay	April 10th to 26th		3

ON REMITTENT (RELAPSING) MELANCHOLIA.

BY WILLIAM B. NEFTEL, M.D.

NEW YORK.

IN 1875 I published, in the MEDICAL RECORD and in the *Centralblatt fur die medicinischen Wissenschaften*, my observations and researches on a peculiar form of melancholia, which I called periodical melancholia. The article had quite a remarkable fate. My views were accepted by such authorities as Meynert, Westphal, Krafft-Ebing, Eulenburg, Kirn, and others; and the term periodical melancholia received the right of citizenship in all the text-books on diseases of the nervous system. The reason for this prompt recognition is obvious: the periodical form of melancholia throws light upon the melancholic process in general, upon its etiology, symptomatology, and prognosis. The disease attacks the patient in the midst of perfect health, often without any premonitory symptoms, and, having lasted for weeks and months, suddenly disappears and the patient regains his former health, until it is again interrupted by the melancholic attack. I could, therefore, easily compare the condition of the patient during the healthy intervals with his condition during the melancholic attacks, and the difference in his functions during the two conditions offered the pathognomonic symptoms of the melancholic state. Thus it could be demonstrated that in the melancholic state the patient constantly loses flesh, sometimes very considerably; this loss of weight begins with the attack and stops immediately at its disappearance. There is no exception to this rule. Furthermore, all the functions, both psychical and somatic, are retarded during the melancholic attack (the circulation, respiration, sleep, appetite, digestion, body temperature, all muscular and mental activity, the secretions and excretions, are greatly diminished); there are considerable general anæmia and, especially, anæmia of the brain. Besides, there are always vasomotor disturbances, which are very probably the cause of the anæmia and of the psychical depression. Finally, the periodic form of melancholia is invariably the expression of an inherited psycho-neuropathic disposition; hence its prognosis is unfavorable.

The periodical form of melancholia has proved of such theoretical interest and practical importance that a new chapter has been added to neuropathology, viz., periodical psychoneuroses (periodical mania, periodical paranoia, etc.).

At the time of making my first observations on periodical melancholia, some thirty years ago, I frequently met with cases apparently resembling this affection, but differing in some points; and I was inclined to consider them as modifications of the same neurosis. Gradually, however, I came to the conclusion that they belonged to quite another type and were entirely different as regards their etiology, prognosis, and treatment. Indeed, while periodical melancholia always presupposes an inherited neuropathic constitution and may be considered incurable, the other form of melancholia affects persons who are free from any neuropathic disposition; it requires a different treatment and is almost always curable. Moreover, in periodical melancholia there are perfectly healthy intervals between the attacks, while in the other form there are only remissions. In my notes I have been in the habit of calling this affection remittent or relapsing melancholia, and still continue to do so for want of a better term. For a long time I hesitated to publish my observations under this name, because the remarkable researches of Charcot's school on hysteria and those of Beard on neurasthenia made it necessary for me to reinvestigate the whole subject in its relations to hysteria and neurasthenia. Moreover, neuroses like periodical melancholia, and still more remittent melancholia, hardly ever occur in hospital practice, and it necessarily requires a long time to collect detailed facts from single cases in private practice. It takes many years to study the affection in all its phases in order to complete the neuropathological picture, and I now offer the result of observations extending over more than a quarter of a century. What was lost in time might perhaps be compensated by a contribution to the etiology, pathogenesis, and therapeutics of melancholia and other psychoneuroses.

Before describing remittent melancholia, I will illustrate it with a few selected cases.

Mr. B——, aged forty-three, comes of a healthy, long-lived family. He is without any neuropathic disposition and of regular habits. He neither drinks nor smokes, and, with the exception of typhoid fever in his twenty-third year, has always been healthy and had no acute or chronic affection. He was a good student in school and college, of a cheerful disposition, and very fond of outdoor exercise. Later on he had to work hard, and by industry and perseverance succeeded in establishing a prosperous business. During the panic of 1873 he sustained severe losses, which involved almost the whole of his fortune, on which depended the welfare of his family. His income having dwindled to a mere trifle, the consequences appeared to him so much the more disastrous as he saw no prospect of retrieving his fortune. He struggled for a time to keep up appearances, but physical disabilities began to develop and soon assumed an alarming character. One of the consulted physicians pronounced the case incipient diabetes with a gradual impairment of vision. The patient became depressed, suffered from insomnia, lost appetite and flesh, and grew weak and anæmic. The depression steadily increased, although it followed an irregular course, being at times greatly aggravated and occasionally showing remissions for days and weeks, until the depression would again attain its former intensity or even surpass it. This psychical condition was often accompanied by a most distressing sensation in the precordial or epigastric regions, extending into the thoracic or abdominal cavities, but could not be exactly located. The patient called it not a pain, but an exceedingly unpleasant and undefinable sensation, somewhat resembling seasickness, but causing much more distress and prostration. Even during the remissions the patient was not entirely free from this sensation. Next to the psychical depression, insomnia

was the most dreaded symptom. During the sleepless nights the patient brooded and worried over his unpleasant affairs: precordial distress and palpitation would set in, and leave the patient utterly exhausted and prostrated. This was followed toward morning by abundant and frequent urinary secretion and profuse perspiration. During the day he was able to attend to his business, though physically weak and without mental vigor; his memory, which used to be excellent, lost some of its acuteness. Besides medical treatment, change of climate had been resorted to at the advice of several eminent physicians; the seaside, the mountains, travelling in Europe and at home had been repeatedly tried, but seemed to bring little benefit.

I examined the patient for the first time in the fall of 1878, and continued to observe him for several years. He was a well-developed, muscular man of more than medium size, in whom the most careful examination could not detect anything abnormal. The organs of respiration, circulation, and digestion were perfectly normal, and so were the functions of the cerebro-spinal nerves, both sensitive and motor; in fact, the whole nervous system was normal. The urine contained neither sugar nor albumin, nor any morphotic elements; the skin and the visible mucous membranes were pale. The patient was thin, but said he was well nourished formerly and used to have a very healthy complexion. His depressed condition resembled, to a certain extent, the melancholia agitans without delusions, but differed from it by remissions. I examined the urine after the patient had a sleepless night and had passed a large quantity in the morning. It contained a small amount of sugar (about one per cent.), but the glycosuria was ephemeral and entirely disappeared the next day, returning only under similar circumstances. A most remarkable cardiac symptom appeared every time the patient suffered from what he called his attacks, which usually began with a feeling of cold in the extremities, a chill, followed by precordial distress, physical and mental prostration, accelerated and small pulse. The heart, at the height of the attack, showed an enlarged area, especially to the right, while the apex was felt lower and more to the left. This dilatation of the heart lasted for hours, until the attack ended under profuse perspiration and urinary secretion, when the heart resumed its normal dimensions. The diagnoses made at different times varied greatly, owing doubtless to the changeable condition of the patient. The majority of physicians who observed the case considered it as one of neurasthenia, especially cerebral neurasthenia; some pronounced it to be a cardiac disease, functional or even organic; others thought it was diabetes or some obscure visceral disease, possibly of the pancreas; and others apprehended incipient insanity.

After a careful analysis of all the symptoms, I came at last to the conclusion that the patient was suffering from a peculiar kind of melancholia, induced by depressing emotions, resembling periodical melancholia. Two reasons, however, excluded the latter: there were no healthy intermissions between the melancholic attacks, the patient remaining more or less depressed during remissions; and, besides, there was no hereditary neuropathic disposition. I therefore considered the case as remittent melancholia and treated him accordingly, with a satisfactory result.

During the panic of 1893 I saw him again professionally. At the same time I had quite a number of analogous cases, especially among brokers and business men. It looked almost like an epidemic, and was called forth by financial losses and business troubles. I purposely selected the above case as an illustration of remittent melancholia, because it was simple and free from complications. The patient had no hereditary neuropathic disposition, no previous organic or functional affection, and the cause and effect could be traced from beginning to end. But such uncomplicated cases are exceedingly rare and almost exceptional. In the majority of cases the complications obscure the essential nature of the disease and make a correct diagnosis very difficult. This explains why the affection has not yet been described by clinical observers.

Remittent melancholia in the majority of men is induced by financial losses, although other causes are not uncommon. Among women, however, while depressing emotions of a different character mostly produce the affection, financial troubles may occasionally be found as an etiological factor.

Mrs. K——, over seventy years old, widow of a wealthy banker, consulted me two years ago. Although of a nervous temperament, she was formerly healthy, but for the last ten years suffered from insomnia, nervous prostration, etc. Of her two sons, the elder is intemperate and unable to attend to any business. The second son was unfortunate in Wall Street speculations and lost even the greatest part of his mother's capital; the old lady and her daughter were obliged to give up their luxurious home and reside in a country boarding-house. When she consulted me in May, 1895, she was emaciated and her face was flushed, with an anxious expression; the pulse was small and accelerated; the extremities were cold; the respiration was superficial and accelerated; the area of the heart was enlarged, especially to the right, and the apex was lowered and more to the left. She suffered from insomnia, with great distress, depression, and prostration. I was prepared to corroborate the previous diagnosis of cardiac disease, and, with a palliative object in view, I employed the galvanic method I generally use to produce a soothing effect and to induce sleep. The next day there was a complete change in the patient's countenance and sensations. She had had a prolonged and refreshing sleep, had no distress, and felt quite cheerful, with a good appetite and normal respiration and pulse. The physical examination of the heart revealed nothing abnormal. This improvement lasted about a week, when renewed worry brought back the insomnia with all the other morbid symptoms, which again yielded temporarily to the same treatment.

Mr. T——, forty-nine years old, well built and of an excellent constitution, free from any hereditary morbid disposition and belonging to a healthy, long-lived family, very muscular and a great sportsman, placed himself under my care in the winter of 1893. Eighteen years ago he first complained of dyspepsia, which became more and more severe in the course of time and assumed a complicated form. The disease was at first considered gastric catarrh and treated accordingly, without the desired result. Later on it became characterized by attacks of acute pain in the hepatic and gastric regions, by nausea, vomiting, diarrhœa, great prostration, complete loss of appetite, icteric discoloration of the skin, scanty and dark urine, insomnia, mental depression, loss of flesh, and anæmia. Such attacks would last from several days to several weeks, when he would gradually improve, to be pulled down again by the next attack. Some of these attacks would be so severe and the pain in the region of the liver and in the left hypochondrium so persistent and intense, that a malignant disease of the stomach, of the liver, or of some other abdominal viscus was suspected. He had been subjected to different methods of treatment, which he carried out conscientiously for months and years. He was kept on a strict, almost starvation diet; he tried the milk cure, kumyss cure, meat-and-hot-water cure, rest cure, Turkish baths, massage, gymnastics; was treated with opiates and other

narcotics, with stimulants, cathartics, change of climate, etc. The physical examination showed nothing abnormal besides general anæmia and emaciation and a slight dilatation of the stomach and enlargement of the spleen.

Having regulated his diet and mode of living, I prescribed hydrochloric acid and quinine; the patient gradually improved, but was soon attacked again with the symptoms above described, and after a sleepless night was entirely prostrated and suffering from pain in the left and right hypochondriac regions, with complete loss of appetite, diarrhœa, scanty and dark urine containing biliary coloring matter, icteric discoloration of the skin and mucous membranes, weak pulse. It was impossible to make a diagnosis; a malignant tumor of the stomach could be suspected, an organic affection of the liver, cholelithiasis, or inflammation of the pancreas, etc. But gradually, in the course of careful observation, several of these suppositions had to be excluded. The urine examined during the healthy intervals was normal, a malignant tumor could not possibly exist so long, and the intervals of comparative health between the attacks excluded the existence of any organic disease. The anamnesis furnished points for a different diagnosis; it showed that long-continued depressing emotions were the primary cause of the affection. In his youth he became infatuated with a lady twenty years his senior. The relations between them lasted for many years, entailed great expenses, and precluded the possibility of his settling in life according to his high social standing. This was a source of continual worry and depression, culminating in melancholia with vasomotor disturbances simulating different organic affections. The secondary somatic complications attracted the attention of the patient and the attending physicians, while the primary psychical cause was lost sight of. The vasomotor phenomena were not concentrated so much in the cardiac as in the various abdominal plexuses—solar, gastric, hepatic, mesenteric, hypogastric—and manifested themselves as diseases of the various abdominal viscera. Taking into consideration the absence of any organic disease and of a hereditary neuropathic disposition, I made a diagnosis of remittent melancholia, with a favorable prognosis, which was confirmed by the result.

Mr. W——, aged forty-two, a widower, cultivated, of a nervous temperament but of a good constitution, of healthy parentage and himself formerly in good health, consulted me in 1889. He suffered from insomnia, great mental depression, and a peculiar feeling of distress, accompanied by very unpleasant sensations in the head, cardiac and epigastric regions. These sensations were more or less constant, but reached their highest degree during the sleepless nights. This condition incapacitated him for any steady work, and, though endowed with literary tastes and having received a most liberal education, he was for the last six years condemned to an enforced mental and physical idleness. His case was considered either severe neurasthenia or dyspepsia with affection of the liver. Various treatments and travelling brought little if any relief. The anamnesis revealed the source of the affection. His young wife, during her first pregnancy, suffered from albuminuria and nearly died of eclampsia at childbirth. Although she slowly recovered and the symptoms of Bright's disease gradually disappeared, the husband was informed by the family physician that a new pregnancy would probably call forth the same symptoms, with a fatal termination. Indeed, when she again became pregnant, the disease of the kidneys did not entirely disappear after the eclampsia, and she died at the end of two years. This was a great shock to the husband, and produced the above-described symptom complex of remittent melancholia.

Mr. J—— consulted me in 1896. He was of a weak constitution, inherited from his mother, who died early in life; on the father's side his ancestors were all healthy. From his infancy he was brought up by a stepmother, who took great care to develop him physically and intellectually. Although he was never robust, his health was fairly good during his college life, and remained so for a while after his return to the parents' home. He could not, however, become reconciled to the idea of another woman taking the place of his own mother, and this idea daily grew in intensity, especially after his father's death. The patient became very irritable, pessimistic, and complained of various morbid conditions—dyspepsia, bilious attacks, diarrhœa, etc.—and was very much emaciated. He was constantly under treatment for liver complaint, chronic intestinal catarrh, spermatorrhœa, sexual neurasthenia, and was subjected to a variety of treatments during many years. Among other methods he was put on calomel treatment, which extremely weakened him; at another time he was kept on a strict diet and sulphur water, and for an alleged stricture of the urethra and inflammation of the prostate he had to undergo a methodical introduction of sounds into the bladder. Later, tenotomies of the eye muscles were performed, and gymnastics, massage, hydropathy, and electricity were resorted to, without benefit. When I first saw this emaciated but intelligent young man, of a sallow complexion, he made the impression of a phthisical person, but on examination the lungs and other thoracic and abdominal organs were found in a normal condition; the nerve centres, the whole peripheric nervous apparatus, the muscular and vascular systems were also normal. The organs of special senses were sound and exceptionally acute. On the other hand, his subjective feelings were morbid to such a degree that he was frequently considered neurasthenic, hysterical, or simply insane. He mostly complained of intense precordial and epigastric distress in the sphere of the various plexuses—thoracic, abdominal, and especially pelvic (prostatic, vesical, and hemorrhoidal); also of unpleasant sensations in the head, eyes, occiput, and nape of the neck. These distressing sensations were accompanied with nausea, vertigo, faintness, nervous prostration, insomnia, and a suicidal tendency. At times the patient would seem relieved and would steadily improve in health, but after a while the same morbid condition would return with increased intensity. My diagnosis was remittent melancholia, from which the patient ultimately recovered.

As already stated, prolonged depressing emotions frequently lead to remittent melancholia, in both men and women; but in the latter case the depressed condition is mostly attributed to some affection of the pelvic organs, and the psychical condition remains entirely overlooked.

Mrs. F——, aged thirty-four, a cultivated lady of healthy parentage and mother of three children, consulted me in November, 1885. She was well before her marriage, although of a nervous and excitable temperament. She menstruated regularly, and has always been free from any female complaint, the pelvic organs being perfectly normal. For the past eight years she has been suffering from attacks of nervous prostration, accompanied with insomnia, precordial distress, palpitation and small pulse, gastric disturbances, loss of appetite, with occasional vomiting. The attacks lasted from several days to several weeks, during which she rapidly lost flesh, became weak and anæmic to an alarming extent. Under the best medical treatment she would slowly recuperate, although a high degree of anæmia, emaciation, and general debility would remain, with occasional vasomotor disturbances. Her health improved rapidly, however, when she was on a long visit to her wealthy relatives and friends,

where she remained for weeks with her children or even alone. After returning home a new attack would be sure to follow sooner or later. The patient consulted excellent physicians here and abroad, and almost every one suspected a cardiac affection. A careful examination of the patient during the intervals between attacks could not reveal any organic disease. Besides general anæmia and emaciation, there were present vasomotor and trophic phenomena. Her hands and fingers were painful, red, and glossy, resembling erythromelalgia (Mitchell). The anamnesis gave a history of long-continued worry, the real cause of all the morbid psychical, vasomotor, and trophic phenomena which produced the symptom complex of remittent melancholia. Accordingly a favorable prognosis was made and a different treatment resorted to.

Mrs. G——, a childless married woman who had been under a prolonged nervous strain, became depressed, melancholic, with occasional remissions. She was treated for some chronic pelvic trouble; the symptom which mostly attracted attention was pain in the left ovarian region, and it was at last decided to extirpate both ovaries, but the operation did not remove the pain. Her general health suffered to such an extent that she could not see even her nearest relatives or bear the slightest noise; even the shortest conversation would set her frantic. She could not sleep at all, lost appetite and flesh, became anæmic, looked cachectic, and was threatened with insanity. Under a treatment for remittent melancholia her health improved.

I designate by remittent melancholia a peculiar psychical affection produced by long-continued depressing emotions. All the functions, psychical and somatic, are lowered and retarded; the skin and mucous membranes are pale; there is general anæmia, especially anæmia of the brain, with loss of flesh and nervous prostration; the secretions are scanty; the pulse is small and weak. Although the intellect remains intact, there is a lack of energy and of will power.

Characteristic of melancholia is the impossibility for the psychical organ to produce any but unpleasant sensations; it reacts with painful emotions to every impression, even to those which at other times would have been agreeable to the patient.

The psychical depression is always accompanied by attacks of vasomotor disturbances in the nerve centres and other viscera. They either affect the vasomotor centre in the medulla oblongata and produce a general angiospasm, or are concentrated in the cardiac or any other plexus. The patient at the height of despondency, especially during a sleepless night, feels cold all over the body, particularly in the extremities, with precordial distress, palpitation, faintness, and complete prostration. The pulse during these attacks is accelerated; the heart is enlarged, especially toward the right side; the apex lower and toward the left. After the attack the heart gradually resumes its normal position and size. The attack may last for hours or days, and usually terminates under profuse perspiration and increased urinary secretion, the urine sometimes containing sugar. It is evident that these attacks are caused by a general angiospasm and temporary dilatation of the heart, which by frequent and prolonged recurrences may lead even to a permanent cardiac affection. The cardiac phenomena, always present in remittent melancholia, are sometimes less pronounced than the disturbances in the sphere of other plexuses—in the solar, gastric, hepatic, mesenteric, splenic, vesical, prostatic, ovarian, or hemorrhoidal. Accordingly the original psychosis may be obscured by the prevailing morbid symptoms of the different affected viscera. Thus the patients are treated for affections of the thoracic, abdominal, or pelvic organs, while the primary psychical disease remains unrecognized. The temporary glycosuria is probably also caused by a vasomotor disturbance in the pancreas.

Among the most distressing symptoms of remittent melancholia is the insomnia which often precedes the attacks. However sleepy may be the patient, on retiring he remains awake and broods over his trouble; should he fall asleep, he is aroused by frightful dreams. He feels entirely prostrated in the morning and unable to get up. When by a great effort he leaves the bed, he is very weak and nauseated and has no appetite. After breakfast he regains a little strength, may sometimes attend to business, and feels better toward the evening. If the patient yields to the disinclination to leave the bed, the prostration increases, and only by great determination and repeated efforts will he be able to rise and gradually to recover the condition in which he was before taking to the bed.

Under favorable hygienic and psychical conditions the patient gradually improves to a certain degree, but does not always entirely recover his former health. He may remain in this improved condition for weeks or even months, until some unpleasant occurrence brings renewed worry and a relapse.

Cases with inherited neuropathic disposition may pass into some kind of insanity. In others some organic disease may develop, among which there may be a cardiac disease or a malignant form of diabetes.

On the whole, the course of remittent melancholia is chronic, lasting for months or years, with remissions, but under a proper treatment a complete recovery is possible.

Differential Diagnosis. — Remittent melancholia can be easily mistaken for periodical melancholia, but in remittent melancholia the morbid condition is invariably induced by long-continued depressing emotions, and develops gradually in persons free from inherited neuropathic disposition. In periodical melancholia, on the other hand, the disease appears suddenly, without any apparent cause, often in the midst of perfect health or after a very short premonitory stage of depression, in persons with an inherited neuropathic constitution. The attack soon reaches its height and remains so until, without any transition, the patient passes into perfect health, which he retains for many months, until the sudden outbreak of a new attack. In remittent melancholia the recovery from the attacks is very gradual and slow, and during the comparatively healthy intervals between the attacks the patient remains slightly depressed and does not completely recover. Remittent melancholia is often diagnosticated as neurasthenia, for both have in common the symptom of nervous prostration, but they differ etiologically. The most characteristic symptoms of remittent melancholia are the angiospastic attacks, the sluggishness of functions, and the absence of inherited disposition.

Hysteria sometimes resembles remittent melancholia, but in hysteria the so-called hysterical stigmata can always be found. In remittent melancholia, on the contrary, they are absent, as a rule, although in exceptional cases they may exist as a complication and disappear spontaneously under the treatment of the principal disease.

Frequently in remittent melancholia an affection of some organ (heart, liver, sexual organs, etc.) is considered the primary cause of the psychical depression; whereas in reality it is the psychical depression, with its accompanying vasomotor disturbances, that is the primary cause of the visceral affection.

A careful analysis of the morbid phenomena in their chronological order, the anamnesis, greatly helps to determine the diagnosis.

Etiology and Pathogenesis.—In the last two decades the greatest advance has been made in the eti-

ology of diseases by the discovery of pathogenic micro-organisms. The constant progress in etiology must necessarily lead to a science of therapeutics which will eventually supplant our present empirical methods of treatment. It would require a special article to give even a superficial review of the subject; within the limits of this paper only brief mention can be made of some of the important points. The pathogenic micro-organisms, by their vital activity, produce toxins and thus cause the morbid symptoms of different acute and chronic diseases, including those of the nervous system. Clinical observations show that in the course of any infectious disease microbic germs or toxins may be carried by the circulation into the nerve tissues and produce different acute and chronic diseases of the brain, of the spinal cord, or of the peripheric nerves; for instance, encephalitis, myelitis, multiple cerebro-spinal sclerosis, polyneuritis, etc. Moreover, long after the disappearance of the primary infectious disease, secondary autointoxication may be produced by the remaining latent germs. These clinical observations have been confirmed by experiments on animals, with injections of microbes or their toxins into the nerve tissue, where they excite inflammatory or degenerative changes of a diffused, focal, disseminative, or even systemic character. And yet in the healthy organism the alimentary canal and the respiratory tract contain normally the most virulent microbes as well as many innocuous saprophytic bacteria. Although they exert no deleterious influence under ordinary circumstances, they may under certain conditions produce auto-infection.

Even before knowing the etiological significance of micro-organisms, we were acquainted with auto-intoxications—uræmia, cholæmia, diabetic coma, etc. Senator was the first to describe in 1868 a case of auto-intoxication with sulphuretted hydrogen absorbed from the intestinal canal. Sir Andrew Clark concluded from clinical observations that products of putrid decomposition in chronic constipation produced auto-intoxication. Later Ewald, Boas, and others described the development of sulphuretted hydrogen in chronic gastric dilatation in consequence of putrid decomposition of albuminous substances produced by bacterium coli. In some other cases of dilatation of the stomach, tetany is caused by the absorption of toxins.

Heubner, Baginsky, and others ascribe to auto-infection some febrile and convulsive diseases in infants with gastro-intestinal catarrh. It was known long ago that hypochondriasis and mental depression often accompany chronic dyspepsia and intestinal catarrh. Of late Wagner found a large amount of aceton and indican in the urine of some acute cases of psychoses, and concluded that auto-intoxication from the gastro-intestinal canal was the cause of the disease. He employed intestinal antisepsis, to which the psychoses yielded.

The researches of Hoppe-Seyler, Kuehne, Salkowski, Baumann, Nencki, and others demonstrated that the aromatic substances—indol, phenol, skatol, etc.—are the products of intestinal putrefaction of proteids caused by bacteria. These aromatic substances are absorbed into the circulation and eliminated with the urine in combination with sulphuric acid; they are called combined ether sulphates, and may be considered, *ceteris paribus*, as an index of the extent of intestinal putrefaction, a certain amount of intestinal putrefaction, however, is always present even in the healthy condition, and probably promotes the intestinal digestion and assimilation.[1]

Auto-intoxication takes place only when the putrefaction is excessive; it is caused less by the combined ether sulphates than by other toxins which are eliminated by the skin and lungs. The critical perspiration in pneumonia and other acute diseases, by which the toxins are eliminated, was known as far back as Hippocrates, and the poisonous effect of the substances eliminated by expiration was demonstrated by Brown-Séquard.

Bouchard, who introduced the term auto-intoxication, designated by it only a general poisoning of the system with bacterial toxins formed in the intestinal canal. But there are many other sources of auto-intoxication besides. Thus a very frequent cause of auto-intoxication is the accumulation of incompletely oxidized products of tissue change. On the whole, auto-intoxications are readily produced whenever the alkalinity of the blood is diminished or the functions of the kidneys, skin, and other emunctories are impaired. Even healthy organs during their functional activity form poisonous substances, which would produce auto-intoxication were they not promptly eliminated by the emunctories. Thus muscular activity produces lactic acid and the so-called fatigue substances, which, if not thrown off at once by perspiration and urine, cause exhaustion and prostration. When accumulated in large quantities after prolonged and violent exercise they may become dangerous and fatal, especially if the kidneys are diseased. Most remarkable are the effects of morbid changes of the glandular secretions; for instance, a nervous shock, a sudden fright, may instantly transform the mammary secretion into poison and cause convulsions in an infant who would take the breast immediately after the shock.

Probably the parotid and the other salivary glands, perhaps all glands, are equally apt to produce toxins. We are now experimentally and clinically acquainted with some of the properties of the thyroid gland and of the suprarenal capsules. They both produce antitoxins which neutralize the poisons formed by the tissue changes, and their extirpation, therefore, or their pathological condition leads to serious affections (myxœdema, Graves' and Addison's diseases, etc.). The extirpation or a disease of the pancreas produces malignant diabetes. The liver also secretes antitoxins, which neutralize the ptomains produced by imperfect digestion.

I believe that the products of cerebral tissue change after prolonged strained and abnormal activity may be a most important factor in the etiology of psychoneuroses. If sufficient time is not given to the overworked brain to recuperate by rest, sleep, and nutrition, or if the accumulated poisons cannot be promptly eliminated from the circulation, an affection of the nervous system must necessarily follow. Possibly the quality and quantity of the toxin produced by the cerebral tissue changes determine the character of the psychoneurosis. We have learned from clinical observations and experimental pathology that different toxins have peculiar affinities to certain nerve centres and functions; for instance, chronic poisoning with ergot produces the symptoms of locomotor ataxia and sclerosis of the posterior columns identical with those of tabes; strychnine produces convulsions and woorara paralysis of cerebro-spinal motor tracts; alcohol and narcotics affect the psychical centres; digitalis and atropine act upon the vasomotor and oculo-pupillary centres, etc. I assume that in melancholia the sluggishness of all the functions (respiratory, circulatory, especially secretory) causes the accumulation of the poisonous products of tissue change, depresses the psychical, and irritates the vasomotor centres.

In acknowledging the great value of bacteriological researches for the progress of etiology, we must not neglect the study of the tissues and their reaction against microbic irritants, organic and inorganic poi-

[1] While working several years in the laboratories of Hoppe-Seyler and Kuehne I often found moderate amounts of indican in the urine of perfectly healthy persons.

sons, and other injurious agents. The results obtained by Nissl's method have greatly increased our knowledge of both the normal structure of the nerve cells and their alterations under various influences. Nissl has shown that the ganglion cells consist of two substances—an amorphous and a formed substance—the latter consisting of corpuscles variously arranged and typical of the different kinds of nerve cells. When treated with alcoholic methyl-blue, these corpuscles in the normal condition assume the dye, while the amorphous substance remains colorless.

Experiments on animals made by Nissl, Ramon y Cajal, Van Gehuchten, Lenhossek, Marinesco, Flemming, Flatau, Goldscheider, and others demonstrated the different characteristic and specific alterations which the nerve cells undergo when subjected to the influence of various agents and poisons—the electric current, mechanical, chemical, thermal, and other irritations. In these cases the structure of the nerve cells undergoes pathological changes: the Nissl bodies either approach each other closely or become more separated by the amorphous substance; they break up into fine granules or are entirely dissolved, and the amorphous substance assumes a blue color, etc. In case of recovery the nerve cells resume their normal structure.

Many other striking results may be expected from Nissl's method. Perhaps it will be found that even psychical impressions cause certain alterations of the cerebral cells, and thus an anatomical basis may be found for the so-called functional and hysterical affections of the nervous system.

The researches of Flechsig cannot be left unnoticed whenever a neurosis or psychosis is under consideration; they mark an epoch in the anatomy and physiology of the brain, and in psychology and psychiatrics. The results obtained by him are based on the following elementary facts of embryology. The mature nerve fibres of the brain consist of the transparent cylinder axis and of the surrounding myelin sheath. The immature nerve fibres in the fœtus and the newborn consist at first of cylinder axis alone, and receive their myelin sheaths much later. The myelin sheaths surround the nerve of various centres at different periods, according to the earlier or later development of their functional activity. On examining, therefore, cerebral sections of the fœtus and the newborn treated by Weigert's method (hæmatoxylon), it is easy to distinguish the mature (stained blue) nerve bundles of certain developed functions from the transparent immature nerve bundles of the still undeveloped functions, and thus to follow up the tracts of the various functional spheres. Thus Flechsig could determine with great accuracy the cortical centres of the different senses, together with the corresponding motor areas and their corona radiata nerve fibres. Their neurons are connected with the subcortical centres of the brain and of the spinal cord, the nuclei of sensitive, motor, or reflex centres. The spheres of senses, although very extensive in the human brain, occupy but one-third of it, and are intercalated between the centres of intellect, which constitute the two other thirds of the brain. This enormous expansion of the intellectual or association centres is peculiar to the human brain. In the higher animals the association centres are only rudimentary, and in the lower animals they are absent, the sense centres being contiguous; for this reason the anatomical and experimental study of the brain of animals is but slightly applicable to the human brain.

An affection of the association centres produces mental diseases, and these centres are the real substratum of psychology and psychiatry.

The intellectual or association centres are devoid of corona radiata fibres, and are not directly connected with peripheric, motor, or sensitive apparatus. Their neurons have innumerable connections among themselves and with all the sense spheres, with the vasomotor and respiratory centres, with the corpus striatum and thalamus opticus (where the higher and lower cerebral functions combine), and with the formatio reticularis (the seat of lower instincts), etc.

The great preponderance in the human brain of the association centres explains their influence upon the whole organism, both in health and disease, especially in nervous and mental affections.

Prognosis and Treatment.—The prognosis in remittent melancholia is favorable in simple, uncomplicated cases; it is doubtful in cases with neuropathic disposition; and in complicated cases it depends on the nature of the complication.

The acute angiospastic attacks often terminate spontaneously under profuse perspiration and increased urinary secretion. Therefore I tried an empirical method, suggested by this observation, and advised hot water or hot lemonade, to be taken by sips until perspiration would ensue. This was generally followed by a complete relief from the vasomotor disturbance—the precordial distress, palpitation, etc., and by a refreshing sleep from which the patient awakened feeling better than he did for days or weeks.

As regards the chronic neurosis, the therapeutic indications are as follows: to remove the psychical cause and to improve the functions of circulation, secretion, etc., in order to hasten the metamorphosis of matter and the elimination of toxins; also to increase the amount of blood and strengthen the nervous system. The first iddication, viz., the removal of the primary cause, although theoretically the most rational, is certainly the most difficult to carry out. As a rule, when a case comes to our notice, the psychical impression which produced the melancholia has already lasted for some length of time, and we have to deal with its consequences, the fully developed disease, which may now continue independently even if the primary cause be removed. Besides, the patient may have become physically weakened to such an extent that we must somewhat improve his general condition and palliate certain severe symptoms before expecting any effort on his part. Later on it will be easier for the physician to impress upon the patient the necessity of giving up worry in order to get well, as prolonged worry often causes incurable diseases. Indeed, I have seen diabetes, cardiac and other affections brought on in healthy persons by continued depressing emotions, and benign affections become malignant under their influence. As soon as the acute attack is over, I commence the general treatment of the chronic neurosis. It is important for the patient to have daily outdoor exercise; at first, short walks which must be gradually increased. He is advised to return directly home after each exercise, and take something hot until he gets into perspiration, as the profuse acid secretion of the skin and kidneys increases the alkalinity of the blood. Any one who wishes to appreciate this simple remedy ought to try it on himself. Every sip not only stimulates the gastric nerves in a direct manner, but by reflex stimulates the cardiac branch of the pneumogastric; the heart acts more vigorously, the circulation is quickened, the pulse becomes stronger, the blood rushes to the skin and other emunctories; all secretions are increased, and the patient feels revived. After the hot drinking the patient takes a short rest; when possible, another walk is taken in the afternoon, also followed by hot drinking. The outdoor exercise is gradually increased until the patient is able to take long walks, bicycle or horseback rides, rowing or skating, etc., and as a rule should exercise until a general reaction is produced and he is in a glow.

At first I was in doubt whether the exercise or the

perspiration is the most important factor. If the perspiration alone were productive of the good result, outdoor exercise could be dispensed with and the patient given a Turkish bath or some diaphoretic. I found, however, that neither the hot drinks nor the muscular activity alone was sufficient. In both cases the result was unsatisfactory. It is evident that exercise and perspiration combined produce the beneficial effect. Besides the exercise and hot drinking I prescribe some of the bitter waters to be taken before breakfast. These bitter waters wash out and stimulate the stomach, increase the peristalsis, and act as the best intestinal antiseptic. Before retiring the patient is advised to take hot milk, which acts as a mild hypnotic. In the morning a warm bath is taken, followed by a cold douche or sponging. These simple hygienic remedies accomplish a great deal if properly and systematically used; they improve all the functions (the respiratory, circulatory, digestive, secretory, etc.), and increase the metamorphosis of matter. The more energetic the latter, the more vigorous the health, provided the products of tissue change are promptly eliminated.

Weak digestion and anæmia require hydrochloric acid and iron, the former about three-quarters of an hour after the principal meals. In order to produce the desired effect, the hydrochloric acid ought not to be taken immediately after the meals, as the hydrocarbons must first undergo the action of the saliva before the nitrogenous substances are digested by the acid secretion of the stomach. Iron can best be taken with the meals.

An old-fashioned remedy, almost forgotten at present, is, however, most valuable, especially in nervous affections, for the simple reason that it is an indispensable constituent part of the nerve tissue, just as iron is a part of the blood tissue. I mean sulphur. I usually prescribe it in combination with sugar of milk, a very good diuretic. I generally begin with the hydrochloric acid for a week or ten days, then I give iron for about a month, after which I prescribe the sulphur. If necessary, the iron can be resumed and alternate with the sulphur for any length of time.

The most valuable remedy in the treatment of chronic psychoneurosis is the galvanization of the brain, according to my method described in Virchow's *Archiv für pathologische Anatomie*, Bd. 79, 1880, and in Westphal's *Archiv für Psychiatrie und Nervenkrankheiten*, Bd. 8, Heft 2, and Bd. 16, Heft 1. The galvanic current regulates the circulation in the nerve centres and improves their nutrition. Moreover, the brain being the principal central organ of all the psychical and somatic functions, its galvanization affects favorably the whole system. I therefore employ the galvanization of the brain not only in affections of the nervous system, but in a great many other chronic diseases. In the very many cases treated by me in the last thirty years, I cannot single out an instance when it acted injuriously or did not prove beneficial.

As in other chronic diseases, simple cases are very rare in remittent melancholia. The majority of cases are complicated with malaria, gout, rheumatism, tuberculosis, hysteria, etc. Accordingly, the treatment has to be somewhat modified by combining the remedies for both the neurosis and the complicating disease. I will here limit myself to a few remarks with regard to malaria, the most frequent complication. It sometimes imparts to the exacerbations and to the angiospastic attacks of remittent melancholia an intermittent character. As in these cases there is always an enlargement of the spleen, I used formerly to consider them simply as malaria; they would improve under a quinine treatment, but neither the neurosis nor the vasomotor disturbances could be permanently benefited. In 1868 I made the following observation concerning malaria in its relation to the galvanic current. A middle-aged lady, of a strong constitution, placed herself under my care for rheumatic pains in the shoulder. Two applications of a strong galvanic current relieved the pain, but during the third application she was seized by a chill, followed by high fever with profuse perspiration, similar attacks recurring every other day. The patient was promptly cured by quinine. I had several other cases of obscure chronic diseases, in which a strong galvanic current called forth regular attacks of intermittent fever and thus unmasked the latent malaria. Since then, in cases of melancholia or any other chronic neurosis, if I find an enlarged spleen not caused by typhoid or rheumatic fever, I search for the plasmodium malariæ and prescribe quinine before resorting to the galvanic current.

Having considered the indications for the rational treatment of remittent melancholia, the counter-indications can be easily pointed out. The majority of my patients before coming under my care had tried all possible remedies and different methods of treatment, and I have thus been able to discard those which proved useless or injurious. Narcotics and stimulants should be avoided; the first on account of their debilitating effect on the nervous system and their tendency to lessen the secretions. Besides, neuropathic patients are very apt to acquire the morphine, cocaine, and ether habits, etc. Stimulants, if often administered, are injurious and may also lead to a morbid habit. The moderate use of light wines, however, may be recommended as a tonic.

The most popular method of treatment seems to be the rest cure, as almost all of my patients, at one or another period of their illness, were treated by this method. Although I have not employed it myself, I have thus been able to observe its after-effects. As far as I can judge, the rest cure acts favorably only in cases of hysteria, principally by its moral influence. Many hysterical patients are averse to outdoor exercise and persuade themselves that the least exertion aggravates their morbid condition. In this auto-suggestion they are usually upheld by their near relatives and friends, and make it hard for the physician to overcome their combined notions. But when such patients are isolated and compelled to remain almost motionless for days and weeks, they feel greatly relieved when permitted to leave the bed and resume activity, which is naturally followed by an improvement in health. That the rest cure is not meant, however, to suppress altogether muscular activity, is evident from the fact that massage is employed and faradic current applied to induce muscular contractions.

In other chronic neuroses the patients generally find that their condition was not improved by the rest cure; in melancholia, for instance, the physical rest increased the internal agitation. This is quite in accordance with *a-priori* reasoning and with experience. If we consider that the muscles constitute more than half of the weight of the body, it is evident that the system must suffer when their functional activity is suppressed. No doubt in cases of exhaustion and emaciation an entire rest is absolutely necessary, but as soon as the patient is able he should resume outdoor exercise. For healthy persons the night's rest is sufficient; for the invalid an additional hour or two may be required during the day.

Finally, it is best to avoid gynæcological treatment in melancholia, except in urgent cases like hemorrhage, vesico-vaginal fistula, etc. In women who were subjected to the usual local treatment, the neurosis was invariably aggravated and prolonged. The same rule applies to men. Melancholics often complain of some genito-urinary trouble, and on examination a spasmodic stricture or an enlargement of the

prostate is found and treated with sounds, etc. This local treatment aggravates and prolongs the nervous affection, which for some reason or other often becomes complicated with a catarrh of the bladder or cystitis. I therefore consider local treatment contraindicated during the melancholic process; it is wiser to postpone it until the patient recovers from the neurosis, so much the more that these genito-urinary troubles generally disappear spontaneously after the cure of the neurosis—the best proof that they were of a vasomotor or neurotic character.

November, 1897.

OBSERVATIONS UPON THE DIAGNOSIS AND SURGICAL TREATMENT OF CERTAIN DISEASES OF THE STOMACH, BASED UPON PERSONAL EXPERIENCE.[1]

By W. J. MAYO, M.D.,

ROCHESTER, MINN.,

SURGEON TO ST. MARY'S HOSPITAL.

In the short paper which I have the honor to present to you this evening I have avoided, as far as possible, reference to the labors of many workers in this field of surgery, especially those whose efforts in this direction have become a matter of history. This is not due to a lack of appreciation of the pioneers in gastric surgery, but rather to the wide extent of territory which I have attempted to cover. The cases which form the basis of this paper have been operated upon by myself and my brother, Dr. C. H. Mayo, with few exceptions in St. Mary's Hospital, Rochester, Minn. Our experience in this field comprises twenty-six cases in which the stomach itself has been the object of attack, and twenty-five operations made for the relief of marked gastric distress, caused either by adhesions between the stomach and the gall bladder, duodenum, or neighboring organs, or to adherent omentum in hernial pouches, or to ventral herniæ. This makes a rather natural division into two general classes:

1st. Those due to causes acting from within the stomach.

2d. Those due to causes acting outside the stomach itself.

There are a few facts in regard to the anatomy of the stomach which are of so much importance in its surgical relations that I take the liberty of referring to them. The blood supply is from three principal sources, and the various anastomoses are so complete as to resemble the palmar arch or the circle of Willis.

This enormous blood supply allows free incisions into the stomach walls or resections of any desired amount, and gives a certainty of well-nourished flaps. In this respect it vastly differs from the intestines, in which the utmost care as to nourishment of the bowel periphery is of such importance in dealing with the mesentery.

The smaller vessels lie along the surface of the mucous membrane, and this latter structure is very thick and easily separated from the outer coverings. Independent suture of the mucous coat, therefore, gives firmness and checks oozing.

The gastro-hepatic omentum anchors the stomach well under the ribs, and if this be divided first the pylorus and lesser curvature can be easily delivered and the fingers pass at once behind the stomach and pylorus into the lesser cavity of the peritoneum. In operations upon the living subject, and in a number of cadavers upon which I experimented, the value of this manœuvre was readily apparent.

Volumes have been written about the functions of the stomach, especially by the specialist in internal medicine, but to the surgeon at least the mechanical theories have the greatest attraction. From my standpoint, the stomach represents a combination of the hopper and the silo. The fundus can be compared to the magazine of a coal stove, making it self-feeding, while the great muscular power of the pyloric region, with the aid of a weak solution of pepsin and hydrochloric acid, softens the food masses and slowly passes them into the intestines for digestion and absorption. As Wendt points out, the stomach also absorbs fluids, prevents intestinal overloading, and corrects the varying temperatures of the ingesta. The gastric juices, while not markedly antiseptic, are hostile to germ growth—a factor of considerable importance.

Cancer of the Stomach.—The differential diagnosis of cancer of the stomach, especially the obstructive type, may be difficult, and many an individual has perished because of this too ready opinion based upon insufficient evidence. The history in cancer of the stomach is of the greatest importance. The patients can usually fix a time in which the symptoms became marked; not a definite date, but a period within from one mouth to three months, in which, they will state, the disease became very noticeable, and from which time the symptoms had been more or less continuous. In cicatricial stenosis the history covers a longer period of time. The not infrequent malignant degeneration of former scars is confusing in this respect.

Vomiting is a symptom of some value. In pyloric obstruction it is usually infrequent, once or twice in twenty-four hours, and a large quantity of material is ejected. This is not materially different in character from the vomiting of cicatricial pyloric obstruction. The obstruction and resulting dilatation of the stomach are in either case easily demonstrated by filling the stomach with air through a stomach tube by the aid of an enema syringe. This procedure is one of great diagnostic value; it also aids in locating the pylorus.

In cancerous disease, even with only a moderate obstruction, vomiting is often met with, and, if the walls of the stomach are extensively infiltrated, vomiting may be both frequent and painful, resembling ulcer. Pain and emaciation are the rule, and I am always suspicious of a person of middle or later life who presents these symptoms, with a cachexia which, while not peculiar to cancer, differs from the pale, bloodless appearance frequently seen in ulcer. The presence of a tumor, while most often noted in cancer, may be found in cicatricial contraction. I have several times felt masses of this character, which appeared prior to operation to be too well marked for any other disease than malignancy.

Examinations of test meals for the absence of hydrochloric acid and the presence of lactic acid have some diagnostic value. Dr. Christopher Graham has made a great many examinations of this description, and, as a whole, they have been fairly satisfactory; but the tests are of value only when corroborated by better testimony. The tests with iodides for stomach absorption and with salol as to the motor power are essentially laboratory tests and of no great aid in this class of cases.

The gastroscope and gastrodiaphanoscope are of little practical use.

Time will not permit me to refer to the many valuable diagnostic features of cancer of the stomach, and it must be left to the exploratory incision to clear up the doubtful cases if a radical cure is to be attempted.

In such explorations the enlargement covered with dilated veins is easily differentiated from the whitish scars of former ulceration, while the extent of the disease and adhesions to important viscera render the radical treatment more or less feasible.

We have made seven exploratory operations for supposed cancer of the stomach. In one case the tumor

[1] Read before the meeting of the Minneapolis Academy of Medicine, at Minneapolis, February 2, 1898.

proved to be tuberculous omentum, and the patient was benefited by the exploration, as often happens in tuberculous peritonitis. Another case, thought at the time to be cancer, I now believe to have been a benign obstruction, too much attention being given to enlarged glands in the omenta. I have almost always found enlarged glands in pyloric obstruction, whether the disease was cancerous or not, due to chronic sepsis from the absorption of decomposing stomach contents, and, unless microscopical examination is made, such findings are of small value. In five cases the cancer was inoperable. In one of these five hopeless cases great improvement followed, and the patient, who was a butcher, worked nearly a year at his trade before the growth again became active. Similar cases have been reported by Lawson Tait. J. William White has extensively investigated this and kindred phenomena, in which tumors had disappeared or greatly improved after such exploratory manipulations, and reference to his statistics will show a number of such cases. The relatively large number of such explorations is a confession of failures as to exact diagnosis, either as to the existing condition or as to the stage of the disease; but, as such an exploration is the only way an early diagnosis of the operable cases can be established, it is in my opinion fully justified.

Unfortunately, radical operation upon cancer of the stomach depends upon an early and often, without incision, an impossible diagnosis; as in cancer of the uterus, the large majority of cases will be seen at a time when the diagnosis is only too apparent and the prognosis equally so. I will not discuss the advisability of active interference in this otherwise hopeless malady. I can only say that for myself the results, the nature of the disease being considered, have been satisfactory.

For cancer we have made three gastro-enterostomies and three pylorectomies, one of the gastro-enterostomies proving fatal from broncho-pneumonia on the fourteenth day, due to the aspiration of material vomited into the throat during the manipulations. With the stomach partly out of the abdomen, the elevation gravitated the contents into the dependent œsophagus. This should have been avoided by raising the head and the upper œsophagus. The preliminary emptying and cleansing are often more apparent than real, and it is the rule in my experience that the stomach at the operation will be found containing a considerable quantity of material, although emptied and washed through the tube immediately before operation.

The remaining patients upon whom gastro-enterostomy was performed lived for a year or more. One, under the care of Dr. R. C. Dugan, of Eyota, from a state of starvation, not only gained rapidly in flesh and strength, but labored on a farm for more than a year. The second, I was informed by his attending physician nearly a year afterward, was up to that time comfortable and about. In the three cases of pylorectomy all the patients recovered from the operation, and all are now in good condition, though sufficient time has not elapsed to speak of them as cured.

The method of pylorectomy we have followed has been so speedy and satisfactory that I would like to call your attention to it. The ease with which any desired amount of stomach can be excised is especially noticeable—in one case the upper suture angle lying behind the left costal arch in close proximity to the cardiac orifice and passing obliquely downward and to the right more than six inches in length, making a sort of shovel nose to the amputated end. I make no claim to originality, although I know of no method of equal simplicity, and in the cases referred to and also in a number of cadaver operations the details were readily carried out. The steps are as follows:

1st. A median incision above the umbilicus, and, if needed, a cross-cut of the rectus.

2d. Double ligation and division of the necessary amount of gastro-hepatic omentum: this allows the pylorus and lesser curvature to be delivered. The fingers are now in the lesser cavity of the peritoneum, and at once slip under the pylorus and act as a guide to the careful double ligation and division of the gastro-colic omentum attached to the malignant area.

3d. The diseased part is isolated by a piece of gauze drawn under it, and a pair of forceps are caught from each side, separating the diseased from the healthy stomach and also preventing leakage from below. With a knife a circular cut is made completely around the healthy portion of the stomach to the mucous coat. The muscular and peritoneal coats are stripped back and a few bleeding points caught with forceps. The mucous coat is cut inch by inch and at once closed with a continuous catgut suture; this is cut short and the detached pylorus and tumor are covered and turned out of the way. A second continuous catgut suture of the muscular coat rolls in the mucous, while outside of this a good silk Lembert of the peritoneum and muscular coats protects and rolls in the two first rows of sutures.

4th. The end of the stomach is slipped to the right and the ends of the tied omenta are sutured to each other and to the suture line, not only making further protection, but also anchoring the stomach to the right and preventing undue traction upon the duodenum after it is fastened in place.

5th. The duodenum is cleanly amputated at a healthy point and buttoned with a Murphy button to the anterior lower wall of the stomach.

We have done this operation once in forty-five minutes, once in one hour and five minutes, and once in one hour and twenty-five minutes. I mean by this, from the time the operation was commenced until the dressings were in place, and in each case from four to six and one-half inches of stomach had been excised.

Benign Obstruction.—Time forbids remarks on the diagnosis of cicatricial stenosis of the pylorus, if, indeed, they are necessary after what has been said on malignant disease. Valve formation, either with or without scar contraction, I called attention to in papers read before the meeting of the American Medical Association in 1896 and again in 1897. It is undoubtedly a common condition and responsible for many cases of dilated stomach which have been thought to be due to chronic gastritis.

For cicatricial stenosis and valve formation we have made four pyloroplasties on three patients and five gastro-enterostomies. Of the pyloroplasties, two were followed by good results: one relapsed and after a second pyloroplasty eventually required a gastro-enterostomy.

In the last operation for pyloroplasty we made a very long incision, three or four inches in length, and, while it required careful suturing, the opening was of ample and permanent size.

The method of suture employed by Ochsner, of Chicago, and published in the *Journal of the American Medical Association* for October 16, 1897, can be commended in this operation.

Of the five cases of gastro enterostomy for cicatricial stenosis, one proved fatal from aspiration pneumonia on the eleventh day (this patient was the one upon whom the two pyloroplasties had failed). The four remaining patients made fine and so far permanent recoveries, and I must say that, while I was prejudiced against the operation in this class of cases and was forced in each instance to do it by reason of extensive adhesions or great extent of scar tissue, the ultimate results have been uniformly good, and equally so with pyloroplasty which has been done in easier cases. All of our gastro-

enterostomies have been button operations. The muscular walls of the stomach in cicatricial stenosis are always very thick, and, on account of the length of time the obstruction has existed, much more so than in cancerous disease. For this reason the walls of the stomach should be incised to the mucous coat before the button suture is put in, and only a small bit of these tissues included in the grasp of the button, to prevent it hanging too long in place. In all of our cases the jejunum was caught at its origin and a coil formed and united to the anterior wall of the stomach, after such fashion as would not cause traction or kinking; and in the eight gastro-enterostomies of all sorts performed none of the cases had regurgitant vomiting.

The objection to the Murphy button that it may be retained in the stomach is legitimate, but as no cases have been reported in which such retention has caused harm, and experience has shown that the button may be passed at a very late date after the patient has been discharged as cured, the objections do not overcome its advantages in the way of speed, certainty of approximation, and permanency of opening. Two years ago I advised a kite-tail guide of silk to act as a tractor down the intestine; the value of this is uncertain.

Gastrostomy was performed three times for stomach feeding necessitated by œsophageal obstruction. One operation was by the Fenger method; this case required constant attention on account of leakage. The other two operations, done after the Witsel plan, gave ideal results, and I have not been convinced as to the superiority of the Frank operation, which Meyer and others recommend.

Gastrorrhaphy was done in one case of gunshot wound of the stomach eight hours after the injury, and the large wound of the anterior wall sutured; the case terminated in recovery. The patient was brought into St. Mary's Hospital by Drs. Way and Edgerton, of Claremont, as quickly as possible after the accident, and to their prompt action the good result was undoubtedly due.

Causes of Stomach Distress Acting from without the Stomach.—Cases of this description are very common and usually due to well-understood conditions, such as chronic appendicitis, intestinal adhesions, movable kidney, and similar ailments; but in these instances the resulting stomach disturbance is largely through the nervous system.

There are, however, a number of cases in which adhesions of the stomach or pylorus to a neighboring organ, hampering its free action, are sources of more or less disability, and the separation of these adhesive bands will relieve the difficulty.

Of these we have seen three marked instances—one due to an old, adherent gall bladder, without stones, although it had undoubtedly once contained them; one due to a duodenal ulcer, with a mass of adhesions binding the pylorus and limiting its calibre; in the third case I am unable to state the exact cause, but it was probably a recurrent regional peritonitis about a diseased gall bladder. This caption does not include the many instances of gall stones in which stomach symptoms were present.

Such results are also easily understood when the omentum has become adherent to a hernial sac and remains irreducible, causing a certain amount of dragging and interfering with the free action of the stomach. We have seen this happen three times in umbilical hernias, eight times in inguinal hernias, and three times in femoral hernias; and in each instance release of the adherent omentum and radical operation on the hernia gave complete and lasting relief to the gastric symptom. In these cases the patient came complaining of stomach trouble and not of the hernia. The list does not include cases in which the intention of the patient was merely to be rid of the annoyance of the hernia, and in which, as a part of the radical cure, the omentum was freed.

Just why the ventral hernia protrusion through little defects in the median line above the umbilicus should cause gastric distress, I am unable to state; but that such is the fact I feel sure, and recent surgical literature contains many reported cases.

In our earlier operations I believed that the protrusion was always omentum, but careful dissection has shown me that it is often preperitoneal fat, and the constant congestion causes it to become lipomatous—a condition exceedingly common about old femoral hernial sacs. In all these cases of ventral hernia a glove-like protrusion of peritoneum occupies the central part, and this may be empty, although I have seen omentum and also a part of the fatty contents of the suspensory ligament of the liver in the sac. We have operated upon eight such herniæ, and the results have been very satisfactory.

In closing, I cannot do better than quote a passage from Mayo Robson: "Although difficult to lay down hard-and-fast rules, it is certainly wise, in cases of obscure gastric pain producing invalidism or debility, after medical treatment has been fully tried and failed, to open the abdomen in order to clear up the diagnosis and then adopt that line of treatment which seems indicated."

THE VALUE OF THE BUCCAL ERUPTION OF MEASLES (KOPLIK) FOR EARLY DIAGNOSIS.

By E. LIBMAN, M.D.,
NEW YORK.

The experience I have had with the buccal eruption of measles dates back to the spring of 1895, when I was made cognizant of its occurrence and diagnostic import by Dr. Koplik, of this city. He later published an article on the subject in the *Archives of Pediatrics*,[1] but little interest in the matter seems to have been aroused until a second paper recently appeared in the Medical Record.[2] Since then there has appeared a contribution to the subject, from Heubner's clinic, by Slawyk.[3] Writing from the observation of a large number of cases, he confirms all the statements made by Koplik.

For an account of the characteristics of the spots described by Koplik, I refer to his articles. As to their value, he says that the spots are absolutely diagnostic of measles; that they occur during the invasion period of measles, and begin to disappear as the skin exanthema reaches its height.

My own observations extend over a series of fifty cases. Of these cases, thirteen were seen in the isolation house of the Mt. Sinai Hospital during the spring of 1895. Twelve of the latter were children transferred from the children's ward of the hospital, in the service of Dr. Scharlau, through whose kindness I am enabled to make use of the cases for publication. These children came under notice with either a beginning rash or immediately after a diffuse rash had appeared. In every case the spots described by Koplik were present in large numbers on the buccal mucous membrane, and in some cases on the lips. The children with the measles eruption already markedly developed had, in general, fewer spots. The thirteenth case was that of a patient, aged nineteen years, who was first seen when the measles rash had already covered the larger part of the body. In this case also the spots were plainly seen.

The second group of cases came under observation in the children's ward of the hospital in 1896. The first case of this series was especially striking. A boy,

[1] December, 1898. [2] April, 1896.
[3] Deutsche medicinische Wochenschrift, April 28, 1898.

six years old, was admitted to the ward with a history of having been sick three weeks with fever, cough, and pain in the chest. When first seen, he had no coryza and no conjunctivitis. The physical examination revealed a slight bronchitis and a mitral regurgitation with hypertrophy of the right ventricle. The child had a temperature of 102.8° F. The diagnosis seemed doubtful until on examination of the mouth the measles spots were seen. The child was at once isolated. Two days later a typical measles eruption developed on the chest and neck.

This case seemed so demonstrative to us that later, when we feared a measles outbreak because of the occurrence of another case in the wards, we determined to put the sign to a careful test. We began, after the occurrence of this last-mentioned case, to inspect daily the mouths of all the children in the ward. Twelve days later the spots were seen in another child, and in a short time thereafter they developed in nine other cases. These ten children were removed from the ward as soon as the spots became evident, and all of them developed the measles eruption in the succeeding twenty-four to forty-eight hours. The children not presenting the spots did not develop measles.

There can be no discussion as to the very great necessity of early isolating measles cases occurring in the wards of hospitals and in kindred institutions. In the set of cases just detailed, had we not been aware of the existence of the buccal eruption we could not have so early picked out the infected children. The occurrence of temperature rises could not have been of much service to us, as most of the children already had high fever from various causes. Furthermore, in children already suffering from disease, the temperature often does not rise to any marked degree during the invasion period of measles nor at the eruption stage. Thus in two cases of the above series the children had temperatures of 100° to 100.5° F. before they entered the invasion period. In these two cases the temperature never rose above 101° F. during the entire course of the disease.

The early diagnosis of measles in sick children is frequently made still more difficult because of the absence of catarrhal symptoms at the invasion, and when the eruption appears in such cases it is often atypical in arrangement and distribution, and pale in color. In children suffering from broncho-pneumonia or empyema, the question may well arise whether we have to do with one of the exanthemata complicating the original disease, or whether the rash is a septic manifestation or due to drugs. In diphtheria cases we may be in doubt as to whether there exists an antitoxin rash or a complication with measles. In several of the cases cited above, for example, the catarrhal symptoms were very insignificant, and in four of them the rash appeared irregularly and was very sparse.

From a consideration of these points, it becomes clear what a great aid in the prevention of measles epidemics the Koplik spots are, and it is not going too far to say that the mouths of children applying for admission to hospitals should regularly be examined for the measles spots, just as we look into their throats for membranous deposits and at their skin for desquamation.

Besides these cases, seen in hospital work, the measles spots were observed in a number of cases in various dispensaries. In no case when the spots were noted did we fail to find a measles eruption present then or in the course of the following few days. Among these cases, the diagnosis of some of which was first made clear by the finding of the Koplik spots, five occurred in adults. Two observations are of sufficient interest to be detailed.

Case I.—Man, forty-eight years old, who had been sick four days with fever, coryza, and bronchitis, and who, for the past twelve hours, had had a maculo-papular eruption on the face, chest, and abdomen. A diagnosis had been made by the physician in attendance of influenza with a drug eruption (antipyrin and phenacetin had been administered). The case, although presenting a fairly typical measles eruption, was not clear till a buccal exanthema was looked for and found. A positive diagnosis of measles was made, and this was confirmed by the appearance of measles in two of the patient's children two weeks later.

Case II.—Man, twenty-two years old, who, six weeks previously, had a sore on the penis, diagnosed as a hard chancre. He now presented a rash, consisting of papules and maculo-papules, over almost the whole surface. He also had coryza and conjunctivitis. Because of his history, and notwithstanding the fact that the eruption looked decidedly like measles, the family physician considered it a secondary syphilide. The presence of the Koplik spots made the diagnosis of measles evident. This diagnosis was confirmed by a leading dermatologist, and subsequent events proved its correctness.

In the series of cases above given only those seen before the rash appeared on the skin, or within twenty-four hours after its complete efflorescence, are included. At a later period than the latter, the spots are often not to be found. In healthy children and in those suffering from other diseases than measles, I have never observed the spots described by Koplik. In two cases recently, one of purpura rheumatica and one of secondary syphilis, there were to be seen spots on the mucous membrane of the cheeks, resembling the central whitish part of the measles spots; but they could be easily distinguished by their larger size and by the absence of the surrounding congested zone. These two cases are mentioned to show the importance of accurately noting the description, as given by Koplik, when looking for the spots.[1]

108 East Sixty-Fourth Street.

THE POSSIBILITIES AND LIMITATIONS OF SERUM THERAPY.[2]

By W. E. SANDERS, M.D.,

ALTA, IOWA.

Mr. President and Gentlemen: Under the above title I wish to call your attention to a system of therapy which has been elaborated in the past few years, and its agents placed before the profession as a valuable addition to our therapeutic armamentarium.

My reason for directing your attention to this subject on this occasion is a conscientious belief that its curative value has in many instances been greatly overestimated, through the influence of auto-suggestion and commercial interests operating upon the minds of their promulgators, and also that its possibilities and limitations and the scientific basis upon which its curative value rests, are too little understood by the profession of medicine at large.

Before we enter upon the consideration of the subject proper, I respectfully ask attention to a fundamental biological manifestation, whose operation is universal throughout the domain of protoplasmic organization.

It not only marks the distinction between animate and inanimate nature, but also upon this psycho-physical attribute depends the power of the organism to maintain its integrity, perpetuate its species, and like-

[1] Filatow (cited in Slawyk's article) seems to have observed the spots described by Koplik, but in his description only the central, white part of the measles spot is mentioned.

[2] Address delivered before the Sioux Valley Medical Association at Sioux City, Ia., January 20, 1898.

wise so to adjust its internal relations as to effect an immunity against an adverse environment.

In the history of biological science this protoplasmic esssence was known two or three hundred years ago under the provisional term of *consensus partium*, which implies the concurrence of parts in action in such manner that each does *quod suum est.*

At the beginning of the present century Treviranus, of Germany, and the father of modern biology, adopted the term adaptation, which has since come into general use.

Again, about twenty-four years ago Prof: Ernst Haeckel in his "History of Creation,"[1] made use of the word œcology, under which he designates the relation of an organism to its organic and inorganic environments, particularly its hostile and friendly relations with the plants and animals with which it comes in contact, and identifies it with "those complicated mutual relations which Darwin specifies as the conditions of the struggle for existence."

But this is not so much a question of terms as of a vital manifestation; however, its operation within the host and its concomitant effect upon the specific nature of an invading organism in an infectious disease, will serve in a measure at least to justify me in calling it to your attention.

The operation of this universal law in the higher animal organizations is too obvious to require consideration, but it is my purpose to show that it extends to the lowest unicellular micro-organisms, at least in so far as phototaxis and chemiotaxis obtain.

The rod-like organism called by Engelmann the bacterium photometricum[2] is such a lover of light that if we place a drop of water containing these organisms under the microscope and focus the smallest possible ray of light upon a particular spot, this spot exercises a phototactic influence, in so much that it becomes crowded with the organisms.

By means of the projection of a white-light spectrum in the field it shows a selective influence for certain spectral colors, which are absorbed when transmitted through its body.

By illuminating with a spectrum water containing a filament of confervoid alga, and what was formerly known as the bacterium termo, it will be seen that they are most agile in that part of the filament which receives the red rays and consequently where the assimilation of carbon and the disengagement of oxygen are most active.

Certain plasmodia of the myxomycetes have also been proven to exercise a selective influence for certain chemical substances.

In view of the above facts, Pfeiffer has been able to demonstrate that there is a definite relation of reaction to stimuli, not in the force of the stimulus alone but also as compared to the intensity of a previous excitation.[3]

But this specific faculty of adaptation is set within certain limitations for every organism.

According to the researches of Tyndall, Geisler, Buchner, Blunt, and others, very many micro-organisms cannot survive the actinic rays of the spectrum, or those rays which lie just beyond the red and where vibrations are somewhat less than four hundred trillion a second, but direct oxidation occurs in this zone.

This has a practical bearing upon hygiene and public sanitation, because these rays not only affect the vitality of the bacteria, but also the media upon which they grow.[4]

Many other like examples could be mentioned, but I think I have given sufficient data to show that upon this immutable biological law, whether you regard it as a physical or psychical manifestation, depends the power of every organism so to modify its intrinsic activities as to adjust itself to new conditions, and that previously adverse conditions become innocuous.

We have therefore brought immunity in conformity to a general law—the law of adaptation.

In this light an infected organism can so modify the œcological influences under which the *contagium vivum* operates, that it in turn by means of adaptation will become non-pathogenic or extinct.

In the state of our modern scientific knowledge no man can entertain a serious doubt that the *causa excitans sensu strictu* of every infectious disease is due to the invasion of a *contagium animatum*, and that the symptoms are simply the life manifestations of the tissues and organs of the body in seeking to adjust themselves to a new enivronment.

If such adaptation is effected, health is restored; if not, disease or death ensues.

The great majority of infectious diseases have been proven to arise from the invasion of these *materies morbi*, most of which have been made to conform to the requirements of Koch's postulates, and are hence regarded as the specific etiological factors in the pathogenesis of disease.

Others, perhaps owing to their obligate parasitic nature, can never be cultivated on artificial media, or inoculated into the lower animals, and, so far as this particular proof is concerned, must remain questionable.

The growth and multiplication of these fission fungi on any media are characterized by certain well-marked changes in the substances upon which they grow.

In the human body the presence of these bacteria, not only by osmosis deprives the tissues of a certain amount of nourishment which they appropriate to build up new organisms, but at the point of inoculation are produced extensive katabolic metamorphoses of tissue, various degenerations, necrosis, inflammation with often the consecutive formation of new tissue. Also by a process of hydration, reduction, and oxidation, there are produced ptomains, nitrogenous bases, organic fatty acids, aromatic substances, toxins, and toxalbumins, depending to a great extent upon the specific nature of the invading organism.[1]

The last two substances, toxins and toxalbumins, are the most potent agents, and to their presence is due that train of constitutional symptoms characterizing the infection, and which it is the object of our therapeutics to neutralize or destroy.

Chief among the pathogenic bacteria which owe their specific action to the production of toxalbumins may be mentioned the cocci pyogenes, bacilli tetani, diphtheriæ, anthracis, typhosi, and the spirillum choleræ asiaticæ.

It has been a question in the minds of investigators whether toxalbumins are formed by bacteria from the albuminoids of the juices of the body, or are the direct product of the bacteria *per se.*

According to the experiments of Buchner the latter is the case, since he has succeeded in producing them by the artificial culture of the bacilli tetani and diphtheriæ in non-albuminous media.

I wish now to call your attention to the protective and restorative powers of the body, because no system of therapeutics which disregards these can be said in any sense to rest upon a scientific basis.

Every human organism is endowed with certain means of defence which ward off noxious influences. These may be arranged under five heads:

1st. Those which prevent the entrance of bacteria into the body, as the protective epithelium and the normal secretions.

[1] Ziegler's "General Pathology" (Wood's edition), p. 437.

[1] English edition, ii., 354.

[2] Pflüger's Archiv, vol. xxiv., p. 387.

[3] Pfeiffer: "Untersuchungen aus dem botanischen Institute Tübingen," vol. i., part 1884.

[4] "Climate and Health," No. 3, September, 1895, U. S. Weather Bureau; and Sternberg's "Bacteriology," p. 154.

2d. Those which limit the spread of bacteria after lodgement is effected, inhibit their development, or neutralize their poisonous products; obviously due to vital action of the tissues or chemical substances.

3d. Phagocytosis, as elaborated by Metchnikoff. Protective in some cases, it often furnishes an example of symbiosis, by means of which germs are carried to other parts of the body; notably is this true in leprosy and tuberculosis.

4th. The presence of bactericidal substances in the blood and lymph. This probably explains racial and natural immunity.

5th. The elimination of the poisonous product of bacteria by means of the kidneys, intestines, and skin.

The protection and restoration of the body are obviously due to the operation of the above forces, to which is added in constitutional infectious maladies a new substance, antitoxin, the reactive product of the organism which antagonizes the bacteriotoxins.

At the moment that the potency of the antitoxins equals that of toxic products of the bacteria, the forces are equilibrated and immunity exists.[1]

This phenomenon is accompanied by the death of the bacteria or a neutralization of their poisonous products.

The latter is usually the case, because at the crisis or termination of an infection millions of the specific organism are still present in the body.

Just whether this immunization is effected by the formation of a non-poisonous substance through the synthesis of the bacteriotoxins and the antitoxins, or the prevention of the formation of bacteriotoxins, or the modification of the specific functions of the microbes incident to an altered environment furnished by its host, is a question that cannot at present be answered.

Immunity may be conferred, 1st, by the chemical products of bacteria; 2d, by attenuated bacteria; 3d, by immunizing serums. The latter constitutes serum therapy.

From the above facts it will be observed that serum therapy is limited to the prophylaxis of disease, and to the hastening of immunity in disease.

It cannot in any sense be regarded as a therapeutic agent in stimulating any of natural protective or restorative forces of the body, with this special exception.

It is limited to the acute constitutional affections, and is not applicable to local morbid conditions, nor that class of diseases which Virchow has designated chronic infectious granulomata, such as tuberculosis, syphilis, leprosy, rhinoscleroma, molluscum contagiosum, and, in the minds of some pathologists, leukæmia.

In regard to the cure of diseases of the human species by serum we possess reliable information regarding tetanus and diphtheria.

There can hardly be a question that the mortality and morbidity of these diseases will be lessened by its judicious use.

Its application should be in prophylactic directions, and also in connection with other well-selected measures calculated to stimulate the normal protective forces, chief among which is the maintenance of nutrition.

We may reasonably hope for some measure of success in the acute infections, but logically no generalizations can be established upon the data now at our command.

I am aware of the general interest now manifest in Professor Koch's latest product, and am not unmindful of the statistical evidence advanced by Paquin, of St. Louis, regarding the cure of tuberculosis by serum.

It would seem that about twenty-five per cent. of Paquin's cases show permanent improvement or cure, but until he can demonstrate the pathologico-anatomical status of the processes in his cases, they do not carry conviction to a thoughtful mind.

No man can have had the opportunity of any considerable pathological observation without having been struck by the multiplicity of tuberculous processes, around which nature has effected as near a cure as is possible in this disease, viz., a fibroid limitation.

A liberal percentage of tuberculous processes assumes this form without the exhibition of immunizing serum. Besides, it must be remembered that very many of the so-called tuberculous symptoms are due to a secondary infection by pyogenic organisms.

Let me reiterate. Tuberculosis, as usually met with, is a local disease. Man does not acquire immunity after infection. If cure is accomplished, it is due to fibroid limitation. Hence serum is of no avail.

Our only hope, it seems to me, in eradicating this disease which carries off fully fifteen per cent. of our population,[1] lies in legislative enactments preventing the propagation of individuals tuberculously predisposed, or eventually at some far distant age by the "survival of the fittest" the human species may gain that condition of natural immunity, such as characterizes the native African against malarial infection.

Burk, the Irish economist, says: "There are but two things to which we can hold—truth and charity."

This should be the watch-word of our profession.

The science of medicine is not an absolute science.

We know no creed, no dogma, and subscribe to no ritualistic discipline but that of invincible truth.

Time was when we were "wont to look down the well-beaten and honorable path of tradition with profoundest reverence:" but now we should profit by the thought given us by the eminent English novelist, Lord Lytton, which should be the motto of every honest student of medicine, "The knowledge of to-day is the ignorance of to-morrow."

[1] "Les Microbes Pathogènes," Ch. Bouchard, Paris.

FOREIGN BODIES IN THE EAR OR NOSE.

By R. D. BARRET, B.S., M.D.,

PATTONVILLE, MO.

The general practitioner, especially one living in a small town or in the country, is often called upon to remove foreign bodies from the nose or ears, and many times, I am sorry to say, is at a loss as to how to proceed, or else makes clumsy, awkward, and ineffectual attempts that succeed only in frightening the patient and making matters worse instead of better. This is not the case now so much as it was a few years ago, for the lengthened courses of study and the enlarged clinical facilities of our colleges make it possible for every student to have some practical experience in examining and treating diseases of the ear and nose at some time during his college course, and hence he graduates better fitted to handle such cases than did the students of ten, fifteen, or more years ago.

Every practitioner who is so situated that he cannot send patients to a specialist should possess the few necessary instruments and familiarize himself with their use in removing foreign bodies from the nose or ear, for a little skill in this direction will often enable him to relieve a frightened patient easily and quickly, and add greatly to his reputation, if nothing else.

Foreign bodies that find their way into the nose or ear may be divided into two classes—animate and inanimate. It is with the latter that we have to deal most frequently. Of the former I will merely say that they are usually some insect which has crawled into the spaces in question during the patient's sleep.

[1] Wood and Fitz "Practice of Medicine," p. 249.

Flies are the most common, and they not infrequently deposit their eggs, sometimes within a suppurating ear, but especially in the nasal cavities, which hatch in due time, and then we have the distressing and disgusting condition of maggots in the nose or ear to contend with. But the treatment of such conditions must be reserved for consideration at some future time.

Inanimate bodies may enter the nasal cavities in one of three ways — through the anterior nares, the posterior nares, or the walls of the cavities. The latter are usually shot or bullets from gunshot wounds, and with these we have nothing to do in this paper. Bodies entering through the posterior nares are particles of food, etc., forced in by severe spells of vomiting or attempts at swallowing when the food "goes the wrong way;" and these also we will merely mention.

Foreign bodies in the ears or nose most commonly occur in children, or sometimes in lunatics, placed there of their own account. Almost anything of convenient size and shape may be found in such cases — peas, beans, pebbles, buttons, cherry stones, plum seed, sponges, paper pellets, metal rings, coins, etc. Vegetable substances, such as peas, beans, etc., are apt to swell from the heat and moisture, and thus become more difficult of extraction the longer they remain. Some writers have said that they are apt to germinate within the cavities in question, but I am inclined to doubt this.

Very few instruments are needed for the operation of removing such foreign bodies, and in fact the fewer instruments displayed the better, for a large array will only serve to frighten the patient, especially if it is a child, and thus make matters the more complicated. But a few are absolutely necessary, and, as I have said before, every practitioner in the country or small town should provide himself with them and accustom himself to their use. A good head mirror — I prefer one three inches in diameter—two pairs of angular forceps, one serrated and the other rat toothed, a pair of foreign-body forceps for the nose, a good long flexible probe, a "nest" each of nasal and aural specula, and a cotton carrier, are about all that will be needed for such work. Either daylight from a good large north window, or artificial light from an Argand burner or a good coal-oil lamp may be used. The latter with a good broad wick and clean globe can be found in almost every house, and is generally about as satisfactory as any light I have ever tried.

Have the mother or nurse take her seat upon a straight-backed, steady chair, with her back to the table or stand on which the lamp is placed in such a position that the light shines over her right shoulder. Then she should take the child on her lap, clasp its limbs between her knees, and with her right arm thrown across its body secure its arms, while with the left hand on its forehead she holds its head firmly and steadily against her right shoulder. The operator then places himself in front of the patient, seating himself upon a straight chair or stool (never use a rocking chair), and with the thumb of the left hand slightly tips up the end of the nose, while the right hand so adjusts the head mirror as to throw a flood of reflected light into the nostrils. Having located the foreign body, proceed as quickly as possible to remove it before the child becomes frightened or the nervous strain upon the mother becomes too great. No force should be used under any circumstances, lest the delicate parts be seriously injured. If possible, grasp the offending body with a pair of forceps, and by gentle traction withdraw it; or very often, as in the case appended, the flexible probe may be bent in the form of a hook of suitable size and slipped past the obstruction, then turned, and the foreign body rolled along the floor of the nasal fossa, until it either drops out or can be grasped by the fingers. Sometimes it is necessary to use a nasal speculum and dilate the nares considerably before we can locate a foreign body or effect its removal. There are a number of instruments suitable for this purpose, and the choice may be left to the fancy of the operator. For the examination, and in the majority of cases for the operation for removing the body also, the ordinary speculum resembling an open-end thimble will suffice. They are made of German silver and come in "nests" of three, of different sizes. If one wishes a more elaborate operating instrument, I would recommend the self-retaining nasal speculum devised a few years ago by Dr. H. N. Spencer, of St. Louis, Mo. It is light, easy of manipulation, dilates perfectly and strongly, and is absolutely self-retaining.

Removing foreign bodies from the ear is usually more difficult, though the procedure is much the same as that just given. The child's head should be turned so as to bring the affected ear toward the operator, and held as directed above.

A syringe and warm water may be tried, taking care, however, not to use too much force and thereby rupture the drumhead, and also to dry the ear thoroughly afterward with a little absorbent cotton on a cotton carrier. In examining the ear the lobule is grasped between the index and middle fingers and gentle traction made upward and backward, while the thumb and index finger insinuate the speculum into the orifice with a slight rolling motion. The speculum most generally used resembles the one for the nose, except it is longer and more pointed. Like the others, they come in "nests" of three, and are made of German silver. The peculiarities of each case will suggest whether to use the syringe or the forceps in the ear and the forceps or the bent probe, etc., in the nose.

In the case of the ear great care must be exercised not to lacerate the walls of the auditory canal, as severe inflammation is apt to result from careless and rough manipulations. If the child becomes too unruly and its struggles interfere with the success of the operation, or are liable to cause the nose or ear to be injured by the instruments, it is best to administer a little chloroform. Children take chloroform easily and safely, and often only a few whiffs are enough to quiet the child sufficiently to allow the operator to proceed easily and without the danger of a sudden jerk doing considerable damage to the parts involved. It is well always to explain to the parents that you are only going to give a very little of the anæsthetic, and that it will do no harm and that there is no danger, for most persons have a great dread of chloroform and become frightened at its mere mention. But if they are rightly and positively assured that their fears are groundless, very few will continue to oppose its use in the manner and to the extent I have mentioned.

The following case, met with among others in a general practice in the country, illustrates well the points I have tried to present: One evening about dark I was hastily summned to see a child who was said to have something in her nose. On arriving at the house I found the family in a state of great excitement and alarm. The mother said that the patient, a little girl of about three and one-half years of age, while playing in the yard had put a pebble into her nose and it had slipped so far back that she could not get it out. I assured her that there was no occasion for any alarm: that it would be very easy to remove, and that even if it could not be removed at once it would do no harm should it be allowed to remain several days.

Then securing a good lamp, which I placed on the sewing-machine in lieu of a stand, I told the mother to take the child and seat herself in a chair, which I

placed in position, and to hold her in the manner I have already described. When the light from my head mirror was thrown into the nostril I could easily make out the pebble lying on the floor of the right nasal fossa, well back. I grasped it with a pair of forceps, but they slipped off of its smooth, round surface; so taking a flexible probe I made a small hook of it which I readily slipped past the pebble, then turned and pulled it forward until it protruded sufficiently to be grasped by the fingers, and removed. The child was but very little frightened, struggled some, but the mother held it firmly, and it was all done so easily and quickly that she hardly had time to cry before it was all over with. Of course all cases are not so easily managed as this one; on the contrary, many of them present difficulties that will tax the ingenuity and skill of the physician to the utmost, but with a little care and patience and plenty of tact in the management of the patient and assistants, almost every case will at the first trial have as successful and happy a termination, and the physician's reputation be added to thereby.

REPORT OF FIFTY-THREE CASES OF ANÆSTHESIA BY THE SCHLEICH METHOD.

By A. E. ENGZELIUS, M.D.,

ST. LUKE'S HOSPITAL, NEW BEDFORD, MASS.

Having administered Schleich's anæsthetic mixture in fifty-three cases during the months of February and March in St. Luke's Hospital, New Bedford, Mass., I desire to report the same, principally because of the remarkably small quantities of this mixture which in my experience have been required. This series of cases includes twenty-one laparotomies and a large number of various vaginal operations, among which one vaginal hysterectomy. Only eight of the operations were of less than one-half hour's duration. The average length of operation was fifty-three minutes. The mixture No. 1 was employed in thirty, No. 2 in six, and No. 3 in seventeen cases. The average total quantity of No. 1 used was one and seven-tenths ounces; of Nos. 2 and 3, one and six-tenths ounces. The longest operation in which No. 1 was used lasted two hours (cholecystotomy), requiring four ounces of the anæsthetic. The longest operation with mixture No. 2 lasted two hours and five minutes (for cystocele, rectocele, and prolapsus uteri), requiring two ounces of the anæsthetic. The longest operation with mixture No. 3 lasted two hours and ten minutes (operation for prolapse of the uterus and the vagina, followed by laparotomy and ventrofixation), requiring three ounces of the anæsthetic. The inhaler employed was the towel-and-paper cone. From one-fourth to one-half of an ounce was in most cases sufficient to induce anæsthesia within ten to twelve minutes. To maintain complete anæsthesia the cone is removed from the face at frequent intervals, and, a few drops of the mixture having been quickly dropped into it, the cone is immediately replaced over the face.

The stage of excitement was present to a slight degree in ten cases, and in marked degree in two cases, one of which was that of an alcoholic. In the remaining forty-one cases the excitement stage was entirely wanting. Vomiting from the anæsthetic occurred in fifteen cases. In eight of these the vomiting was very slight and insignificant. Of the seven cases of more decided vomiting, two had eaten breakfast some few hours before the operation. The majority of the patients experienced, however, some nausea after consciousness had been restored. In a few cases dry retching occurred during the operation, and in some cases actual vomiting took place while the patient was on the table, and often without being repeated after the operation. Slight cyanosis was present in six cases.

In one case, that of a robust woman, twenty-six years of age, cyanosis became quite pronounced and the respiration very shallow in the beginning of the anæsthesia after only three drachms of the mixture No. 2 had been used. Ether and oxygen were promptly substituted for the mixture, and the operation (laparotomy and ventrofixation) was carried on to an uneventful completion.

In a case of strangulated inguinal hernia in a man, sixty-six years old, and in a generally poor condition, oxygen was administered along with the anæsthetic for the latter half of the time, the entire length of the operation being one and one-half hours. Notwithstanding the simultaneous employment of oxygen in this case, only two ounces of the anæsthetic were required. The pulse at the end of the operation was 96, strong and good, and the patient regained consciousness in about fifteen minutes.

The youngest patient in the series was a boy, one and one-half years old, the operation being for the radical cure of hernia, lasting one and one-half hours, requiring two-thirds of an ounce of the mixture No. 1. The oldest patient was a man, seventy-six years old, upon whom external urethrotomy was performed, the operation lasting one hour, requiring one and one-half ounces of the mixture No. 3.

There is no case of heart lesion in the series, but in three cases albuminuria was present before the operation, with no aggravation of symptoms following the anæsthetic. In no case was a hypodermic injection given as preparatory to the operation. In a very few and exceptional cases, which I have not recorded, I found it desirable to give a hypodermic of strychnine either during or immediately after the operation.

Progress of Medical Science.

A New Method of Treatment for Pharyngeal and Laryngeal Affections.—Dr. Smester (*Revue de Thérapeutique*, January 1, 1898) suggests a new treatment for laryngeal and pharyngeal affections by means of medicated siphons. The apparatus resembles the siphon for seltzer water; it is portable and admits of medicated mixtures being used in all proportions. The author has employed for fifteen years the ordinary seltzer water and siphon, with which he has obtained mechanical and anæsthetic effects, for the jet projected into the back part of the throat cleanses the mucous membrane and the carbonic acid causes local anæsthesia. The medicated siphon is charged with sterilized water, but may also receive active substances, such as bicarbonate of sodium and chlorate of sodium. It is advisable to fit to the beak of the siphon a rubber tube, which may be directed toward the diseased parts. The patient rarely swallows the liquid; experience has shown that the jet ought to be directed with force at first and afterward gradually diminished.

Mechanical Treatment of Obesity.—Dr. Winternitz (*Therapeutische Wochenschrift*, December 5, 1897) objects to the dietetic treatment of obesity, whether the method employed is that of Harvey, Banting, or Ebstein, as these means establish inanition and are capable of producing gout, serious digestive troubles, and rebellious neurasthenic states. The recent agents, Pochl's spermin, thyroid extract, etc., favor intraorganic oxidation in a high degree, but have dangers which have been made the object of numerous communications, these troubles being especially circulatory and nervous. Muscular activity that has been so

widely advised is not always good, on account of the hyperthermia that this activity produces. In noticing the change in temperature in cases in which obese patients have undergone violent exercise, we find that it is sometimes of a febrile character and that the organic albumin loses its vitality. This process consequently causes nervous debility, anæmia, and albuminuria. It is necessary to invent a means of increasing oxidation and at the same time avoid hyperthermia, in such a way as to destroy the fat without affecting the albumin. To this end Winternitz advises lowering the temperature of the body before exercise. It is easy to do this by means of a bath of 12° or 14° C., lasting fifteen or twenty minutes; by this means one can take away five hundred calories from the organism. To recuperate these, fifty grams of fat must be consumed. In order that lowering of the temperature may not cause contraction of the cutaneous vessels, he proceeds as follows: In the morning submit the patient to an energetic rubbing with a towel wet in cold water; then place him for five or ten minutes in a steam room; on leaving this room he takes a bath at a low temperature, lasting from three to six minutes. Severe muscular exercise terminates the treatment. This may be repeated two or three times in twenty-four hours. It is useless with this method to prescribe a rigid diet; the results are rapid and are never accompanied by troubles similar to those observed with the other methods.

The Treatment of Epidemic Cerebro-Spinal Meningitis.—In a discourse on the above subject, delivered before the Society of Hospital Physicians on September 15, 1897, Dr. Béla Angyán (*Ung. med. Presse*, 1897) outlines its treatment with special reference to his employment of corrosive sublimate. As there is no specific remedy for this disease, treatment must be symptomatic. As antiphlogistics, venesection, local blood letting, ice applications, and finally mercurial inunctions are recommended. Leeches, according to the speaker's experience, lessen the headache and the nervous manifestations; he recommends blood letting only in the so-called hyperacute cases, and even then only in strong individuals and in the beginning of the disease. The patients do not bear cold baths well, and a resulting collapse is not infrequent. Cold douches applied to the head and back of the neck for several minutes every three or four hours is very beneficial, especially in attacks of soporous coma. Prolonged ice poultices produce a marked antiphlogistic effect; an ice bag should be applied to the head and nape of the neck, and the Chapman coil to the spine, but only so long as they are borne with comfort by the patient. The pain is lessened, the nervous manifestations are allayed, and often a quiet sleep supervenes. The mercurial treatment in the form of calomel or inunctions, which the French were first to recommend, continues at the present day to play an important rôle in the therapy of epidemic meningitis. Narcotics are to be used with great caution, and only in those cases marked by intense nervous excitability, by uncontrollable vomiting, or by marked wakefulness. They are contraindicated when somnolence, lethargy, or depression of the nervous system exists, or when collapse is to be feared. The indication for excitants and analeptics is restricted to a very narrow field, chiefly to cases in which narcotics are contraindicated. Vesicants and the like are not to be used. Since in epidemic meningitis the brain and cord are subjected to great pressure by the accumulation of cerebro-spinal fluid, it would seem *a priori* that Quincke's procedure—aspiration of the cerebro-spinal fluid by lumbar puncture, to relieve the pressure on the brain and cord—is a rational one. Warm baths, recommended by Aufrecht, seem to have a favorable influence on the heart's action, but no conclusions should be based on the small number of cases thus far treated. The speaker confines his treatment to the use of the ice bag and the subcutaneous injection of bichloride of mercury. The sublimate, given hypodermatically, is more rapid and energetic in its action; entering the circulation, it has an antimycotic effect on the toxic blood serum. Injections of one centigram in adults, and of from 0.005 to 0.05 gm. in children, are made daily along the course of the spinal column. In acute cases they are repeated as long as fever continues and the headache, backache, and stiffness of the neck remain; in subacute cases they are repeated as long as exacerbations exist. In this manner he has treated twenty-seven cases, acute and subacute—six females and twenty-one males, ranging in age from three to thirty years. Nineteen, or 70.3 per cent., recovered. As to the number of injections individual cases varied from four to twenty-four. The injections were well borne by the patients: in one case after the fourteenth injection there resulted slight salivation; in six others there was diarrhœa unaccompanied by salivation. The following results from the injections were observed: 1. In most cases after the second or third injection the mind became clearer, the excitability was allayed, the headache was less marked, and the patient could sleep. 2. After five or six injections clear cerebration usually reappeared, and sleep became quieter and was of longer duration. 3. After seven, eight, or nine injections the retraction of the head was less marked and gradually disappeared: the fever diminished and finally subsided. 4. The sublimate injections seem neither to lengthen nor to shorten the progress of the disease. 5. The sublimate seems, after employment for several days, to check the formation of products of inflammation. In confirmation of this are those cases seen at autopsy in which a small amount only of inflammatory product could be demonstrated; and even this was more often fibrinous than purulent in character.

Hydrocephalus Idiopathicus Acutus.—The *Wiener klinische Rundschau* (No. 36, 1897) briefly reviews Dr. Georg Boenninghaus' work on "Die Meningitis serosa acuta," in which he seeks to establish the existence of an acute idiopathic hydrocephalus, the result of an acute serous meningitis. The result of his studies may be summarized as follows: 1. An acute idiopathic hydrocephalus does exist. 2. It is the product of an acute serous meningitis. 3. The acute serous meningitis may have a malignant character and is then usually an acute serous meningo-encephalitis. This form has but little clinical significance. 4. Or it may have a benign character, and is then most often a meningitis serosa interna (ventricularis). This is always a sequel of a meningitis serosa externa, and develops in consequence an active (automatic) closure of the ventricle. This form is of considerable clinical importance. 5. The benign acute serous meningitis may run its course masked as a purulent meningitis, a tuberculous meningitis, a brain abscess, or a brain tumor. It may have a lethal termination or recovery may take place. 6. It can be recognized with certainty only when, after operative evacuation of the cerebro-spinal fluid, the symptoms of purulent meningitis, tuberculous meningitis, brain abscess, or brain tumor immediately, completely, and permanently disappear. 7. It is to be suspected when the symptoms indicative of purulent meningitis, tuberculous meningitis, brain abscess, or brain tumor disappear completely without operation. The more sudden the disappearance the greater is the probability that a meningitis serosa acuta benigna was present. 8. It can with certainty be cured by evacuation of the cerebro-spinal fluid.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 11, 1898.

THE CONDITION OF THE VOLUNTEERS IN CAMP BLACK AND CAMP ALGER.

THE announcement has just been made that General Miles will probably recommend in his report to the government that three large permanent camps be established for the volunteer army. One of these will certainly be at Montauk Point, L. I., another at Chickamauga, and a third at some place in Florida not yet named. Consequently the three regiments which are still at Camp Black will shortly be moved. As yet their destination is not definitely known, for, although the general opinion is that Montauk Point will be the rendezvous, the impression prevails among both officers and men that they will be sent South or West and not to Montauk Point. However, it matters but little where they are stationed, provided that the location selected be suitable and healthy. Mount Black does not fulfil these requirements, and is not by any means an ideal spot for the encampment of a large body of men, and it is well that the authorities have seen fit to alter their first determination to establish there a permanent camp. True, the air of Hempstead Plains may be healthy and bracing, but the place itself is wofully lacking in some of the requirements usually considered necessary to keep men in sound bodily vigor. Cleanliness of both person and clothing is esteemed almost a *sine qua non* for the preservation of good health. Hempstead Plains is a treeless heath, and while the site of the encampment certainly possesses some natural advantages, it is wanting in what must be regarded as the most important and one that is indispensable to the health and comfort of a large body of men, especially when the majority of them are green recruits, and the remainder men who have not become hardened by exposure and hardships to the stern exigencies of a soldier's life. There is a great need of pure and wholesome water for drinking and cooking purposes, as well as for bathing and washing clothes. But perhaps the chief objection that can be urged against Camp Black is its proximity to New York. Owing to this fact, Hempstead has been overrun with a continuous stream of soldiers' relations and idle sightseers. Indeed, in many ways it more resembles a country fair than a military encampment. Men, and particularly untrained men, as a large proportion of the volunteers are, need all their time to learn their duties as soldiers, and the distraction of constantly seeing relations and friends does not tend to the attainment of that object. Viewed, too, from a medical standpoint, these visits have had a bad effect, for the visitors, out of the kindness of their hearts, would come and bring with them dainty articles of food and stimulating drinks for the behoof of the soldiers.

Montauk Point is a more desirable location in every respect. It is situated at the extreme eastern end of Long Island; is an elevated plateau surrounded on three sides by the sea, thus affording ample facilities for bathing. Again, it is a day's journey there and back from New York, which will virtually put an end to the visiting-nuisance.

The water supply at Camp Alger is being made the subject of serious complaint; it is stated that the water procurable is for the most part unfit for drinking or cooking purposes unless treated with greater care than raw and inexperienced soldiers are likely to employ. This is a defect which should be remedied in all the camps as quickly as is possible.

In the house of representatives the other day a question was asked concerning the food supplied to the volunteers. In most of the camps severe strictures have been passed on the food both as regards quality and quantity. In all probability these objections are due either to the fault of the commissary sergeant or to the too dainty stomachs of the men themselves, as the sum allowed for food is quite sufficient, if judiciously expended, to provide every volunteer with good and wholesome, although perhaps not luxurious food.

The last cause of dissatisfaction is the one not the least deserving of notice, viz., that the volunteer regiments are without many of the necessaries that would be needed in a campaign in Cuba. Many regiments have no uniforms, and many more have no shoes and underclothing. The report runs that fifty per cent. of the men are wearing unserviceable shoes, and that quite a large number are barefooted. Shoes, are, undoubtedly, the most important detail of an infantryman's outfit. Not only should he have stout and strong shoes, but they should also be easy and well-fitting. Napoleon, or some other distinguished French general, remarked that "the infantry proves its valor less in fighting than in walking so much." Therefore the foot soldier should be shod in such a way that he can walk with ease and comfort. Notwithstanding, however, these drawbacks, many of which under the circumstances are unavoidable, it is agreeable to notice that the health of the men in camp is on the whole good: in fact, considering the change of water, climate, and diet, better than might have been expected.

Resignations from Bellevue Hospital Medical College.—The following gentlemen have resigned from the faculty of the Bellevue Hospital Medical College: Drs. Austin Flint, professor of physiology; Frederic S. Dennis, professor of principles and practice of surgery; and Samuel Alexander, professor of genito-urinary surgery.

HEALTH OF THE ARMY.

Conflicting reports have appeared in the public press during the past week as to the actual physical condition of our regular and volunteer armies.

In a war which has thus far been so singularly free from casualties to our forces from shot and shell, it would be well if the end might come without great loss of life from disease. Excessive rains in one part of the country and the great heat in another, together with suspected water supply for the camps, have been blamed for an amount of sickness among the troops which has been thought by some writers excessive. While measles has appeared in several camps, as is often the case when large bodies of recruits are brought together, typhoid is the form of fever most dreaded in the home camp, because of the great mortality likely to attend its extended outbreak.

Fortunately, so far, there has been no alarming report concerning the prevalence of typhoid fever, and this we can surely attribute to the supervision and care of the water supply. We read that water pipes are laid throughout some camps just as for a small city. If now the supply source can be kept free from contamination, no great danger from typhoid should be looked for in the various camps. On the march, however, the same conditions will not prevail, and the utmost care in methods of sterilization or purification will have to be carried out to insure freedom from disease. Expense and trouble should not enter into the question. Let it not be said at the close of the war that more men succumbed to bacilli, which could have been guarded against, than to the enemy's bullets. There have undoubtedly been hardships which foresight might have averted and others which were unavoidable; but that sickness, the result of negligence, has prevailed to any great extent cannot be claimed, if we are to accept official reports. Colonel Pope, chief surgeon of the fifth army corps, is quoted to the effect that the sick list embraces but two per cent., while the normal army rate is four and a half per cent. If these figures hold good for the whole army, it is indeed a surprising and most satisfactory condition, and one which we may hope will continue to prevail.

USE OF QUININE IN LABOR.

The somewhat indiscriminate and unintelligent use of ergot which prevailed in midwifery practice but a comparatively short time ago is now a thing of the past. This custom was especially to be deprecated as resorted to by midwives, who often administered ergot with a too generous hand both during labor and after, with disastrous results, of course, in many cases. However, it seems probable that the reaction against the use of ergot is being carried too far, and that, like mercury, the drug will sooner or later be appreciated at its real worth. Dr. Owen C. Mackness, in an interesting paper contributed to the May number of the *Edinburgh Medical Journal*, recommends in some cases of labor the administration of quinine in the place of ergot. Ergot, he says, is contraindicated in all cases of labor in which its ecbolic action is desired, but for the arrest of hemorrhage from the uterus it is decidedly useful. When the hemorrhage occurs during labor, quinine, however, is of more avail, since the hæmostatic action of ergot is here of little use, while the regular contractions set up by quinine will do more for its arrest and more quickly effect delivery than the tetanic contractions set up by ergot. It is in post-partum hemorrhage that ergot finds its principal use. Here the hæmostatic action comes into play perhaps to some extent, while the tetanic contractions set up in the uterine muscles tend to close the gaping blood-vessels and arrest the hemorrhage. It must of course be administered in large doses. When abortion is threatened and there is bleeding, while pains are absent and the os uteri is closed, ergot in small doses is of great use—doses which will bring into play the hæmostatic action of the drug without being large enough to set up uterine contractions. In subinvolution of the uterus after delivery, ergot is of great use, more especially if there be much hemorrhage.

Finally, Dr. Mackness concludes that:

(1) Ergot is contraindicated during labor, but should post-partum hemorrhage occur it is useful in large doses.

(2) Ergot is useful in repeated small doses when abortion is threatened, hemorrhage occurring without pains and the os uteri being closed. Further, it is useful in small doses in subinvolution of the uterus.

(3) Quinine, eight grains, followed by four grains in an hour and repeated after another hour if required, should be given whenever there is delay in the labor due to exhaustion of the uterine muscles, provided the delay is not caused by obstruction in the passages or deviation from the normal in the fœtus. In these latter cases or when quinine fails to produce sufficient uterine contractions, forceps should be applied or other means of delivery resorted to.

A Bequest to the University of Michigan.—By the will of Dr. Elizabeth H. Bates, of Port Chester, N. Y., the University of Michigan will receive property which will yield about $6,000 a year, subject to an annuity of $1,200 to be paid to a friend of the testator. According to the will the bequest goes to the medical department, to be used in the support of a chair of diseases of women and children. Dr. Bates left property of the value of $200,000, said to have been made in the practice of her profession in Owego, N. Y. For a number of years she was secretary and treasurer of the Port Chester board of health.

The Woman's Hospital.—An appeal for funds for this institution has recently been issued. It says that all connected with the hospital are doing what they can to meet its needs, but with every effort on their part an annual deficiency of over $27,000 threatens. The appeal says that "these are hard times for hospitals." We may add that the hospitals have the remedy in their own hands, and this remedy does not consist in the opening of more private rooms for the reception of pay patients taken from the *clientèle* of physicians unconnected with the hospitals.

News of the Week.

Surgeons in the Volunteer Army. — President McKinley sent the following nominations to Congress May 20th: To be chief surgeons, with the rank of major—George Cook, of New Hampshire; William H. Daly, of Pennsylvania; Clayton Parkhill, of Colorado; James M. Jenne, of Vermont; Herbert W. Cardwell, of Oregon; James B. Hysell, of Ohio; Leonard B. Almy, of Connecticut; Charles B. Nancred, of Michigan; Henry F. White, of Minnesota; Thomas Earl Evans, of Alabama; Jefferson D. Griffith, of Missouri; R. Emmett Griffin, of Nebraska; and Edward Boeckman, of Minnesota. On June 4th the following additional nominations were sent: To be chief surgeons of divisions, with the rank of major—Captain William H. Arthur, assistant surgeon; Captain George E. Bushnell, assistant surgeon; Donald MacLean, of Michigan, and George R. Fowler, of New York.

The following assistant surgeons with the rank of captain, to be brigade surgeons with the rank of major: William C. Gargas, Henry P. Birmingham, Marlborough C. Wyeth, Richard W. Johnson, Edward C. Carter, William O. Owen, Peter R. Egan, William J. Wakeman, William Stephenson, Adrian S. Polhemus, John L. Phillips, William C. Borden, Edgar A. Mearns, Guy L. Edie, William D. Crosby, William L. Kneedler, Charles M. Gandy, James E. Pilcher, Charles B. Ewing, Walter D. McCaw, Jefferson R. Kean, Henry I. Raymond, Francis J. Ives, William P. Kendall, Edward R. Morris, Henry S. T. Harris, William B. Banister, Paul Clendenin, Charles E. Woodruff, Eugene L. Swift, Paul Shillock, Ogden Rafferty, Charles F. Mason, James D. Glennan, Alfred E. Bradley, Philip G. Wales, Samuel T. Armstrong, acting assistant surgeon, and George T. Vaughan of the Marine Hospital service; also the following from civil life: Willis G. MacDonald, of New York; Charles M. Drake, of Georgia; Joseph K. Weaver, of Pennsylvania; John Guitéras, of Pennsylvania; Charles E. Ruth, of Iowa; John W. Bayle, of the District of Columbia; Milo B. Ward, of Missouri; Schuyler C. Graves, of Michigan; Nathan S. Jarvis, of New York; William Devine, of Massachusetts; John C. Martin, of Ohio; Peter D. MacNaughton, of Michigan; John Patterson Dodge, of Ohio; John R. McDill, of Mississippi; Samuel O. L. Potter, of California; George A. Smith, of Iowa; Arthur Snowden, of Virginia; R. Stansbury Sutton, of Pennsylvania; and Frank Bruso, of New York.

Sir Lyon Playfair, the well-known chemist and publicist, the author of many addresses and articles on chemistry, state medicine, and political economy, died in London on May 30th, at the age of eighty years.

The Naval Hospital Ship "Solace" arrived in this port from the West Indies on Sunday, bringing fifty-four sick and wounded sailors from the fleet in Cuban waters. Among them were men who took part in the bombardment of San Juan, others who received their injuries while engaged in the perilous work of cutting cables from small boats within forty yards of the Cuban coast and under the fire of Spanish sharpshooters, and others who have been engaged in blockade duty off Havana. The *Solace* met Admiral Sampson's fleet two days after the San Juan bombardment of May 12th. They met about one hundred and eighty miles from Porto Rico, and three men from the *Iowa* and one from the *New York* were transferred to the hospital ship in small boats at night. The *Solace* got orders immediately afterward to proceed to Key West, and take on the sick and wounded there. She left Key West at four o'clock last Wednesday afternoon. The weather was very bad on Friday and Saturday, but the patients were little inconvenienced. The men were transferred to the Naval Hospital in Brooklyn.

Aid for Sick and Wounded Soldiers.—Surgeon-General Sternberg, in reply to numerous letters asking what articles would be most acceptable for the use of sick and wounded soldiers, has prepared the following memorandum: "Money may be sent to the surgeon-general of the army as a contribution to the hospital funds of the hospital ship *Relief* and of the United States general hospitals. This will be sent to the surgeons in charge, to be expended for delicacies for the sick, such as canned soups, jellies, lemons, oranges, etc. Those who prefer may contribute canned soups, clam broth, orange marmalade, ginger ale, biscuit, water crackers, and similar articles in hermetically sealed cans for use on the hospital ship *Relief* and at the United States general hospitals at Key West, Fla.; Fort McPherson, Ga.; Fort Thomas, Ky.; and Fort Myer, Va. Bandages, lint, and other surgical dressings are not desired, as these can now be obtained from the manufacturers, sterilized for use and of the quality which experience has shown to be best suited for our purposes. Shirts and drawers are provided by the government, but will be accepted and can be given convalescents upon their discharge from the hospital. Pajamas made of light gingham will be useful for the sick in hospital and on the hospital ship, as they can be worn by convalescents who are able to be out of bed. Long nightshirts of light muslin can also be utilized. Broad bandages of light flannel to protect the abdomen are highly recommended, and may be worn to advantage by our soldiers in the field. The articles mentioned may be sent direct to the surgeon-general of the army or to the surgeons in charge of the general hospitals named."

Medical Society of New Jersey.—The next annual meeting of this society will be held on June 28th, 29th, and 30th, and not on June 21st, as previously announced.

A Permanent Naval Hospital Corps.—Senator Hale recently reported a bill providing for the organization of a hospital corps for the navy, which has already passed the house. The naval committee recommends favorable action on the measure, but proposes to amend it by striking out the provision disbanding the corps at the expiration of the present war, thus making the corps permanent.

Dr. T. W. Cleaveland, who was recently arraigned before Judge McMahon to answer to an indictment, obtained by the district attorney, for manslaughter in causing the death of an infant, has been discharged from custody, the court holding that there was no evidence to warrant a trial.

The Hospital Ship "Relief."—Capt. William C. Gargas has been appointed assistant surgeon on the army hospital ship *Relief*. Seven trained nurses, graduates of the Mills Training-School for male nurses of Bellevue Hospital, have been ordered to the ship.

The American Dermatological Association has completed during the past week probably the most satisfactory meetings in its history. The meetings for the transaction of business and for the reading of papers were held at the Princeton Inn, while the third day was set apart for the clinical exhibition of rare and interesting cases, microscopic specimens, etc. One of the features of this day's programme was a gallery exhibition of photographs and paintings, to which visiting as well as local members freely contributed. The last day's session was held at the New York Academy of Medicine, whose rooms were generously placed at the disposal of the local committee. About fifty patients were shown, who presented lesions which were for the most part either rare or difficult of diagnosis. The success attending this practical form of exhibition makes it quite certain that it will be repeated whenever the future meetings are held in or near a large city. The German Dermatological Association, to which an invitation had been extended, met by a strange coincidence upon the very same dates in Strasburg. The next meeting will be held at some point near Philadelphia on or about the first Tuesday of June, 1899. Dr. Fordyce was elected president and Dr. Jackson secretary, both of New York.

"The Columbus Medical Journal."—A fire in the building of the printers of the *Columbus Medical Journal*, on the morning of May 12th, destroyed all the copy for the May issue of that journal, causing great inconvenience and some delay in the appearance of the number. We extend our sympathy to our excellent contemporary, and trust that its hope of securing duplicates of the papers destroyed will be speedily realized.

Dr. William Osler, professor of medicine at the Johns Hopkins University and physician in charge of the Johns Hopkins Hospital, is one of the fifteen scientists selected this year by the committee of the Royal Society to be recommended for membership in the Royal Society of England. The society embraces the most distinguished scientists of the world, and only a few Americans have received the high honor of recommendation.

A National Society for the Study of Epilepsy.—At a meeting held at the Academy of Medicine in New York City on the 24th of May, representatives from eight States were present to organize a "National Society for the Study of Epilepsy and the Care and Treatment of Epileptics." The society organized with forty-four members. The following officers were elected: *President*, Hon. William Pryor Letchworth, LL.D., New York; *First Vice-President*, Dr. Frederick Peterson, New York; *Second Vice-President*, Dr. William Osler, Maryland; *Secretary*, Dr. William P. Spratling, New York; *Treasurer*, Dr. H. C. Rutter, Ohio. Application for membership should be addressed to the secretary at Craig Colony, Sonyea, N. Y.

Dr. John J. Morrissy has been elected professor of Practice and Pathology at the New York School of Clinical Medicine.

American Gynæcological Society.—At the recent meeting of this Society at Boston the following officers were elected for the ensuing year: *President*, Joseph Taber Johnson, of Washington, D. C.; *Vice-Presidents*, Howard A. Kelly, of Baltimore, and Albert F. A. King, of Washington, D. C.; *Treasurer*, J. Montgomery Baldy, of Philadelphia; *Secretary*, J. Riddle Goffe, of New York. The next annual meeting will be held in Philadelphia.

Acting Assistant Surgeons of the Marine Hospital Service.—The United States civil service commission announces that on June 7, 1898, examination may be taken at any city in the United States where the commission has a competent board of examiners, for the grade of acting assistant surgeon in the Marine Hospital service, treasury department. There is at present a vacancy in this grade at Chicago, Ill., at a salary of $100 a month, which it is desired to fill. In filling this vacancy preference will be given to eligibles who are legal residents of Chicago or vicinity. Future vacancies will be filled by selections from eligibles who are legal residents of the cities or vicinity where vacanies occur. Applicants for this position must be at least twenty years of age, and must be competent physicians and surgeons, graduates of reputable medical colleges, and must furnish satisfactory certificates relative to their moral character and professional capacity. The examination will consist of the subjects named below, which will be rated as follows:

Letter-writing	5
Anatomy and physiology	15
Chemistry, materia medica, and therapeutics	10
Theory and practice of medicine, and general pathology	25
Surgery and surgical pathology	20
Bacteriology and hygiene	10
Obstetrics and gynæcology	15
	100

This examination is open to all reputable citizens of the United States. Persons desiring to enter this examination should at once write to the United States civil service commission, Washington, D. C., for application blanks, forms 304 and 375, which should be properly executed and promptly forwarded to the commission.

Dr. Andrew Manning, of Plainfield, N. J., died suddenly on May 19th, at the age of thirty-seven years. He was a graduate of the College of Physicians and Surgeons in this city in 1883. He leaves a widow and one daughter.

American Pediatric Society.—At the annual meeting, held in Cincinnati, Ohio, June 1–3, 1898, the following officers were elected: *President*, W. P. Northrup, New York; *First Vice-President*, G. N. Acker, Washington; *Second Vice-President*, Irving M. Snow, Buffalo; *Treasurer*, Edward M. Buckingham, Boston; *Secretary*, S. S. Adams, Washington; *Additional Member of the Council*, F. Forchheimer, Cincinnati; *Editor*, F. M. Crandall, New York. It was voted to hold the next meeting of the society at Deer Park, Md.

Making Game of the Medical Journals.—In an editorial note under the above caption we recently commented upon the apparent readiness of sundry medical journals to accept patent-medicine advertisements, and mentioned, among others that had signified their willingness to take the tempter's gold in a specific instance, the *Journal of the American Medical Association*. It gives us great pleasure to learn, however, that this statement, which we made on the authority of *Printers' Ink*, and the proprietor of the medicine, was incorrect. The letter of inquiry regarding the advertisement was addressed to the publisher of the *Journal*, and an affirmtive reply was sent to the writer. But our esteemed contemporary asserts that this reply was a clumsy forgery. It says that it did not answer the letter, owing to the fact that the advertisement had previously been declined, and later it makes its assertion even more forcible by affirming that the letter was never received. Either of these reasons is certainly a sufficient excuse for the seeming discourtesy of not replying to the would-be advertiser's inquiry, and the two together convince us absolutely that we were wrong in allowing the positive statement of *Printers' Ink* to outweigh the presumption of virtue and astuteness on the part of our esteemed contemporary. We trust that the *Journal's* search for the forger, which no doubt is being vigorously prosecuted, will be crowned with success.

Dr. W. B. Pritchard, editor of *The Polyclinic* of this city, writes that the advertisement may have been tentatively accepted by the business manager of that journal, "but such acceptance was by no means a guarantee that it would be published. As a matter of fact, we never saw or heard of the advertisement in question until reference to it appeared in the MEDICAL RECORD. The *New York Polyclinic* is not one of the 'I am holier than thou' type by any means, but we do claim a sufficient sense of ethical propriety to have preserved our grace in this instance, had the advertisement been submitted to us, as was necessary before it could have been published." We are glad to learn that the acceptance of this advertisement had not editorial sanction.

Practitioners in Great Britain.—According to the "Medical Register" for 1898, the total number of legal medical practitioners in the United Kingdom is 34,642. There were 1,066 names removed from the "Register," and 1,230 names were added to the list. This is nearly 200 less than the average number admitted annually during the past five years. The net gain in the number of medical practitioners is therefore only 164.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Forty-Ninth Annual Meeting. Held in Denver, Col., June 7, 8, 9, and 10, 1898.

(For Telegraph to the MEDICAL RECORD.)

GENERAL SESSION.

First Day—Tuesday, June 7th.

THE meeting was held in the Broadway Theatre, and was called to order by the first vice-president, DR. JOSEPH M. MATTHEWS, of Louisville. The session was opened with prayer by Chancellor W. F. McDOWELL. A telegram was read from the president of the association, Dr. George M. Sternberg, expressing his deep regret that imperative official duties prevented his attendance and offering his congratulations and best wishes for the success of the meeting.

The session opened with a very large attendance, as may be inferred from the statement that even at that early hour 1,100 members had already registered.

Addresses of welcome were delivered by DR. J. W. GRAHAM, chairman of the committee of arrangements; by His Excellency ALVA ADAMS, governor of Colorado; and by Hon. W. S. MCMURRAY, mayor of Denver.

President's Address.—In the absence of Surgeon-General George M. Sternberg, the president, his address was read by COL. WOODHULL. After expressing his high appreciation of the honor conferred upon him, the writer said that the day was perhaps not far distant when no reputable physician would be willing to confess that he did not belong to the American Medical Association. In order that every physician of good professional standing might enjoy the privileges of membership he thought it desirable that permanent members should be elected, upon application, without reference to their membership in State, county, or district medical societies, when they presented satisfactory evidence that they were graduates in medicine of reputable standing in the profession, and were willing to subscribe to the code of ethics of the American Medical Association. In other words, he would not exclude a reputable physician from membership because the State, county, or district medical society to which he belonged declined to adopt the code of ethics. A liberal and progressive spirit would do much toward promoting the growth and influence of the association. The medical profession in this country had suffered more, in his opinion, from the ignorance of some of its members who held diplomas from regular schools of medicine than from the attacks of those who were called irregulars or quacks.

Scientific medicine, being founded upon demonstrable truths, must in the end maintain itself and secure the confidence of the people. Reliance must be had, not upon diplomas, or membership in medical societies, but upon superior knowledge and skill. We were still often spoken of as "old-school" physicians, but that term was really applicable only to those who had fallen behind the rest. At the present time, the only distinctive name which was applicable was "the new school of scientific medicine." Positive denials of the well established achievements of scientific medicine were often made, unfortunately too often by men who were authorized to attach the letters M.D. to their signatures. This led to the frequent repetition of the old question as to "Who shall decide when doctors disagree?" No matter how well a fact might be established by repeated experiments or by the common experience of the profession, some doctor could be found who through ignorance or that obliquity of mental vision which characterized the

crank would deny its truth. Thus there were doctors who denied the value of vaccination; others who failed to recognize any value in results obtained by experiments on the lower animals; others who denied the etiological rôle to well-known pathogenic bacteria. As a result the antivaccination and antivivisection societies were able to fortify their position by quoting the opinion of medical men of more or less repute. But opinion was of no value when opposed to evidence, and it seemed to the writer that those familiar with the evidence would do well to give to the public concise and comprehensible statements suitable for publication in newspapers and popular magazines, setting forth the facts and the evidence upon which these facts were accepted by well-informed physicians. But in doing so great care should be taken not to make any assertions that were not based upon reliable data.

Speaking of the *x*-ray, Dr. Sternberg said that it was to have been expected the *x*-ray would already be made a source of revenue by more than one pseudo-scientist. The following account of the modus operandi of its supposed therapeutic action had recently been published in the newspapers: "After the Crookes tube is excited by the coil the magnetic lines of force are projected down in the same manner as they pass off from a magnet, and, traversing the intervening space, pass through the body down to the floor and back to the coil and tube again, completing the circuit. The *x*-ray is electrostatic in character and of a very high potential. With every discharge from the Crookes tube oxygen is liberated in the body as well as the surrounding atmosphere, which, combining with nascent oxygen, forms ozone. It is due to the electrolysis produced in the body that we are able to destroy the bacilli in contagious diseases, ozone being the most powerful germicide known."

In commenting upon this quotation Dr. Sternberg remarked that he did not fully understand why the magnetic lines of force were reflected back by the floor, completing the circuit, and, inasmuch as the *x*-rays pass through wood, this mysterious action of the floor appeared to call for some further explanation. Passing by the ingenious explanation of the formation of ozone as a result of the action of the *x*-ray, he called attention to the mistaken statement that ozone "is the most powerful germicide known." The experiments of Fraenkel, he said, showed that the aerobic bacteria grew abundantly in the presence of pure oxygen and some species even more so than in ordinary air. It was formerly supposed that ozone would prove to be a most valuable agent for disinfecting-purposes, but recent experiments had shown that it was not so active a germicide as had been anticipated, and that from a practical point of view it had comparatively little value. Lukaschewitsch found that one gram, in a space of a cubic metre, failed to kill anthrax spores in twenty-four hours. The cholera sporule in a moist state was killed in this time by the same amount, but fifteen hours' exposure failed to destroy it. The ozone for these experiments was developed by means of electricity. Again, Wyssokowicz had found that the presence of ozone in a culture medium restrained the development of the anthrax bacillus, the bacillus of typhoid fever, and others tested, but concluded that this was due rather to the oxidation of bases contained in the nutrient medium than to direct action upon the pathogenic bacteria. The conclusion reached by Nissen from his own experiments and careful consideration of those previously made by others was that ozone was of no practical value as a germicide in therapeutics or disinfection.

Dr. Sternberg said that unfortunately lack of information relating to the definite results of scientific investigations was not confined to the non-medical members of the community. With the progress of scientific medicine had come improved methods of teaching, and it was now generally recognized that reading medical books and listening to lectures were not a sufficient preparation for the practice of medicine, any more than the reading of books on navigation would be for the responsibility of the captain of an ocean steamer. It was for this reason that we insisted upon the study of anatomy in the dissecting-room, the teaching of methods of diagnosis and treatment at the bedside, and of chemistry, physiology, and pathology in the laboratory. The painstaking work and attention to details required of students engaged in chemical, physiological, bacteriological, or histological studies, and the failure in their attempts to repeat an experiment or demonstration if through haste or carelessness they neglected any step in the necessary technical process, constituted an invaluable lesson. Indeed, the scientific medicine of the present day could be taught only by such methods, and the scientific physician of the future must make his way to fame and fortune by travelling this somewhat difficult and time-consuming road.

Reference was made to Pasteur's treatment of hydrophobia. This in his opinion was one of the great and well-established achievements of scientific medicine. Scientific medicine must be founded upon an exact knowledge of the structure and functions of the human body in a healthy condition and of the changes in structure and function which resulted from various disease processes; of the causes, natural history, and regional distribution of the diseases which afflicted mankind and the lower animals; of the toxic action of various substances from the animal and vegetable kingdoms; of the use of these and of other non-toxic substances and physical agents in the treatment of disease; and of the prevention of disease by disinfection, quarantine, protective inoculations, etc.

Mention was made of the recent investigations of Loeffler and Frosch, relative to the etiology of foot-and-mouth disease of cattle. These observers had failed to demonstrate the specific organism in the lymph drawn from the infected cows. Nevertheless, experiments showed that this lymph was infectious, and that cows when inoculated with it invariably developed the disease. The inoculations were successful even after the lymph had been passed through a porcelain filter proved by experiment to be capable of filtering out the known varieties of bacteria. The very small dose required to produce this result proved that the infection was not due to a soluble constituent, but to an agent capable of self-multiplication. The smallest hitherto known bacterium was the influenza bacillus, and Professor Jena had calculated that a bacillus much smaller than this one would be beyond the power of our microscopes to detect. The importance of the observations was in showing the present limitation of microscopic investigations and the possibilities of future research in this field.

Recently several additions had been made to the list of specific therapeutic agents, and there was good reason for believing that further discoveries in this direction would follow as a result of investigations now being conducted in pathological laboratories in various parts of the world. Among the more important recent discoveries in this department of scientific medicine were mentioned the use of thyroid extract for the cure of myxœdema, and of the antitoxin of diphtheria. The discovery of the diphtheria antitoxin promised to be as important for therapeutics as the discovery of the anthrax bacillus was for etiology, and would no doubt henceforth be regarded as one of the most notable achievements of the century. While the practical results of this discovery had been notable in the case of diphtheria, some success had been attained in the specific treatment of tetanus, streptococcus in-

fection, pneumonia, and even in tuberculosis. A recent discovery, of considerable importance from several points of view, was the so-called Widal reaction. The curative action of thyroid extract in myxœdema was well established and some success appeared to have been attained in the treatment of Addison's disease by an extract from the suprarenal bodies. The active substance in the thyroid had been called iodothyrin. According to Professor Chittenden, this substance was a non-proteid cleavage product of a more complex body naturally present in the gland and characterized by containing both iodine and phosphorus. He considered it pretty thoroughly established that iodothyrin "possessed all the peculiarities associated with thyroid therapy."

The author next directed attention to prophylaxis, saying that here the progress of medical science had been even more prolific in practical results. Where thousands had been saved by the timely administration of suitable medicines, or by a skilfully performed operation on the part of the surgeon, tens of thousands had been rescued by preventive medicine. Preventive medicine was to-day established upon a strictly scientific foundation. The mortality from tuberculosis was constantly diminishing in our large cities, and the complete destruction of the infectious sputa of those suffering from pulmonary tuberculosis would no doubt go a long way toward the extermination of this fatal disease.

In conclusion Dr. Sternberg said that he thought enough had been presented to show that the medical profession as represented by this association was not made up of "old-school doctors" and that medicine was not behind other branches of science in establishing itself on a sound basis of facts demonstrated by observation and experiment with instruments of precision. It was evident that there was no room for creeds and pathies in medicine, any more than in astronomy, geology, or botany. Every man was entitled to his own opinions upon any settled problem, but if he entertained an opinion in conflict with ascertained facts he simply showed his ignorance. There was no restriction placed upon any physician who had graduated from a regular school as to the mode of treatment he should pursue in a given case. If he saw fit to prescribe a bread pill, or a one-hundredth trituration of carbo vegetabilis, there was no rule preventing him from doing so; but if the patient should die of diphtheria because of his failure to administer the proper remedy, or if he recklessly infected a wound with dirty fingers or instruments, or if he transferred pathogenic streptococci from a case of phlegmonous erysipelas to the interior of the uterus of a puerperal woman, it would appear that the courts should have something to say as to his fitness to practise medicine. There was, however, nothing in the code of ethics which would prevent him from associating with reputable practitioners of medicine; but, no matter where or when he obtained his medical degree, such a man could scarcely be said to belong to the profession of scientific medicine. We must not fail to recognize, however, that the progress of knowledge had been so rapid, that it was impossible for a busy practitioner to keep pace with it, and that even the requirement now generally adopted by our leading medical schools, of a four years' course of study, was inadequate for the attainment of such a degree of professional knowledge and practical skill in diagnosis and therapeutics as was desirable for one who intended to practise scientific medicine.

At the conclusion of the reading of the address, the association directed that a telegram be sent to Dr. Sternberg expressing its regret that circumstances national in character prevented his being present at the meeting in Denver, and thanking him for his very able address.

Report of the Rush Monument Committee.—Dr. A. L. Gihon, on behalf of this committee, reported that in spite of the fact that, at the last meeting of the association, held in Philadelphia, it had been decided that $100,000 should be raised for the erection of a fitting monument to America's great patriot physician, he had so far received only $162, or one-sixth of one per cent. of the amount pledged. This sum, together with the interest accruing on what was already on hand, had made the total increment $312, and the total amount of the fund $4,424.44. Colorado and New York then contributed $2,000 each to the fund. Pennsylvania signified its willingness to contribute $2,000 when the contract for the monument had been made; Maine added $100; Ohio, $336; California, $110 and $1,000 more at the time of commencing the actual work of erecting the monument; and Indiana reported about $500 already collected, but desired to do still better before reporting finally. These additions, counting those given both conditionally and unconditionally, bring the total sum to $12,460.44.

Treasurer's Report.—This report showed the receipts for 1897 to have been $32,200, and the balance on hand $14,092.85. In the year ending January 1, 1898, 1,500 members were added to the roll of the association.

Second Day—Wednesday, June 8th.

Dr. T. J. Hoppeloe, of Tennessee, presided.

Meetings of the Sections.—A resolution was adopted directing that the sections should not hold sessions during the hours set apart for the general sessions, and also making the hour for beginning of the general session 10 A.M. on the first day, and 11 A.M. on the succeeding days of the meeting of the association.

An Essential of the Art of Medicine.—Dr. J. H. Musser, of Philadelphia, then delivered the annual address on medicine. The closing years of the eighteenth century and the early years of the nineteenth century, he said, marked an epoch in medicine as transcendent for its welfare as the events of the past decades bespeak for the glory of the medicine of the future. The state of medicine in the eighteenth century was described as the result of deductive methods of reason, made possible because of the lack of instruments of precision. Elaborate classification of disease and refinements of symptomatology which served only to amuse and appall were the result. The sway of the imagination and the rule of theory were all-powerful. Speculative modes of treatment grew out of the specious pathology. These modes of treatment were referred to. Venesection, polypharmacy, and stimulation were followed by expectant treatment and nihilismus. The limitations of the inquiry in diagnosis were outlined. Diagnosis was an intuition and an art. Cullen said theory could control observation. But medicine as a science was no higher and no lower than were cognate departments of knowledge. The development of other sciences was also outlined. Science was not applied to industrial arts at this time, and so they were carried on by rule-of-thumb methods. Medicine had ceased to be deductive: its practice began to be scientific. Medicine had now grown to be a science—a department of the science of biology. Its history was the history of the application of scientific habits of thought to experiment, observation, and analysis. Medicine had grown to a science by the labors of physicians who were naturalists. The influence of inductive reason on other sciences was elaborated and its effect on theology, history, and sociology stated. Clinical medicine, as a science, embraced diagnosis and therapeutics. Methods of diagnosis of the present day required a scien-

tific habit of mind and skill in the use of instruments of precision. The scope and positivism of diagnosis were shown, as fifteen diseases could now be recognized positively, without any possibility of error. Diagnosis had grown to be scientific, precise, and positive. Error in method led to error in diagnosis. Therapeutics had grown to a science by the influence of various forces, all the outcome of the mode of thought of the naturalist. The science of statistics showed the fallacy of determining the value of a drug from a small number of cases. Analysis of 12,000 prescriptions showed that various drugs were called for about 31,000 times; preparations of nux vomica, iron, opium, mineral acids, cinchona and its salts, mercury, ipecac, bismuth, belladonna, arsenic, squills, hyoscyamus, and digitalis were called for in one-third of the total, or, if external remedies and excipients were excluded, in one-half. Scepticism arose because too much was claimed. The more incurable the disease the greater the number of drugs claimed to cure it. The more virtues a drug was said to have, the less its probable value. Polypharmacy had been assaulted in the past, but still held sway. The treatment of diphtheria by antitoxin was the only scientifically established mode of therapeusis. Drugs had no doubt an action in health and disease. Their use might be of advantage, but usually they were not necessary. We need not be sceptical about the power of the drug, but about its necessity. If robbed of the power of mental expectancy, drugs were not given. Such expectancy and hypnotism, for therapeutic purposes, could be secured by an honest examination of the patient. The "lie" was not required in medicine any more than in religion, as Zola had pointed out. Application of science to industrial art at the present time showed that in every department scientific methods were necessary. Brewing, iron making, leather making, were no longer an art—they were a science. Art had gone; science held sway. The large amounts of capital involved and great competition had forced out the element of chance as in art and instituted the element of certainty that was approached in science. As the science of medicine was essential to the art of healing, we must educate students to a scientific habit of thought. The truths of medical science and their practical application were cosmopolitan. Law was estimated by political barriers, religion by race and mental development; the promulgation of truths in medicine or the establishment of a method of its art affected for good the entire universe—not only man, but all animal creation. The labors of Mitchell in Philadelphia on snake poisoning touched the welfare of the entire population of India; the result of Lister's research was as valuable in China as in England; the words of Koch were as powerful in Japan as in Berlin. What greater reward was there than to be a humble fellow-worker in a field so broad, and what higher inspiration than the stimulus attending such labors? Let us then not be impatient. The adamantine position secured to the labors of Lister and Koch and Pasteur; the advanced state of preventive medicine at this day; the scientific method of the treatment of disease, as seen in that of diphtheria; the vistas that were opening with the advent of organo-therapy showed the dawn of a new science of medicine. Unfortunately we were to witness the dawn only; as to what the high noon of medicine would show, we only had the whisperings.

Officers.—The following were reported favorably by the nominating committee: *President*, Joseph M. Matthews, of Louisville; *First Vice-President*, W. W. Keen, of Philadelphia; *Second Vice-President*, J. W. Graham, of Denver; *Third Vice-President*, H. A. West, of Texas; *Fourth Vice-President*, J. E. Minney, of Topeka; *Treasurer*, Henry P. Newman, of Chicago; *Librarian*, George W. Webster, of Chicago; *Chairman of Committee of Arrangements*, Sterling Loving, of Columbus, Ohio.

Place of meeting, Columbus, Ohio.

(*To be Continued.*)

AMERICAN GYNÆCOLOGICAL SOCIETY.

Twenty-Third Annual Meeting, Held in Boston, May 24, 25, and 26, 1898.

PAUL F. MUNDÉ, M.D., PRESIDENT.

(*Concluded from page 836.*)

Third Day—Thursday, May 26th.

Patency of the Stump after Salpingectomy.—DR. J. WESLEY BOVÉE, of Washington, D. C., read this paper. He said that he had taken a special interest in this subject since 1892, and had found in five specimens from cases of salpingectomy that the stumps were still pervious. So far as he knew, only three well authenticated cases had previously been reported. The ligatures might become infected and slip in course of time, or "mass" ligatures might slip off after closure of the abdomen. He suggested that these stumps might be successfully occluded by cutting out the Fallopian tube by a wedge-shaped incision into the uterine wall at the tubo-uterine junction. If the muscle was approximated over it and well sutured, the occlusion would be complete. Care must be taken in the ligation of the uterine artery in this situation, and also not to pass the sutures through the mucosa.

DR. H. A. KELLY said that in practice the ovary was constantly sacrificed for some technical reason only. It had been his practice to free a cirrhotic ovary from adhesions and leave it, and the results had been most gratifying.

DR. W. GILL WYLIE said that he had not found many cases of uterine fibroids in which it had seemed to him such conservative operations as myomectomy were advisable.

DR. J. TABER JOHNSON, of Washington, D. C., said that he had practised Dr. Bovée's method of occluding the Fallopian tube, and had found it a useful procedure to prevent the outward spread of septic matter.

DR. MANN said he believed thoroughly in this conservative surgery, and had been pleased with its effect both on the general health and upon the occurrence of conception.

Discussion: The Surgical Treatment of Sterility; How Far is it Justifiable or Expedient?—DR. MATTHEW D. MANN, of Buffalo, opened this discussion. He said that deformity of the cervix and stenosis should be treated by forcible dilatation and packing with iodoform gauze, the uterus and cervical canal being curetted if there were sufficient indications. Endometritis could be cured by forcible dilatation and curettage and a sufficiently prolonged packing with iodoform gauze or gauze soaked in a ten-per-cent. solution of ichthyol in glycerin.

DR. W. GILL WYLIE was sceptical about the part played by mechanical conditions alone in producing sterility, believing that the chief cause was defective development of the genital organs and consequent endometritis. Much could be accomplished by the insertion of his hard-rubber cervical drainage, together with the use of an Albert Smith pessary.

Removal by Abdominal Incision of the Remains of an Extra-Uterine Fœtation of Fourteen Years' Duration.—DR. ANDREW F. CURRIER, of New York, reported such a case, and said it was interesting to note how quickly sepsis occurred after the thin dividing layer of new tissue had been broken.

Removal of Hairpins from the Bladder in Women.—Dr. Currier also read a paper on this subject. After reviewing the literature and citing many curious cases, he said that the vaginal incision was his preference in the effort at removal of the hairpin. In long-standing cases the bladder should be opened to secure drainage and to remove calculi, if any were present.

Dr. Mann said that he had followed one case of extra-uterine fœtation for eight years, during which time the woman had had three children.

Dr. Bovée also reported a case of eight years' duration presenting some very unusual features.

A Case of Endothelioma Lymphangiomatodes of the Cervix Uteri.—Dr. Hunter Robb, of Cleveland, in reporting this case, said that the condition must be very rare or quite generally overlooked, as he had been unable to find any other cases on record. He described the microscopical appearances of sections of the neoplasm, and stated that clinically it had presented the appearance of an ordinary cylindrical-cell carcinoma.

Postoperative Saline Infusions.—Dr. Eugene Boise, of Grand Rapids, read this paper. He said that the five post-operative conditions endangering life were hemorrhage, shock, sepsis, uræmia, and intestinal obstruction; and in all of these the intravenous use of a saline solution was indicated, and would be found a life-saving measure. The intravenous route should be given the preference: (1) because it was practically no more dangerous than the other methods; (2) because it supplied the fluid most quickly to the system; (3) because it brought heat to the cardiac and arterial ganglia; and (4) because the stimulating action of the saline solution on the heart muscle was more immediate and more marked. The solution should always be used at a temperature of about 116° F.

Dr. Robb said that he used saline solution not only in the veins, but in the cellular tissue, and left it in the abdominal cavity after abdominal section.

Dr. Bovée said that with intravenous injections there was danger of overdistention of the circulatory organs and resulting paralysis, a risk which did not attend the subcutaneous method.

Dr. S. C. Gordon remarked that in conjunction with the use of saline solution it would be found that most extraordinary doses of strychnine could be used with great advantage.

Dr. Chadwick said that if the salt solution was introduced into the cellular tissue it became serum by the time it reached the general circulation—an obvious advantage over the intravenous injections.

Dr. William Jones, of Rochester, remarked that the work of Dawbarn seemed to show certain advantages from arterial injections.

Dr. Noble replied that he knew of at least one case in which gangrene of the extremity had resulted from the intra-arterial injection of saline solution.

Dr. Mann and Dr. Reynolds both spoke at length of the very great advantages of giving laparotomy patients large quantities of water to drink.

Streptococcic Infection in Childbirth and the Application of Serum Therapy.—Dr. Henry D. Fry, of Washington, D. C., presented a paper on this subject. He said that the diagnosis must rest on the clinical appearances and on bacteriological examination. As a result of a circular letter that he had sent out in order to ascertain the views of leaders in the profession regarding the value of serum therapy, he had received 46 replies, representing all shades of opinion. Of this number, 30 stated that the writers had had no experience with it, 14 reported favorably, and 5 unfavorably. A total of 83 cases was reported. Of these 83, the result was said to be "good" in 10, in 8 it was decidedly negative, and in 65 it was considered to have been of doubtful utility. These wide differences in opinion were probably explained by the imperfections of bacteriology at the present time. The initial dose of Marmorek's serum should be five or ten cubic centimetres, repeated daily. Relapses were common. In the cases in which the fatal result had been attributed to the serum, the symptoms had been collapse, rapid pulse, low temperature, and uncontrollable vomiting. He had collected a total of one hundred and nineteen cases, in seventy-seven of which, or about thirty-five per cent., recovery ensued.

Dr. J. W. Williams said that the reports from Pinard's clinic show that the prophylactic value of the serum was much less than claimed by Marmorek. One great source of error was the extremely variable clinical history of cases of streptococcus infection. At present he was extremely sceptical regarding the value of the treatment.

Dr. Reynolds said that in only one case of pure streptococcus infection had he seen recovery, and that patient had been curetted and subjected to treatment within an hour after the first rise of temperature and before the initial chill. If used freely, Marmorek's serum seemed to him a dangerous remedy.

Dr. Richard C. Norris, of Philadelphia, said that success in this treatment would come only when the bacteriologists were able to separate the different species and knew more about their natural history. If it was essential to have a bacteriological diagnosis, the value of the treatment in the hands of the general practitioner would be almost nothing.

Committee on Treatment by Antistreptococcus Serum.—The following committee was appointed to study the subject and report at the next annual meeting: Drs. H. D. Fry, J. W. Williams, E. Reynolds, and W. R. Pryor.

Dr. J. Taber Johnson, of Washington, D. C., was elected president of the society for the ensuing year.

ILLINOIS STATE MEDICAL SOCIETY.

Forty-Eighth Annual Meeting, Held at Galesburg, May 17, 18, and 19, 1898.

SECTION ON THE PRACTICE OF MEDICINE.

Malnutrition in Infants.—Dr. Frank P. Norbury said that nearly all cases of malnutrition were the result of gastro-intestinal disorders incidental to errors of diet. The treatment had two main objects in view, namely, to arrest wasting and to repair the damage done by the disease.

Infantile Scurvy.—Dr. Isaac A. Abt, of Chicago, said the earliest cases reported were erroneously described as cases of acute rachitis. The diagnosis in well-marked cases was not difficult. With reference to the differential diagnosis, congenital syphilis could be excluded by the history of the case, by the absence of syphilitic lesions on the skin and mucous membranes. In congenital syphilis there was never a history of severe pain. The pseudo-paralyses of syphilis were limited nearly always to the upper extremities: the swelling was never so intense as in cases of infantile scurvy, and was more prone to occur on the epiphyses than on the diaphyses. Separation of the epiphyses occurred in both diseases. A spinal paralysis might be thought of, although in such cases there was neither tenderness nor swelling. As to the treatment, brilliant results were obtained by providing a suitable diet, such as fresh cow's milk, or mother's milk, beef juice, orange or lemon juice, fresh vegetables, mashed potatoes, etc. The child should be placed under the best possible hygienic conditions: good ventilation should be provided for, and under favorable conditions of weather the child should be out of doors. Cod-liver oil by mouth or inunction was especially indi-

cated, when the child recovered from the scorbutic condition, to aid nutrition.

Diagnosis of Pleurisy with Effusion, with Especial Reference to Misleading Physical Signs.—This was the title of a paper by Dr. James B. Herrick, of Chicago, in which he first spoke of the importance of careful inquiry into the history of the case, and dwelt upon the fact that in some cases there might be an absence of pain and a cough, the clinical symptoms resembling those of a mild typhoid. In other cases the severity of the symptoms and the explosive onset would remind one of pneumonia. Among the signs that might mislead, he mentioned the occasional inspiratory recession of interspaces and the decubitus upon the sound side. He regarded vocal fremitus as of relatively inferior value, because of the many conditions that might cause it to be retained, even though there was a large amount of fluid. With small amounts of fluid a careful examination should be made in the posterior axillary line just external to the angle of the scapula, for signs were often present here though absent elsewhere. Even with quite large effusions there was a triangular area of relative dulness above the line of flatness posteriorly. Here could frequently be heard quite pronounced bronchial breathing and well-transmitted voice sounds. The crucial test was exploratory puncture, but negative results should not lead to the exclusion of pleurisy with effusion until circumscribed collections of fluid had been ruled out. Palpatory puncture, to use Rosenbach's expression, might be of great value in the diagnosis of underlying tumor, and might be the only means of determining the presence of the thick fibrous plates that sometimes lined the chest.

Significance of Certain Signs and Symptoms in Heart Insufficiency.—Dr. B. W. Sippy, of Chicago, read a paper with this title. He dwelt upon the anatomy of the heart, considering briefly insufficiency of the left and right hearts respectively, and then at length total heart insufficiency. He spoke of how the heart might become crippled in various ways. The two sections of the heart sustained each other in their efforts to carry on the circulation. The passive congestion of the pulmonic vessels occasioned by the insufficient power of the left heart might be overcome by the right heart. As long as the right heart remained competent, the left heart was compensated, the systemic arteries were filled more or less adequately, and the systemic veins were emptied normally.

The Smegma Bacillus.—Dr. J. L. Miller, of Chicago, read a paper with the following conclusions: (1) Over the entire surface of the body and exposed mucous membrane, and especially on the genitals, bacilli were found which resembled the bacillus of tuberculosis. (2) From the external genitalia they frequently gained access to the urine, and might be a source of error in the examination of urine for tubercle bacilli. (3) The smegma bacillus presented wide variations in size and form, thus rendering morphological differentiation frequently impossible. (4) While most smegma bacilli were more readily decolorized by any of the solutions commonly employed, occasionally they possessed equal or even greater resistance than the bacillus of tuberculosis. (5) Methods of decolorization in which acids alone were employed were fallacious; acid alcohol or dilute alcohols, unless long continued, were equally unreliable. Better, but not free from error, was the use of absolute alcohol for at least five minutes. In ammoniacal urine, however, such prolonged use of alcohol might also remove the stain from the tubercle bacillus. (6) Attempts to remove the fat or fatty acids from the bacilli by ether, chloroform, or other solvents failed to furnish us with a means of differentiation. (7) We must rely on means of excluding the smegma bacillus from the urine. By cleansing the external meatus and withdrawing the urine with a catheter, we could exclude this possible source of error.

Treatment of Neurasthenia.—Dr. Hugh T. Patrick, of Chicago, said that for the production of neurasthenia, as for the production of nearly all disease, two conditions were essential: first, a noxious agent; and second, a relative vulnerability of the organism or of some part of it. The ratio of these two factors might be called the etiological index. In some cases the first named factor, *i.e.*, the extraneous agent, would be very prominent, the organism itself being considered as normal. In others the exciting agent would be exceedingly slight, the inherent susceptibility or instability of the patient being an essential causal condition. Each of these two classes of neurasthenia would naturally need radically different treatment. In the first, those in which the patient once possessed a normal nervous system, which had simply been overstrained and overdrained, the important features of treatment were rest and recuperation. In the second class of cases, those in which an unstable nervous system of the individual was at fault, the treatment was essentially mental, and the best way of administering it was by systematic education. For such patients isolation and an initial period of rest might be very useful, but for the further treatment gradually increasing physical exercise and mental occupation were necessary.

Observations on the Blood of Tuberculous Patients.—Dr. George W. Johnson, of Chicago, contributed a paper with this title. These observations were made on patients in the advanced stage of the disease, with cavities and at times hæmoptysis. The observations were made before meals, and no attacks of hæmoptysis occurred between the first and second examinations. Of the thirty-three cases, twenty-five were found to have leucocytosis; *i.e.*, the white cells ranged above seventy-five hundred per cubic millimetre. The twenty-five having leucocytosis also had cavities. Nine of the thirty-three showed a red-cell count of 5,000,000 or above, which, according to Cabot, was a normal basis. The remaining twenty-four showed a red-cell count in many instances far below 5,000,000, and in no case was the hæmoglobin up to normal. In only one case did it reach seventy-five per cent.

Advances in the Domain of Preventive Medicine.—Dr. J. M. G. Carter, of Waukegan, delivered the presidential address. The chief object of the address was to show that a responsibility existed in the field of preventive medicine, and that this responsibility rested upon the State. The speaker presented the following propositions as expressing his ideas of what was necessary: (1) The State or municipality should give men who could not secure other work some kind of employment which would afford them a living. (2) This might be done by introducing public improvements. (3) A minimum rate of wages should be paid, so that only those who could not find work elsewhere would seek such employment. (4) All able-bodied men without work, who had no visible means of support and who did not apply for such government employment, should be subject to draft for this labor. (5) The unfortunate and disabled poor should be cared for as wards of the State. (6) The State should see that the poor were properly or comfortably domiciled in houses provided with good ventilation, supplied with good water, and sufficiently warm. (7) Inspection of the homes of all the people should be conducted regularly and thoroughly, the object being to see that they were in good sanitary condition. (8) All meats, vegetables, fruits, dairy products, milk, and manufactured foods should be inspected as to their source, composition, and present condition. (9) Public baths should be established where the poor could have facilities for bathing free or at a nominal cost.

Intellectual Bacteriology.—In the absence of Dr. Nicholas Senn, of Chicago, who was to have delivered the address on surgery, Dr. John H. Finley delivered a humorous address. He referred to various kinds of germs, such as the micrococcus egotisticus—a germ which impelled one to look out for himself and get everything possible. The wool-gathering microbe often afflicted students, and brought about in them a revulsion to thoughts of labor. Another microbe was the bacillus bombasticus, and still another the micrococcus oratoricus. The spirillum Americanus abounded largely in the blood of such men as Admiral Dewey.

SECTION ON SURGERY.

Uræmia in Child Bearing.—Dr. Henry F. Lewis, of Chicago, read a paper on this subject. Uræmia was defined as a condition of the system resulting from the retention in the blood of toxic products which should normally be eliminated. Eclampsia was a frequent sequel of uræmic phenomena occurring in the course of child bearing. The author, in discussing the subject, included the eclampsias, neuroses, psychoses, and other symptoms due to the toxæmia accompanying or following pregnancy. He also included the albuminuria of pregnancy.

Operative Treatment of Carcinoma Uteri.—Dr. Franklin H. Martin, of Chicago, followed with a paper on this subject. He said that a microscopical examination of the tissue of the three portions of the uterus should be made whenever one of the well-known classical symptoms of carcinoma appeared. Carcinoma of the vaginal portion of the cervix should be treated by vaginal hysterectomy, the upper portion of the vagina and as much of the base of the broad ligament as it was possible to include being removed and the ureters being pushed well to the side of the pelvis. Carcinoma of the body of the cervix should be treated by vagino-abdominal hysterectomy, with thorough removal of the broad ligament and the deep iliac glands. Carcinoma of the body of the uterus should be treated by thorough removal of the uterus by vagina or abdomen, so as to include the tubes and ovaries. The iliac glands should be removed if involved. Neglected carcinoma should never be abandoned, but should be symptomatically relieved by curettage and cauterization, if the more radical procedure no longer seemed practicable, with the possible hope of permanent relief in a small percentage of cases.

Conservation of Tissue and Function in Pelvic Surgery.—Dr. Henry P. Newman, of Chicago, said that the object of his paper was to stimulate investigation along the line of greater conservatism of the genital health of women. This might be aided: (1) By a deeper study into the problems of cell nutrition and general metabolism, in order to determine the relative value of glandular and other structures, and the relation of the pelvic organs to the great systemic laws. (2) By seeking the habits and regimen of individual patients as to diet, dress, social and educational life, etc., for the causes of disease, remembering that these, if allowed to go uncorrected, might handicap the best efforts of medical science and effectually undo all that might be accomplished. (3) By giving to every definitely diseased structure the best opportunity to recover its function that science could devise, by prophylactic supervision of life and habits. By palliative treatment when it offered relief, and by prompt resort to surgical interference when it was called for in the interests of true conservatism.

Operations on the Anus.—Dr. Weller Van Hook, of Chicago, described a new device for facilitating operations about the anus. Starting from the proposition that existing technical methods failed to provide means of aseptic or even approximately aseptic operations, especially in view of Cohn's demonstration of the penetrability of fresh cautery eschars by pathogenic micro-organisms, he reasoned that we should seek means of operating upon hemorrhoids and other anal lesions by dissection and suture. The device, he said, consisted of a half-inch rubber drainage tube, perforated near one end, and drawn through a minute opening in a piece of medium-weight dentist's rubber-dam tissue, twelve inches square. It was essential to success that the bowels be prepared beforehand. The method recommended was: (1) laxatives thoroughly to evacuate the bowels, on one occasion only, four or five days before the operation; (2) daily colonic flushings thereafter; (3) after the laxatives had acted, one or two drachms of bismuth subnitrate daily in divided doses, to keep the colon empty. In operating upon hemorrhoids, the following technique was employed: The sphincters were stretched, the rectum was irrigated, and the tube with its covering was introduced by means of eight-inch forceps. To keep the umbrella-like device from slipping out and to keep the dam in contact with the rectal wall, some strips of gauze were pushed up into it, between the tube and the dam. The dam was then pushed aside; the tissues were washed again with antiseptics; then the hemorrhoids were excised and the wound was sutured. A piece of iodoform gauze saturated with compound tincture of benzoin was then inserted between the dam and the anal wall. The apparatus and dressing were left undisturbed for four or five days.

Treatment of Acute Abscess and Gangrene of the Lung.—Dr. A. E. Halstead, of Chicago, said it was only within the last few years that well-known surgical principles had been applied to intrathoracic suppurative conditions. The term abscess of the lung was employed in the paper to designate only acute suppurative inflammation, non-gangrenous, which had its seat within the lung tissue; therefore cavities filled with pus, formed either by a dilated bronchial tube or by destruction of lung tissue from tuberculous infection, were not considered. The causes of acute abscess of the lung were dwelt upon, the principal one being lobar pneumonia. The surgical treatment of lung abscess comprehended puncture of the abscess, aspiration, incision of the lung, and drainage. The author dwelt at length upon the technique of pneumotomy for abscess or gangrene of the lung.

Pathological Histology of Intestinal Union after the Use of the Bone Coupler.—Dr. Jacob Frank, of Chicago, read a paper with this title. From a microscopical study of the healing of intestinal wounds after the various suture methods and the employment of mechanical devices, he had arrived at the following conclusions: (1) No suture method insured an exact coaptation of the various layers. (2) In regard to the invagination suture method, he referred briefly to that of Harris, which he said would stand as a type for others. Union took place, but the different layers were not in juxtaposition and the lumen of the bowel was greatly encroached upon. (3) All suture methods left the subsequent lumen of the bowel more stenosed than did either the Murphy button or the author's coupler.

Plea for Early Operation for Lacerations of the Cervix Uteri.—Dr. Joseph B. Bacon, of Chicago, read a paper on this subject. After referring to the Emmet and Schröder operations for the repair of the cervix, he described a new adaptation of pathological facts, as recognized in the disease affecting non-striped muscles and fibrous tissues in other organs, and showed how like conditions might help to cause some of the serious results found in neglected cases of severe lacerations of the cervix. He claimed that the destructive changes found in both fibrous and muscular tissue of the cervix, and later in the body of the uterus, were

due to the persistent chronic inflammation, and that these changes could be avoided by an early operation. But if they were neglected, there was no limit to the destruction, and in time no operative procedure would more than relieve a part of the symptoms and could not remove the diseased tissue and cure the woman. He claimed that the same pathological laws that explained cicatricial strictures of the rectum, as advocated by Harrison Cripps, applied equally well to the cicatricial changes that were found in the cervix uteri, because there was a like anatomical make-up of the muscles, glands, and excessive fibrous tissue normally present in both—first, the tendency of fibrous tissue, subjected to chronic inflammation, to become both hypertrophied and contracted; second, the tendency of muscular fibre, when subjected to undue and persistent nerve irritation, to undergo fibroid degeneration with permanent atrophic contraction of its fibrous elements.

Officers.—The following officers were elected: *President*, T. J. Pitner, Jacksonville; *First Vice-President*, Harold N. Moyer, Chicago: *Second Vice-President*, J. T. McAnally, Carbondale; *Permanent Secretary*, Edmund W. Weis, Ottawa; *Assistant Secretary*, W. F. Grinstead, Cairo: *Treasurer*, George N. Kreider, Springfield.

The next meeting will be held in Cairo on the third Tuesday in May, 1899.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 23, 1898.

ARTHUR M. JACOBUS, M.D., PRESIDENT.

What We Find in Interval Appendicitis Specimens.—DR. ROBERT T. MORRIS discussed this topic. He said that he had found concretions in the lumen of the appendix in about twelve per cent. of his cases. He had excluded from this estimate cases in which soft fæcal matter was rolled up into a ball, but not hard enough to cause ulceration of the mucosa. It was impossible to draw a sharp line between these two classes of concretions. In about five per cent. of his interval cases he had found tuberculosis. Some had thought this percentage rather high, but further examination had proved to them that they had overlooked the tuberculous nature of the lesion in a number of their cases. The appendix, he said, began to degenerate shortly after birth, and the involution process was going on during the life of the individual. As a result, at the age of fifty very few appendices contained much mucosa or submucosa. This degenerative change was not observed in other parts of the body, and was due to the appendix being a rudimentary structure. Like other rudimentary structures, the appendix was quite liable to be affected by tuberculosis. Not infrequently the tuberculous inflammation extended to the peritoneum, or metastasis occurred to the lungs, giving rise to pulmonary tuberculosis. Tuberculosis of the appendix was much more apt to be overlooked than infection with the streptococcus, the staphylococcus, or the colon bacillus, because of its mild character and insidious development. In another class of interval cases the appendicitis was associated with an encapsulated abscess.

DR. JOHN F. ERDMANN said that he had recently had a case in which there were six enteroliths, none of them hard, and yet there were a number of points of ulceration. It seemed to him that prolapse of the appendix and the formation of a twist or kink were often the starting-point. He had met with concretions in the appendix in ten to fifteen per cent. of his interval cases, but this larger percentage was possibly due to the fact that a certain number of the softer concretions had been included in this count. He agreed with DR. MORRIS regarding the pathology, and particularly as to the occurrence of endarteritis obliterans.

DR. GEORGE M. EDEBOHLS referred to the cases which should be called chronic catarrhal rather than "interval" cases, because they could hardly be said to have an acute stage. These cases were diagnosticated by palpation. By this method it was found that the appendix was painful on pressure. In many of these cases the operation would show a hyperæmia in the neighborhood and on the surface of the appendix. There would also be found a hyperplasia of fat in the meso-appendix; which was quite characteristic, and which was the result of the increased blood supply to the inflamed appendix. The irregular thickenings in the wall of the appendix could readily be felt by the practised touch. These appendices contained coproliths, which were supposed to result from a "kink" in the appendix: but he had met with these so often when there was no constriction or twisting that he could not accept this theory of their causation. He attributed them to an uneven thickening of the wall, which allowed the coproliths to form behind it, and through interference with the normal muscular action they remained there. The danger from these coproliths was that they might be retained until they caused sufficient pressure to give rise to ulceration or inflammation.

DR. MORRIS, in closing the discussion, said that in four cases he had found ulceration of the mucosa as a result of the presence of entozoa. He accepted the explanation given by the last speaker of the formation of coproliths. He did not regard the cases that Dr. Edebohls had designated "chronic catarrhal appendicitis" as appendicitis. He frequently saw these cases, but did not operate upon them. The cases in which he operated were those in which a definite infective process had developed, marked by tension of the abdominal wall, tenderness at McBurney's point, and vomiting. He was willing to admit that there were circumstances in which it might be perfectly justifiable to operate in these chronic cases, but he had not made it a practice himself.

Clinical Contribution to Tubal Pregnancy.—DR. HERMAN J. BOLDT made the following report: Mrs. C. C——, thirty-three years of age, married nine years, had had one child eight years previously, after a normal labor. Her menstruation had been regular up to 1894. It then became irregular and the flow prolonged. She was subjected to a curettage by another physician, and in 1896 the speaker saw her for the first time. She was again curetted, and the scrapings revealed a hyperplastic endometritis. She was relieved of the dysmenorrhœa and irregular menstruation. On April 4, 1898, he had been again consulted, and was told that she had been perfectly well up to one week previously, when she began to bleed too freely. The color of the blood was dark, and it was slightly tenacious. She was positive that she had not gone a day beyond the regular time for her menstrual period, and she said that she had not suffered at all with menstruation. On examination, the uterus was found to be movable; it was not tender or enlarged. On the right side of the uterus there was slight tenderness to touch in the scar tissue left after an operation which he had done a year previously for the repair of lacerated cervix, and because of this tenderness no attempt was made to palpate the adnexa on this side with exactness. On the left side the tube and ovary were normal. It was therefore supposed that there was a return of the endometritis, and to relieve this a galvanic current of fifty milliamperes was applied for ten minutes, the intra-uterine electrode being the anode, and the cathode covering the whole hypogastrium. She returned for treatment on April 8th, and while waiting

was suddenly seized with pain in the abdomen, which caused her to faint. She had a small, rapid pulse, clammy perspiration, some nausea and vomiting, and appeared decidedly anæmic. Finding in the course of a few minutes that the anæmia was increasing and that the pulse was becoming smaller, the speaker made a diagnosis of internal hemorrhage. Half an hour later she was pulseless. On bimanual examination some pain was evinced on pressure on the lower part of the abdomen, despite the collapse. The right tube was felt to be slightly enlarged, but otherwise the result of this examination was the same as of that made at her first visit. The diagnosis was made of right tubal gestation, with rupture, and the patient was hurriedly taken to hospital. It became necessary to use large quantities of saline solution and to give oxygen in order to keep her alive. Meanwhile the extremities were bandaged and the abdomen was opened. The bleeding tube, which was not prolapsed and was non-adherent, was readily grasped and removed. The abdominal cavity must have contained about two quarts of blood. From the embryo found in the tube it was evident that the pregnancy had progressed to about the third or fourth week.

Successful Operation during Profound Shock.—Dr. Boldt said that he had reported this case in order to refute the idea that there were invariably present periodical attacks of pain in cases of tubal gestation. He had had two or three cases very similar in this respect. Another object in presenting the case was that he wished to retract a former statement, that he did not believe it possible to save life by operating while the patient was in profound shock. His reason for operating in this instance was that a very short time had elapsed since the occurrence of the rupture, and the patient's condition was growing rapidly worse.

Electrical Treatment Utterly Unreliable.—The embryo was not killed, or the rupture would not have taken place, so that this case served to emphasize once more the utter unreliability of the electric current in the treatment of ectopic gestation.

Tubal Pregnancy Twice in the Same Patient.—Dr. Boldt also reported this case. He said that in March, 1896, he had operated upon a woman for ruptured tubal pregnancy, and on September 15, 1897, he had again operated upon her for the same condition, conception having occurred about fifteen months after the first operation. At the time of the first operation he had noted that the unimpregnated tube was in a condition of mild catarrhal salpingitis, but had not considered it sufficiently serious to demand removal of the tube. This case showed that mild inflammation of the tubes predisposed to this deplorable form of gestation. The second time, after having confirmed the diagnosis by vaginal cœliotomy, he had done a hystero-salpingo-oöphorectomy.

Treatment.—He advised the vaginal route when the tube had not ruptured or when one tube had been previously removed. When rupture had taken place he earnestly advised the abdominal route, unless there was only one appendage in the pelvis, as in the case just reported. He said that he had operated seventy-three times for extra-uterine pregnancy under various circumstances, and it was his conviction that vaginal cœliotomy after the rupture of a tubal gestation made the manipulations of the surgeon too uncertain and did not provide sufficient drainage. To wash out the cavity from below was very tedious, and did not easily dislodge the blood clots. If no signs of suppuration presented themselves in cases of ruptured hæmatocele and no pressure symptoms were produced, the patient might be kept at rest, with ice over the abdomen. If, however, there was any indication that absorption was not taking place satisfactorily, the surgeon should not hesitate to open the abdomen and cleanse the cavity, packing it with nosophen gauze. The use of drainage tubes in such cases and the making of a small puncture into the blood tumor should be condemned. All tubal pregnancies should be treated as malignant neoplasms; they should be operated upon as soon as the diagnosis was made.

Double Extra-Uterine Pregnancy and Double Rupture.—Dr. Ralph Waldo said that he also favored abdominal section in preference to the vaginal route in operating in cases of extra-uterine pregnancy after rupture had taken place. He could not agree with the reader of the paper that the diagnosis was in many instances as easy as he seemed to think. He cited a case, seen last winter, in which the abdominal cavity had been opened, the patient being in collapse at the time. The interesting feature was that there was an extra-uterine pregnancy on each side, and both tumors had ruptured.

Rupture of Sac during Etherization.—Dr. C. B. Kelsey said that within the past year he had had a rather curious experience in two cases of extra-uterine pregnancy, in that rupture had occurred during the administration of ether. One of the patients was a hospital case, and subsequent investigation proved that there had evidently been a slight preliminary rupture while she was on her way to the hospital the day previous. At the operation, a fœtus of about six months was found floating in the abdominal cavity. In the other case the patient had been in excellent condition before the abdomen was opened, and there was no sign of collapse. Just before the operation was begun the anæsthetizer called attention to the fact that she was taking ether very badly and was nearly in collapse. On opening the abdomen and coming down to the peritoneum, he found what he at first took to be a piece of adherent intestine. This appearance was due to the fact that the peritoneum was dark with blood. After he discovered his mistake, the abdomen was opened and the clots were turned out. The woman appeared to be almost dead at the time, so no attempt was made to clean out the abdomen, but the cavity was packed with gauze. Provisional sutures only were inserted. She showed scarcely any signs of improvement for about twelve hours, but after that made a smooth recovery.

A Life-Saving Measure.—Dr. R. T. Morris said, regarding these cases seen when *in extremis* by the surgeon, that if the attending physician would make it a rule to use a fine pipette and the douche bag, and would give a liberal infusion of saline solution before the arrival of the surgeon, it would simplify matters a good deal and would undoubtedly save many lives.

Dr. Joseph E. Brettauer said that he was more careful now than formerly about operating until the patient had rallied from the first shock, and believed his results were better for so doing; but this did not mean, of course, that one should delay in the face of active bleeding. Regarding the diagnosis of tubal pregnancy before rupture, he said that the difficulty of making this increased rapidly with the time it was seen prior to rupture.

Dr. J. J. E. Maher referred to three interesting cases, the specimens from which were in his possession. They illustrated the difficulties of diagnosis, particularly as regarded the occurrence of abdominal hemorrhage and of rupture.

Very Early Rupture.—Dr. Theodore K. Tuthill said that he had been called upon as coroner to investigate three cases, all of which were very much alike. The autopsy showed that the right tube was ruptured three-fourths of an inch from its junction with the uterus. In each case the examination was made by Dr. George P. Biggs, and the presence of the chorionic villi had been demonstrated. In each instance the

mass could not have been larger than a small Lima bean, so early had the rupture taken place.

Dr. M. B. Feeny said that in every case he had seen the rupture had occurred while the mass was exceedingly small.

Dr. Boldt denied that he had said that the diagnosis of extra-uterine pregnancy was an easy matter; he had referred only to the diagnosis in typical cases. It was impossible to map out a distinct symptomatology prior to the occurrence of rupture. Intraperitoneal hemorrhage, of course, might occur irrespective of the existence of extra-uterine pregnancy.

Appointments to the City Hospitals.—Dr. N. E. Brill, on behalf of the committee on hospitals, stated that an effort had been made to get the present commissioners to right the wrong done two or three years ago, when the staffs of the various city hospitals had been unceremoniously turned out. The committee held consultations with the committees from the New York County Medical Association and from the New York Medical League, and it was decided to ask Commissioner Keller to give the joint committee an audience. This request was granted, and subsequently the views of the committee were presented in writing. It protested against the injustice done to the medical profession at large by reason of the manner in which the nominations and confirmations had been made, by placing them in the hands of those controlling the four divisions of Bellevue Hospital, and suggested that two-thirds of the vacancies occurring in the city hospitals should be filled from members of the profession at large, not connected with any teaching body, and that as the vacancies occurred this fact should be announced in some of the leading medical journals. Commissioner Keller, after giving the matter full consideration, promised that in the future he would pay no attention to the medical colleges in the matter of appointments, his object being to get the very best men to fill the vacancies, irrespective of their college connections, and that whenever vacancies occurred he would announce the fact in the Medical Record and in the *New York Medical Journal*. He promised to abrogate the rule of 1882, by virtue of which the colleges were placed in control of the hospitals.

Methylene Blue in the Malaria of Children.—Dr. N. Marini (*L'Indépendance Médicale*, August 18, 1897) sums up his experience as follows: 1. Methylene blue possesses a well-marked specific effect in malaria, particularly in children. 2. It is agreeable to take and is harmless. 3. It also works in small doses. Marini gives 0.25 in 40 gms. of water and a little syrup, six to eight hours before the anticipated attack. 4. It may entirely replace quinine, a fact which is of the greatest importance, because it does not possess the disagreeable by-effects of quinine. In adults it also appears to work very well.

Contraindications for the Bicycle.—1. In amenorrhœa connected with pulmonary phthisis, cancerous affections, diabetes, organic diseases of the heart, and diseases of the kidneys, such as albuminuria. 2. In metrorrhagia or excessive menstruation. 3. In inflammation of the uterus and its adnexa, acute metritis, chronic painful metritis, hemorrhagic endometritis, purulent endometritis, leucorrhœa connected with an inflammatory condition of the intra-uterine mucous membrane, inflammation of the adnexa, salpingitis, oöphoritis, salpingo-oöphoritis, perimetritis, pelvic cellulitis, and pelvic abscesses. 4. In pelvic hæmatocele and fibrous tumors during the hemorrhagic stage. 5. In inflammation of the vulva or vagina before complete recovery.—Fanquez, *Journal des Connaissances Médicales*, August 26, 1897.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

INTRAPLEURAL TENSION — MOVABLE LIVER — CARCINOMA OF FALLOPIAN TUBES—LIQUID HYDROGEN AND HELIUM—LONDON UNIVERSITY—THE NEW B. P. —THE LATE DEPUTY SURGEON-GENERAL PARTRIDGE.

London, May 20, 1898.

Intrapleural tension was the subject of discussion at the last meeting of the Medico-Chirurgical Society. It was introduced in an elaborate paper by Dr. S. West, who stated that it was written from a clinical standpoint. This standpoint, however, did not prevent the introduction of many statements which seem to have lent an indirect clinical aspect. Intrapleural tension is said to be for practical purposes equal in amount to the elastic contraction of the chest but opposite in direction. The respiratory movements of course give rise to constant variations of this tension, expressed by an oscillation of two inches of water. Normally the tension is negative both in inspiration and in expiration. The negative value is increased in forced inspiration, but in forced expiration it may become positive. Such positive pressure, while both layers of the pleura are in apposition, is supported by the chest walls and does not affect the pleura except theoretically. Under pathological conditions the effects produced by the pressure vary according as the pleura is occupied by incompressible fluid or by compressible air. Dr. West put forward arguments to show that lung contractility was not merely elasticity but partly muscular, and he seemed to think there may be such a condition as pulmonary tone. The methods of estimating intrapleural pressure were pointed out, and the results of many observations on the pressures in various conditions were stated in the paper.

Dr. Lazarus Barlow said that as to pulmonary tone histological work convinced him that there is no muscular tissue in human lung tissue apart from that in the vessel walls. Cohnheim found it impossible to increase the pressure of air in the pleura of dogs; the air was too quickly absorbed. From this it would seem that a pathological state of the pleural surfaces is probably the cause of the positive pressure noticed in some cases of pneumothorax. Dr. West had said that the lymphatics were the channel for absorption, but Starling's researches show that it takes place chiefly through the veins.

Dr. Norman Moore thought the paper valuable for directing attention to the mode of entrance and exit of air. It used to be thought that serous effusions after a time become purulent. Now, of course, the intervention of microbes is recognized. He thought more empyemata are tuberculous in origin than is generally recognized.

Dr. Calvert said his laboratory experiments showed that in effusion the lung contracted as a whole. It is not absolutely true, as it is often said, that a positive pressure in the pleura cannot be produced until the lung is completely collapsed. The pressure may vary in different parts of the cavity. In the cases in which the pressure is negative at the paracentesis and later on positive, possibly during the interval coughing has torn through adhesions limiting the expansion of the lung. When the lung expands the pressure will be affected.

Dr. Rose Bradford agreed with the last explanation of positive pressure. From a clinical point of view a localized pleural effusion resembles an empyema. If the effusion is localized the lung will not collapse,

but with a free effusion it would, and so the pressure be increased.

Mr. Pearce Gould had found marked positive pressure in a case of traumatic pneumothorax, when there was no evidence of liquid in the pleuræ.

Dr. West in his reply held that the rôle of the lymphatics in leading to absorption cannot be ignored, and as to complementary hypertrophy it is not *a priori* improbable, for it occurs in the kidney.

At the Medical Society Dr. Macnaughton Jones related a case of hæmatemesis recurring at intervals in a married woman, aged thirty-six years, mother of seven children. The abdomen was resonant except in the right hypochondriac, lumbar, and inguinal regions. Here there was a large movable mass, which felt like an enlarged spleen. Neither renal nor hepatic line of demarcation could be felt. Abdominal exploration by the incision for nephrectomy exposed the edge of the liver, the right lobe of which was in the iliac fossa. It was ascertained that both kidneys were normal. The liver rested on the right, was rather darker than normal, its surface somewhat injected. The stomach was then raised on to the wall and carefully examined, but nothing abnormal found. The wound was closed and the patient made an uninterrupted recovery, and is now reported to be better than she has been for years. The operation was done on September 17, 1897. Dr. Jones made a few remarks on the literature of movable liver, or hepatoptosis, as it has been called. Those interested in that or other points should refer to the "Twentieth Century Practice of Medicine," to which he acknowledges his indebtedness for much information.

Mr. Battle mentioned that he had now a patient presenting similar symptoms. This was a woman, aged forty-five years, with severe pains on the right side. The abdomen was pendulous and lax, and a mass thought to be the liver was felt lying transversely just below the umbilicus. This mass sank down to the level of Poupart's ligament when the patient stood upright. He applied a flannel bandage, which afforded relief to her symptoms, and she had since also greatly improved in her appearance.

Dr. Sansom remarked that the association of hæmatemesis with hepatoptosis is very unusual, and with so great displacement of the liver as that recorded in some cases; it is strange that ascites has not more frequently been present.

Primary carcinoma of the Fallopian tube is sufficiently rare to excite interest in any contribution to our knowledge of it. Only twenty-four cases have been recorded up to the present month, and of these in only three had the subjects borne as many as three children. This month, at the meeting on the 4th inst. of the Obstetrical Society Dr. Herbert Roberts read a paper on a case in a woman, aged forty-three years, who had been married seven years but had not been pregnant. In March, 1896, having up till then enjoyed good health, she was seized with violent abdominal pain and vaginal discharge. Similar attacks followed in July and November, and gushes of watery fluid were noticed. In February, 1897, she was thinner; the uterus was displaced to the left side by a fixed mass in the right fornix, about the size of a hen's egg. It was not tender. The right tube was removed by Mr. Meredith, and was found enlarged to the size of a Bologna sausage. It was full of a growth which on microscopic section proved to be carcinoma.

Mr. Alban Doran mentioned a case with similar symptoms, occurring in a woman who had been twelve times pregnant. On operation he found only tough, tortuous tubes with their canals undilated, closely adherent to the uterus and adjacent structures. He believed carcinoma to be more common than papilloma of the tubes, unless the latter was very liable to malignant degeneration. He thought removal through the vagina questionable on account of the difficulty of ascertaining the state of surrounding parts. The uterus had been removed with the tube, but when the uterine end is free from disease, the propriety of doing so is open to question. If the outer end has infected adjacent tissue, operation will be useless.

Dr. Horrocks said carcinoma often affected the cervix in parous women; more rarely the body of the uterus and usually in multiparæ; most rarely the tubes, and then generally in sterile women. He thought that used or damaged tissues were more prone to the disease, and suggested that the microbe might select a damaged part of the cervix, but if that was sound it might travel on toward the tube. Abdominal was better than vaginal operation.

Dr. A. Routh discussed the diagnosis. He thought continuous pelvic pain associated with sanious, often offensive discharge, together with tubal swelling, pointed to some new growth in the tube, especially if by preliminary dilatation the uterus could be excluded as the source of the discharge.

Dr. Addinsell remarked that in nearly all cases pain and watery discharge were prominent, but they could not decide the diagnosis, as they were met in some cases of hydrosalpinx.

Dr. Giles commented on the unfavorable prognosis. Only one operation could be called a cure, seven years having elapsed. In other cases the longest time without recurrence was only eighteen months.

Professor Dewar last week succeeded in producing a quantity of liquid hydrogen by a rapid process. I hear that though others have produced a few drops he obtained quite a wineglassful. The boiling-point is about 240° C. below zero; at this point it solidifies air. Using liquid hydrogen he has liquefied helium, and its boiling-point is not much above that of hydrogen. He has communicated his results in a preliminary paper to the Royal Society.

Lord Herschell made a significant speech at the presentation of degrees at the London University last week. He said there were a general conviction that a change was needed and a preponderating opinion that reorganization of this was preferable to creating a second university. He told the graduates that they must not suppose the present charter gave them rights which would be infringed by legislation. Parliament had a right to intervene in the public interest. He had every hope that the controversy would not be prolonged and that in the future the university would be even more potent for good than it had hitherto been.

The new pharmacopœia is freely talked of when doctors meet, but few of them seem to have digested the changes, and no date has been fixed on which it is to supplant its predecessor. Consequently prescribers feel some doubt as to how their prescriptions may be dispensed. Besides analyses in the journals, several booklets have appeared, professing to give a complete account of the changes. These are mostly by pharmacists, and I have not met with any by therapeutists. The latter authorities are certainly behindhand, though on the previous occasion they were first in the field. The new work is certainly much indebted to the pharmacists, who have exercised an almost preponderating influence in its production.

There are a number among us who think the United States formulary better than our new British Pharmacopœia.

Deputy Surgeon-General S. B. Partridge, C.I.E., Q.H.S., died on the 11th inst. He had a very distinguished Indian career. In due course he held several appointments in the University of Calcutta, including the professorship of surgery and the surgeoncy of the college hospital. He was also a member of the senate, and in turn an examiner and presi-

dent of the Medical Faculty. On returning to England, he was appointed a member of the Indian Medical Board, where his services were highly valued. Failure of sight compelled him to resign and he was made a C.I.E., various other honors and distinctions having been previously awarded him. He seems to have inspired all with whom he came into contact with profound respect and even affection.

THE LIMITATIONS OF THE ELECTROLYTIC METHOD OF TREATMENT.

To the Editor of the Medical Record.

Sir: In his criticism of my paper, Dr. Massey claims that modern electro-therapeutists are not in accord with the views therein expressed. I can well believe that these views are not acceptable to very many, but whether they are really at variance with the experience of men who thoroughly understand the subject—broad enough to know the truth when they see it, and honest enough to tell it—is another matter. No one will accuse me of not being a friend to electro-therapeutics. It has served us well in many ways, but what I contend for is that we should not ask of it more than it is capable of giving or abuse its powerful aid by gross exaggeration. I have been amazed at the many extravagant and utterly untenable claims for electricity in medicine and surgery.

Exaggerated laudation of any therapeutic method by those who claim proficiency in it does far more to hinder its progress and injure its status than all the destructive criticism of opponents who lack practical experience in its use. In saying that the "limitations of electrolysis are distinct and positive," to which objection is made, I had in mind more particularly its chemical formula—the fact that the elements evolved are definite in quantity and electro-chemical equivalents of each other; but at the same time I meant also to imply that, with our present knowledge and methods, the surgical powers of electrolysis are pretty well defined.

True, with adequate power it can reduce the body to its primal elements; but so can heat, which is simply a manifestation of electric energy. A morbid growth, no matter how large or dense, could be quickly destroyed by heat or by electricity of adequate strength; but in the mean time what would become of the other bodily structures under the application of such intense power? Unfortunately we shall never be able to utilize in applications to the human body more than a very small fraction of the illimitable chemical energy of electricity.

Dr. Massey refers to my old-time experiments in cancer, by which I claim to have demonstrated the utter futility of electricity as a curative agent in that disease, referring to them as of only historical value. "These experiments," he says, "must have been made in the dark ages of electricity, in total ignorance of the actual current employed, and are therefore on a par with our ancestors' inability to run cars, light streets, etc., with electricity; in other words, the technique was defective."

The parallel is utterly defective. The conditions in commerce, where we can make use of the almost limitless power of electricity, are vastly different from those of medicine, where the power used must be of necessity exceedingly limited.

The only appliance lacking in those early experiments was an instrument of precision for measuring the current. It is true that we could not then tell the number of milliamperes used; but from what we now know of the exact relation of electro-motive force, resistance, and current strength, and subsequent observations with the milliamperemeter, we can from our records approximately estimate the power then used. It measured up to hundreds of units of current strength, and the technique was not defective. Since then, with the experience of all these years (and I am old fashioned enough to believe that experience rightly guided is no great hindrance), I have experimented fully with Parsons' rapidly alternating method and with every modern appliance at command, but with no better result certainly than in former efforts.

Dr. Massey takes occasion again to speak of his recent successes in the treatment of cancer by the cataphoric method. I sincerely trust that success may crown these efforts, but very much fear that the near future will witness no startling results from the cataphoric action of the galvanic current in malignant tumors.

Of course I speak a good word for the Apostoli treatment of fibroids, notwithstanding the many absurd claims made along this line. It is a great thing by such a simple process to relieve distressing symptoms, when for any reason whatever the knife is not allowed.

Human testimony in general, it has been said, amounts to but little. There are too many sources of error connected with it, and I am not ready to acknowledge that the two cases to which Dr. Massey refers prove very much. Fibroids are said to have disappeared at the climacteric without treatment, but that does not alter the fact that such disappearance is an exceedingly rare occurrence, nor do his cases alter the fact that fibroids seldom disappear under electrolysis, however gratifying the symptomatic relief.

New York

THE O'DYWER AND FISCHER TUBES.

To the Editor of the Medical Record.

Sir: In your issue of April 30, 1898, I find a communication from Dr. Walter Lester Carr, with the headline of "The O'Dwyer and Fischer Tubes." In this communication the writer calls Dr. Edwin Rosenthal, of Philadelphia, to account for having given me the credit of introducing hard-rubber tubes as a means of relieving laryngeal stenosis instead of using the metal tubes used and recommended by O'Dwyer.

The compliment of Dr. Rosenthal, wherein he states "that he has in his operating-bag a set of such tubes and they are the invention of Dr. Louis Fischer" (*vide* Medical Record, April 9, 1898), and further states that they "were presented in Philadelphia by the inventor during the meeting of the American Medical Association, June, 1897, before the section on diseases of children," requires a word of explanation.

Several years ago, when the writer saw a great many cases of laryngeal stenosis in consultation, many points were constantly noted, among them that after the removal of the O'Dwyer (metal) tube large quantities of lime salts were to be found deposited on the tube, requiring careful cleansing and frequently necessitating regilding in order thoroughly to cleanse and render the tube aseptic for the next patient. This was always an annoyance; moreover it frequently necessitated several sets of tubes, which was quite an expensive matter, and in addition it was unsatisfactory.

At that time, after looking over the literature of the subject, I found that Schroetter, inspired by the method of Bouchut, employed "tubes en caoutchouc," which were essentially rubber tubes. These tubes were introduced with the aid of a laryngoscope and electric illumination. Seeing this article, which I have in a text-book at my office, I spent considerable time trying to obtain these tubes, both at home and abroad. As I did not succeed in Europe, I turned my attention to Messrs. George Tiemann & Co. of this city. Not only did they help me look up all improve-

ments but they gave me all possible information leading thereto. They displayed great liberality in aiding my desires and made several models of instruments, which I have from time to time improved, discarded, retained, and in a few instances published. The above explanation, Mr. Editor, I feel is proper, in order that I may not be placed in a false position through the remarks of my learned critic. I have never claimed, nor do I now claim, to have invented "rubber tubes," any more than I claim to have invented rubber. It strikes me, however, that Dr. Carr has not given my first article, published in the MEDICAL RECORD of June 19, 1897, proper consideration, if he has ever done me the honor to read the article at all. Permit me, therefore, to quote therefrom, and thus I hope to relieve myself of the thought of having been placed in a false light. I commenced the article with the following words:

"The instruments herein described are merely improvements of the noble work for which the profession is indebted to the genius of Dr. Joseph O'Dwyer." Does this look like too much assumption? Further I say: "My improved tubes are constructed of vulcanized rubber, which is the purest and best kind of rubber." I do not state that I am the only man ever having used rubber tubes, and I defy Dr. Carr or any other physician to show me any such statement. In fact, I try to show how much I am personally indebted in my work to Dr. O'Dwyer, for on the same page I state: "As to the principle involved regarding the length of the tube, I have adhered strictly to the O'Dwyer teachings."

The statement made by Dr. Carr, that O'Dwyer's investigations and models were on anatomical lines, does not require any answer. On page 875 (article of June 19, 1897) of your esteemed journal, I record my gratitude to Dr. Gallaudet for permission in using anatomical material, and I also thank Dr. Phelps, of Bellevue Hospital, for recent courtesies; so it is reasonable to state that what little experience I have had on the living was aided by anatomical experience from the morgue. Since Dr. Carr is so well versed, however, in this special literature, may I trouble him to inform me who published the first announcement regarding corrugated rubber tubes, and when and where? This I ask, because it is only fair to have an absolute insight into all improvements, and that no credit should be stolen. It is, however, a very strange fact, and one that I note with considerable interest, that less than a few months ago one of my staff of assistants in the children's department of the German Poliklinik reported to me that advocating rubber tubes as a substitute for metallic tubes was ridiculed in a large children's hospital (the proof—written—I retain for the present), and that suddenly within a few weeks some rubber tubes were ordered and recommended. This decided change of front during a practical course of intubation in this city was certainly peculiar, and I leave it to your esteemed readers to form their own conclusions.

In the MEDICAL RECORD of December 19, 1896, O'Dwyer, referring to an article of Dr. Thomas J. Hillis, criticises the use of an intubation tube having an appliance to facilitate extraction. In this same article, page 910, O'Dwyer says: "Let those, therefore, who have inventive genius try to discover some such material as will take the place of metal." He also says in this same article: "No improvement has ever been made, and it requires no prophetic knowledge to say that none ever will be made, except possibly in the material of which the tubes are constructed." So, according to O'Dwyer, at this date no rubber tubes were made.

In the *Archives of Pediatrics* for July, 1897, appears the paper of O'Dwyer on the retained intubation tubes. In this same paper, page 486, O'Dwyer states that the "ideal treatment for these cases, and in fact for all cases requiring intubation, would be a tube constructed of some non-metallic substance not liable to calcareous deposits, which could be worn for a long time without change. Experiments that bid fair to be successful are now being made with hard-rubber tubes," etc.

My experiments, in fact some successful cases, were reported (wherein I had used the rubber tubes made for me by Messrs. George Tiemann & Co.) in the winter of 1896 97. On April 29, 1897, May 5 and May 21, 1897, I successfully intubated, and reported the patients, with names of physicians with whom I saw the cases. They were reported *in extenso* in the MEDICAL RECORD of June 19, 1897. Does this appear as though I had been guilty of adopting methods already in vogue and taking the credit to myself? Several months before my first report appeared in the MEDICAL RECORD, I demonstrated the rubber tubes to Dr. George F. Shrady while in that gentleman's office, and stated that I believed this new tube would do away with metallic tubes. The above statement, while rather lengthy, will explain my humble position, and I beg of you to give my views in full so that my position can be clearly understood.

LOUIS FISCHER, M.D.

187 SECOND AVENUE, NEW YORK.

New Instruments.

APPARATUS FOR STERILIZING DRESSINGS BY FORMALDEHYDE, WITH BACTERIOLOGICAL PROVINGS.[1]

BY CHARLES HARPER RICHARDSON, M.D.,

ALBANY, N. Y.

THE employment of formaldehyde, or its solution, formalin, as a chemical agent for the destruction of bacteria, is becoming of far wider application than its earlier use seemed to indicate. Originally its use was largely confined to household and quarantine disinfection, but its value soon appreciated. The simplicity of its application and its reliability soon commended it as a germicide. One certainly would not go so far as to advise the substitution of formaldehyde for heat, steam, or boiling water for the purposes of sterilization, but it is a useful and desirable substitute under certain conditions.

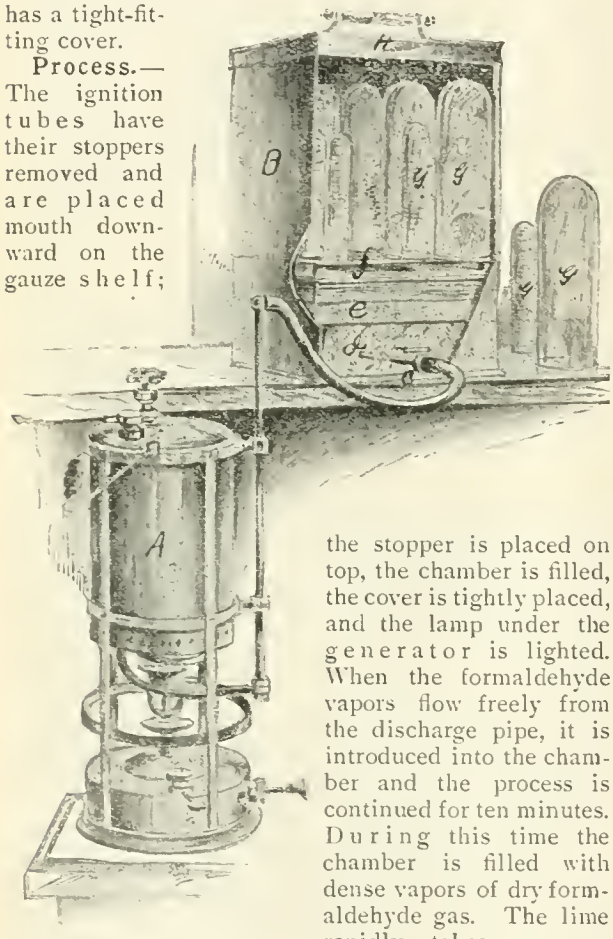
The repeated boiling of instruments, especially edged ones, soon injures them, while the unequal expansion of steel and nickel causes scaling of the plating of the other instruments. Drs. Reik and Watson, in the last bulletin of the Johns Hopkins Hospital, describe an apparatus for formaldehyde sterilization of instruments which has proved most satisfactory.

The apparatus to be subsequently described was primarily designed for the sterilization of iodoform gauze, a hitherto serious problem. It may be said that if the gauze as a finished product of the manufacturer was not sterile, it could not be absolutely sterilized without destroying its properties; *i.e.*, without decomposing the iodoform. Fractional sterilization at sufficiently low temperatures is a tedious and untrustworthy process. Iodoform gauze is a satisfactory and widely employed dressing, usually applied directly to wounded surfaces, or for the tamponade of cavities. No question of its asepsis should arise.

For the disinfection of iodoform gauze by formaldehyde, the following method is used: The gauze from the manufacturer is cut into the required lengths, properly folded, and lightly packed in ignition tubes, each tube containing the quantity likely to be required for

[1] A study from the surgical laboratory of Dr. W. G Macdonald.

a single dressing. The tubes are plugged with cotton as in the laboratory. The apparatus employed is very simple in construction, and completed costs a trifle. The one used for illustration consists of an empty tin box used for shipping quinine, and obtained from the pharmacy. It is fourteen inches square and sixteen inches high. Six inches from the bottom, four pieces of heavy tin turned at right angles were soldered in each corner to support the false bottom of coarse galvanized iron gauze. A small opening was made in the side at the bottom to admit the discharge tube of a household formaldehyde generator (*c*). This tube was protected by a hollow piece of wood, as far as the centre of the sterilizing-chamber. The space between the bottom and the gauze shelf was filled with a four-inch layer of fresh, unslaked lime, and covered with a few layers of plain absorbent gauze. The chamber has a tight-fitting cover.



Process.—The ignition tubes have their stoppers removed and are placed mouth downward on the gauze shelf; the stopper is placed on top, the chamber is filled, the cover is tightly placed, and the lamp under the generator is lighted. When the formaldehyde vapors flow freely from the discharge pipe, it is introduced into the chamber and the process is continued for ten minutes. During this time the chamber is filled with dense vapors of dry formaldehyde gas. The lime rapidly takes up any watery vapor from the generator. After the close of the process, the apparatus is left undisturbed for four hours, when the tubes are removed and restopped with sterilized forceps.

There remains about the apparatus or gauze very little of the disagreeable formaldehyde vapors, all of which can be removed by pouring down the side of the chamber into the lime a few drachms of household ammonia.

The lime will require changing after the apparatus has been in use a half-dozen times.

Clinically the process leaves nothing to be desired. No disagreeable symptoms have been observed, although the method has been employed for months. The only objection that might be raised is the absolute dryness of the gauze. This can be readily overcome by moistening at the time of use with sterilized decinormal salt solution.

Although in a general way we have made many bacteriological tests with formaldehyde, yet in order to make sure the following provings were made at the Bender Hygienic Laboratory by the assistant director, Dr. A. J. Lartigau. Eight ignition tubes were prepared, four with iodoform and four with plain gauze. One of each was kept for control, and the others were infected as follows:

One of each, iodoform and plain, with active bouillon cultures of staphylococcus pyogenes aureus, streptococcus pyogenes (virulent), and bacillus subtilis (hay bacillus). The bacillus subtilis was used on account of the extreme resistance of its spores to sterilization. All the tubes were sterilized in the manner already described and returned to the laboratory. Small portions of gauze were taken from the interior of each roll as removed from the ignition tubes, separated somewhat with sterilized forceps, and placed in bouillon cultures. These were placed in the thermostat for seventy-two hours. At this time, no evidence of growth appeared in any of the cultures. Subsequently these cultures were resown on solid media and returned to the thermostat. No growth was found in any of them.

The experimentation of many investigators shows that formaldehyde is, under ordinary conditions of pressure and moisture, a surface germicide. We have found that if materials are dry (as over quicklime) sterilization is uniformly assured after four hours. This apparatus, primarily devised for the sterilization of iodoform gauze, might find a far wider application in the preparation of dressings. In times of war or riot, conditions are such that it would be impossible for the surgeon to employ the more ponderous forms of apparatus now so successfully employed in our hospitals, but he would be compelled to use the simpler and lighter form or even improvise from materials at hand a sterilizing apparatus. It is not claimed that the method of introducing formaldehyde into the sterilizing chamber is the best one that could be devised; but, the other form of formaldehyde disinfector being at hand, it was utilized for the purpose.

EITHER A POCKET INHALER OR A MIDDLE-EAR INFLATER.

By EDWIN PYNCHON, M.D.,

CHICAGO,

PROFESSOR OF RHINO-LARYNGOLOGY AND OTOLOGY, CHICAGO EYE, EAR, NOSE, AND THROAT COLLEGE; LATE SENIOR ASSISTANT AURAL SURGEON, ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, CHICAGO.

A POCKET inhaler appeals to popular fancy. The idea of absolute ownership, the convenience of portability permitting frequent employment, and, furthermore, the comparative cheapness in view of the service rendered, give a solution as to the reason why proprietary devices of this class are meeting with such commercial success. They are being liberally advertised, and their sales are proportionate.

There is no doubt but that much benefit may be derived from the frequent use of an efficient inhaler suitably medicated in cases wherein its use is indicated. Through such use, owing to the deep inhalations taken, the lungs are alternately distended and emptied far better than would otherwise be done, thus producing a sort of lung gymnastics. The medicament with which it is charged, be it either menthol, eucalyptol, or other volatile agent, produces a pleasantly stimulating and beneficial effect.

In place of the proprietary devices physicians frequently order the old-fashioned Buttles inhaler, it being the best available substitute, even though awkward in form for pocket use and far less inviting in design than are some of its proprietary rivals. With a desire to increase its simplicity and improve its efficiency for pocket use, I have designed the model herewith illustrated, which may be said to be the outgrowth of a

previous modification, the description of which I published under the title "The Evolution of the Buttles Inhaler."[1]

The conical end is for use in either nostril, and will be found to fit any nose. The opposite end is for mouth inhalation, the expanded portion being placed between the lips with the concavity against the teeth. When not being used, evaporation of the medicament can be prevented by stopping one of the openings with the hard-rubber plug shown.

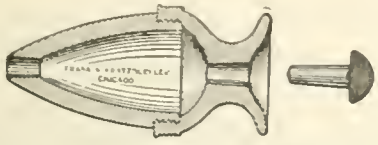


Fig. 1.—As a Pocket Inhaler (⅔ Size).

To prepare for use there should be placed in the interior of the medicine chamber a small piece of sponge of strong texture and of suitable size and shape, which may then be medicated with any fluid volatile medicine, a few drops of which should be dropped upon the sponge through the opening in the funnel-shaped end, and can thus at any time be renewed without taking the trouble to unscrew or open the medicine chamber.

Any remedy indicated can be ordered by the attending physician. As a pleasant inhalent, particularly in acute coryza, the following might be suggested:

℞ Guaiacol,
Oil of pine needles ..... āā ʒ i.
Camphor-menthol ..... ʒ ij.
Oil of eucalyptus ..... ʒ ss.
M.

The attending physician can give the patient a prescription for the inhalent required, and at the same time an order for the inhaler, which any druggist can easily supply.

Having now described the use of this device by the patient as a pocket inhaler, I will next consider its use by the physician, who will find it to be a perfect and improved substitute for any previously suggested modification of the Buttles instrument.

In this device it will be observed that the conical openings at either end are of the same size and are designed to fit a Davidson cut-off; hence the physician can employ it with compressed air of suitable pressure in different ways.

First, as an inhaler, for the administering of forced inhalations to produce alveolar expansion, insert the cut-off in the hole in the pointed end, and, after a full exhalation, place the expanded end between the patient's lips, meantime holding the nose closed; then operate the cut-off and have the patient inhale deeply and fully, when the greatest voluntary inspiration will be intensified by the air pressure employed, which may be as great as fifty or sixty pounds. In this way so-called "impaction" is produced,[2] which *en passant* gives all the advantages of the expensive pneumatic cabinet of bygone days.

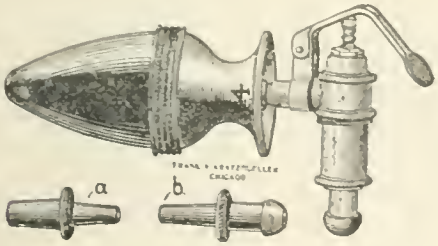

Fig. 2.—As a Middle-Ear Inflater (⅔ Size).

Second, by inserting the cut-off in hole in expanded collar end, as shown in Fig. 2, it can be used to do Politzerization by any of the usual methods which I have fully described in previously alluded to papers. A necessary requisite of efficient inflation by this method is that the outlet hole shall be large enough to permit of the escape of a sufficient volume of air current, as proper volume is of as much importance as is proper intensity.

In order to use this inflater with a Eustachian catheter, introduce the small extension (*a*) in the opening at the conical end. Its use will give less annoyance if the projecting tip be surrounded by a short piece of soft-rubber tubing, which will soften the contact when pressed against the catheter. In this way the instrument, after being prepared for use with the suitable remedy and attached to the cut-off, can be allowed to hang over the operator's knee, being supported by the tubing from the air tank, and thereby leaving both hands free for the proper adjustment of both the catheter and the auscultation tube. Of course it will be understood that when compressed air is used with the Eustachian catheter some means of absolutely limiting and controlling the air pressure must be employed. For this purpose I use an auxiliary tank of special design and provided with an independent meter, and can thus obtain when using the catheter any pressure desired, with either an intermitting or a constant current, and this latter I have in many cases found to be of special value.

In the use of this instrument with a cut-off, the expanded collar admits of its being securely held and easily operated. The expanded end also serves as a pedestal upon which the instrument can be set when not in use, so as to prevent its rolling off the treatment desk. The specialist will require several in his daily work, one for each remedy used, and can easily tell them apart by having them numbered, as shown in the cut. One of the set should be made of metal, which can be heated and with which chloroform can be used.

This inflater, as compared with its predecessors, has been made more simple and easy of manufacture, as the separate parts have been reduced in number from six to four pieces, and the screw fittings from three to one. The small union (*b*), such as is supplied with the Davidson No. 65 spray bottles, is designed for use with a hand ball and its short rubber tube, when the air tank and cut-off are not available.

This improved inflater-inhaler has been neatly constructed for me by Messrs. Frank and Kratzmueller, of Chicago.

Columbus Memorial Buildin..

Tuberculous Peritonitis.—Dr. H. E. Wright, before the Sacramento Society for Medical Improvement, October 19, 1897, concluded his paper as follows: "1. Simple abdominal section, properly performed, sufficiently early, cures all cases of primary tuberculosis of the peritoneum without implication of other organs. 2. Cœliotomy in chronic peritonitis due to tuberculosis of the female pelvic organs may rarely cure if the primary focus is not too far advanced for extirpation; but death usually occurs sooner or later, in spite of operation. 3. Operation is a justifiable but merely palliative measure when the chronic peritonitis is dependent upon tuberculous enteritis. 4. Irrigation of the abdomen in tuberculous peritonitis, secondary to pulmonary disease, may cure a considerable percentage of cases, and gives temporary improvement in the remainder; hence is advisable in all cases not too weak to stand operation."

[1] The Laryngoscope, April, 1897, p. 225.

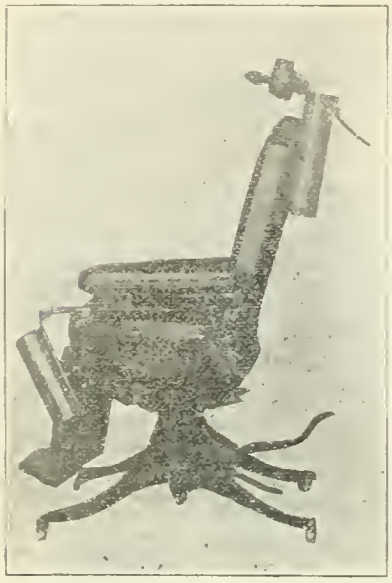
A WASTE COTTON HOLDER.

By J. A. PRATT, M.D.,

AURORA, ILL.

In this advanced age of medical science, we are apt to forget the appearance and comfort of the office. A most favorable and beneficial impression is made upon those seeking our aid, to find it well kept and inviting. Many a physician has lost patients by keeping an untidy office, due to waste cotton, soiled dressings, etc.



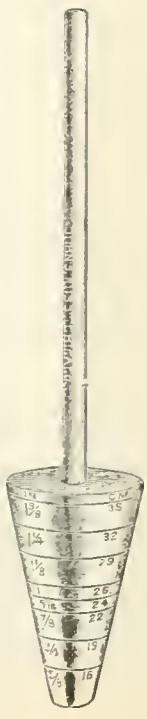
The accompanying illustration shows a simple device to hold waste cotton and the odds and ends accumulating in office practice. It consists of a copper, nickel-plated vessel, ten inches high, four inches in diameter, with the bottom closed and a hook at the top. It can be placed on the floor or table, while the hook allows it to be hung on almost any part of a chair. The mouth is always toward the physician to receive waste material, and, as it drops from view within the vessel, a good appearance is always maintained. The size makes it convenient for cleansing, while it will hold sufficient for emptying once a day. The receptacle was made for me by Karl Brothers, Aurora, Ill.

THE ENTEROMETER. A NEW INSTRUMENT FOR MEASURING THE CALIBRE OF INTESTINAL LUMEN BEFORE INTRODUCING THE ABSORBABLE BONE COUPLER IN INTESTINAL APPROXIMATION.

By JACOB FRANK, M.D.,

SURGEON TO THE ST. ELIZABETH AND GERMAN HOSPITALS, CHICAGO, ILL.

The first question that confronts the surgeon in using my bone coupler, or any other mechanical device for intestinal approximation, is, What size of coupler am I to use in order to perform a successful approximation? This is, indeed, a more important question than we at first realize, as the use of too large a coupler in a small-calibred intestine adds greatly to the many failures that are obtained, and the use of a coupler too small encourages stenosis. These are very important points; for the neglect on the part of the surgeon to select the proper sizes, of which there are eight of my couplers (1⅜, 1¼, 1⅛, 1, 15/16, ⅞, ¾, and ⅝ inches) and different sizes in other mechanical appliances, leads very often to unpleasant results.



The importance attached to this subject, from the standpoint of practical experience, has led me to devise an instrument enterometer, which will do away with all obstacles and enable the surgeon, before introducing any mechanical appliance, first to ascertain the exact calibre of the lumen into which the coupler is to be introduced, and then to select the proper size as ascertained by the enterometer. By doing this, the operator not only obviates unnecessary injury to tissues to be approximated, thereby reducing their vitality and lessening successful results, but also avoids shutting off the circulation of the area occupied by the coupler after being introduced, by putting the gut on the stretch; thus suffering the consequences of seeing the failure of union of approximated ends and claiming such failures to be due to the device.

The enterometer is a cone-shaped graduated instrument with a straight handle. The scale of graduation is in the French and English systems—in the French up to 35 cm., and in the English up to 1⅜ inches. The instrument is nickel-plated, and can readily be sterilized. Each cut end of the bowel should be measured by introducing the enterometer into the lumen without putting the bowel too much on the stretch; the smaller end determines the size of coupler to be used.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending June 4, 1898:

	Cases.	Deaths.
Tuberculosis	154	127
Typhoid fever	11	4
Scarlet fever	176	24
Measles	392	13
Diphtheria	159	23
Laryngeal diphtheria (croup)	7	3
Chicken-pox	22	0
Cerebro-spinal meningitis	0	12

Health Reports.—The following statistics concerning small-pox, cholera, yellow fever, and plague, have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending June 4, 1898:

SMALL-POX—UNITED STATES.

		Cases.	Deaths.
Alabama, Hurricane Bayou	May 14th to 28th	2	
Mobile	May 14th to 28th	2	
Florida, Pensacola	May 15th	1	
Georgia, Macon	January 25th to June 1st	100	3
Mississippi, Laurel	May 28th	3	
Shubuta	May 28th	40	
North Carolina, Wilson County	May 28th	1	

SMALL-POX—FOREIGN.

Belgium, Ghent	May 7th to 14th	..	1
Bohemia, Prague	May 7th to 14th	2	
Brazil, Sao Paulo	March 1st to 31st	43	9
Canada, Halifax	May 14th to 28th	6	
China, Hong Kong	April 2d to 23d	11	5
England, Newcastle on Tyne	May 7th to 14th	1	
Germany, Bremen	May 7th to 14th	1	
India, Calcutta	April 9th to 23d	..	8
Madras	April 16th to 29th	..	5
Norway, Christiania	May 1st to 14th	5	
Russia, Moscow	May 1st to 7th	16	3
Odessa	May 1st to 16th	10	3
Riga	March 1st to 31st	..	5
St. Petersburg	May 1st to 7th	20	4
Warsaw	May 2d to 9th	..	8
Venezuela, Puerto Cabello	March 23d to April 28th	45	15

CHOLERA.

India, Calcutta	April 9th to 23d	..	66
Madras	April 16th to 29th	..	6

YELLOW FEVER.

Brazil, Araraguara	March 1st to 31st	4	3
Jaboticabal	March 1st to 31st	35	16*
Ribeirao	March 1st to 31st	21	3
Rio Clara	March 1st to 31st	9	4
Rio de Janeiro	April 8th to 15th	96	74
Santos	March 1st to 31st	32	13
Sao Carlos	March 1st to 31st	177	47
Sao Paulo	March 1st to 31st	2	
Santo Domingo, Santo Domingo	May 7th to 14th	1	1

PLAGUE.

China, Shanghai	April 21st, 1 case on board S.S. Glenturret from Hong Kong.		
India, Bombay	April 26th to May 3d	..	263

THE SERUM EXANTHEMATA OBSERVED IN THE ANTITOXIN TREATMENT OF DIPHTHERIA: THEIR PATHOGENESIS AND POSSIBLE PREVENTION.[1]

BY HENRY W. BERG, M.D.,
NEW YORK,
VISITING PHYSICIAN TO THE WILLARD PARKER HOSPITAL.

THE convincing results obtained from the antitoxin serum in the treatment of diphtheria having removed all doubt as to the vast superiority of this treatment over all other methods heretofore known, it is unnecessary that much more statistical evidences of the diminished mortality rate should be published. Those of us, therefore, who were early impressed with the utility of this remedy, may turn our attention to a closer study of the epiphenomena which occasionally appear in the course of the progress of cases of diphtheria which have been treated by this remedy.

Among the most interesting of these adventitious symptoms on account of its frequency, and because, being a cutaneous lesion, it admits of ocular demonstration, is the so-called "antitoxin rash."

It is with the desire of adding to the knowledge of this lesion the data to be obtained from the wards of a diphtheria hospital in which the antitoxin treatment has been conscientiously carried out that I have studied a large number of these rashes, from which I present thirty-three selected cases, as being representative of all the cutaneous lesions of this kind that I have seen.

Although the chief manifestation of this complication consists in a more or less well-marked cutaneous eruption, this eruption has not, as is the case in the acute infectious diseases, a constant and characteristic appearance. At one time it resembles scarlet fever, in another case urticaria; in one erythema, in another measles. Its distribution as regards the extent of skin involved is not constant. It does not appear on one portion of the cutaneous surface rather than upon another. The eruption has no fixed duration, being in one case evanescent, in another lasting for days and weeks. Frequently in the same patient and at the same time, one portion of the body may be affected with an urticarial eruption, while in other portions of the body it may be, for example, scarlatiniform in character.

To him who treats diphtheria in private practice and sees comparatively few cases, making but few antitoxin injections, it will appear a stretching of the truth to say that the cutaneous eruptions following the injections of diphtheria antitoxin are of extreme importance, owing to the frequency of their occurrence. But that they are frequent is evidenced by the fact that eruptions from diphtheria antitoxin have been reported by observers of large numbers of cases in all parts of the world. Thus C. Hartung[2] reports 2,183 cases of diphtheria injected with antitoxin, of which 253 developed exanthemata. The table is as follows:

	Eruptions.	Injections.	Per Cent.
Heubner (Berlin cases)	54	298	18
Heubner	22	77	28
Baginsky	49	525	9.4
Soltmann	5	89	5.5
v. Ranke	5	118	4.2
Seitz	20	140	14.3
	4	180	2.22
Förster	7	73	
Schucolty	4	38	
Günther	3	33	
Bokai	11	120	9
	30	147	20
Moizard, Paris	33	231	14
Risel, Halle	6	114	5.2

To this he adds from other various observers sufficient cases to make 2,661 injections, of which 294 developed rashes, or 11.4 per cent. in all. The report of the imperial health board of Germany for January to July, 1895, showed 4,358 cases injected, 354 exanthemata, or 8.1 per cent. That the reports of cases from hospitals are more reliable than those from domestic practice, is due to the fact that in many of these cases reported by health boards and private physicians the eruption may appear, but remains only a very short time, and escapes observation by the medical attendant. It follows therefore that the percentage of eruptions in cases thus reported from domestic practice is only 8.1 per cent., while the percentage in cases seen in hospitals is 11.4 per cent.

In the Willard Parker Hospital in four months the number of cases injected was as follows:

	Cases.	Rash.	Per Cent.
May	107	18	17
June	103	23	23
July	62	19	33
August	65	22	33
Total	337	82	24

In all about twenty-four per cent. of cases injected during those four months developed antitoxin exanthemata. The fact that these rashes have been observed to a greater or less extent in the practice of all observers, in all parts of the world and with every variety of serum, would seem to prove their dependence upon causes inherent in the serum itself, or some circumstances connected with the manufacture or application of all serums.

The frequency with which various observers have met with these eruptions varies markedly, however, as already noted. Thus Monti, of Vienna, found this eruption to occur in fifty-two per cent. of one series of his cases, while Hager[1] did not have a single case of serum exanthema in a series of sixty-one cases. Furthermore, individual observers find a smaller or larger percentage of rashes following various serums of the same manufacture. That is to say, a serum

[1] Read before the New York Academy of Medicine, May 19, 1898.

[1] "Beitrag zur Anwendung des Heilserums gegen Diphtherie," S. 19.

[2] Centralblatt für innere Medicin, 1894, No. 48.

obtained from a given horse may be found to give rise to a relatively large proportion of serum rashes: while that taken from other horses belonging to the same laboratory and subjected to the same technique in its preparation may give rise to eruptions in a much smaller percentage of cases. This fact was noted by Hartung in his paper on this subject.[1] Hartung went so far as to believe that the serum of certain well-known laboratories was less liable to be followed by antitoxin rashes and other adventitious sequelæ of serum injections than that supplied by other laboratories equally well and favorably known for the careful technique observed in the preparation of the serum. My own experience has been limited to the use of the Behring serum and Aronson's serum in private practice, and the serum supplied by the board of health in hospital work. I have observed rashes in private practice and in hospital work, and, while my impression is that I have rashes less frequently in private practice than in the hospital, it must not be forgotten that a temporary rash might occur and fade away before my next visit in private practice: while in a hospital ward the nurses, being on the *qui vive* for all eruptions, would scarcely overlook the most evanescent rash. The two most violent rashes, when measured by the gravity of the symptoms which they caused, were seen by me in private practice after the use of a most reliable foreign serum.

It has been claimed by some authorities that any increase in the bulk of antitoxin serum injected does not increase the frequency of the occurrence of eruptions. In other words, that a larger quantity of a weak serum does not produce eruptions more frequently than the same antitoxic strength of a strong serum, but smaller in quantity. This has not been the experience of Hartung.[2] Hartung found that in 40 cases injected with 600 units 25 per cent. of the cases had rashes, while in 34 cases injected with 1,500 to 3,500 units, 30 per cent. of the cases had rashes. I believe these eruptions are comparatively more frequent after multiple injections than after single injections of the serum.

Other considerations apart from their frequency make the study of these eruptions important. In the wards of a hospital devoted to diphtheria, these eruptions assume a diagnostic importance entirely out of proportion to their relative innocuousness; for so closely do they simulate scarlet fever, or more rarely measles, of which the foregoing diphtheria might be considered a co-ordinate condition, that it is only by careful differentiation, and in cases of doubt careful isolation until time has proved the diagnosis, that we can prevent the infection of our wards by the creeping in of cases of the infectious diseases above mentioned into a pure diphtheria ward.

Rarely the advent of the eruption is contemporary with a decided increase in the general gravity of the disease affecting the patient. The clinical picture, which may have been that of a mild case of diphtheria up to the time of the eruption and its prodromal fever, etc., assumes in exceptional cases a far more serious type. Complicating affections of important vital organs begin to show themselves, and sometimes the fever and other symptoms accompanying the eruption put an additional burden upon the overtaxed vital resources of the patient and retard the recovery. In very many cases the eruption, if at all general, is at least a discomfort.

Clinical Description.—It is uniformly characteristic of these eruptions that they belong to the congestive or hyperæmic class of skin lesions. I would group them under the following heads:

I. Cases which resemble a simple erythema.

II. Cases which resemble erythema scarlatiniforme: (*a*) without desquamation; (*b*) with desquamation.

III. Cases which resemble erythema morbilliforme: (*a*) without desquamation; (*b*) with desquamation.

IV. Cases resembling for the most part erythema multiforme. In this group I class those cases in which the eruption resembles that of urticaria, although differing in many respects from the lesions ordinarily termed urticarial.

In all the groups there may be cases in which the eruption is localized or general. Some examples of "antitoxin rash" belong to one class in one stage of the eruption, and to another class at another stage. Occasionally an eruption disappears after remaining only a short time, and is followed often after an interval of hours or days by an eruption of a totally different character. It is difficult to say which variety of these eruptions is the most frequent, although the rash which resembles that of pronounced measles or scarlet fever is the least frequent. In my fourth group I have included all those more irregular eruptions resembling urticaria, and the various skin lesions classified clinically as erythema multiforme. This group therefore is necessarily the largest. Of thirty-three consecutive cases of eruption that occurred at the Willard Parker Hospital twelve were of the first group or erythema; four were of the second group or scarlatiniform; four were of the third group or morbilliform; and thirteen belonged to the last group, or erythema multiforme. As I have already said, some of these patients presented skin lesions properly classified under two or even more groups.

Some clinical factors are common to all of these varieties of eruptions. Thus prodromal symptoms may be present in all of the cases of whatever class, while in other instances the eruption appears, runs its course, and fades without in any way modifying the clinical course of the diphtheria. By far more frequently, however, a sharp rise of temperature precedes and ushers in the appearance of the eruption. As a rule this increased temperature rapidly declines as soon as the eruption has reached its full development. In other cases the increased temperature continues to a greater or less degree throughout the continuance of the rash, and even after the rash has disappeared. The cases in which the erythema is of the simpler variety or of the first group, and those in which the erythema belongs to the fourth group, or erythema multiforme, show the least febrile disturbance. Those cases in which a marked scarlatiniform or measles eruption develops are apt to be far more feverish preceding and during the progress of the eruption, while its disappearance is not marked by a subsidence of the fever. The latter continues and frequently is found to be due to complications of an inflammatory character involving organs which previous to the appearance of the rash were free from disease. Thus I have seen a nephritis, broncho-pneumonia, otitis media, and other complications show themselves during the continuance or immediately after the subsidence of the rash. Especially is this true of the polyarthritis so frequently complicating these rashes. These joint pains and inflammations often precede the appearance of the rash, and remain during its development and after its subsidence. The cases in which the rash has the appearance of an erythema morbilliforme are apt to be especially seriously affected as far as the temperature is concerned, and are frequently accompanied or followed by serious inflammatory disturbances. Indeed the appearance of a morbilliform rash has in my experience been a factor in cases in which the prognosis was bad.

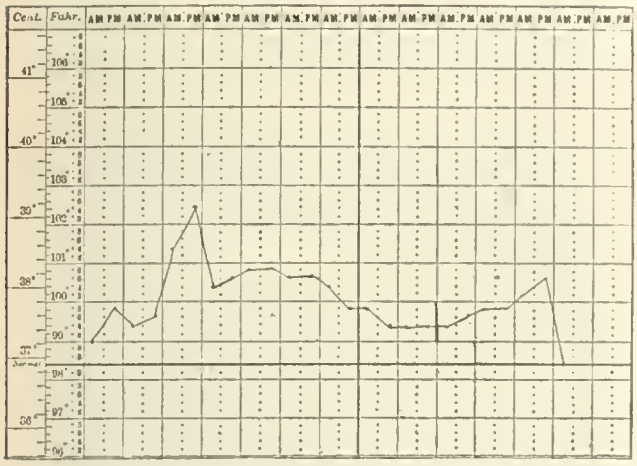
[2] Jahresbericht der Gesellschaft für Natur- und Heil-Kunde. Dresden, 1894, 1895, p. 12.

The following temperature curve is the composite curve of ten consecutive cases of antitoxin rash. As to whether the fever accompanying these rashes is ever due to the rash is proved by the experiments of Dr. A. Johannessen, who found that in forty-one individuals not suffering from diphtheria or any febrile disease, whom he injected with diphtheria antitoxin for immunization purposes, thirty-one developed rashes, and in many of these fever occurred. We can therefore positively ascribe the increased temperature accompanying the appearance of the eruption to this lesion.



Composite Temperature Curve of Ten Cases of Antitoxin Rash. Three cases lasted 2 days; 2, 4 days; 3, 5 days; 1 case, 7 days; 1, 10 days.

These rashes may be localized or general, covering the whole body as thoroughly as a scarlet fever or measles. The partial eruptions are very much more frequent. These are apt to be around the site of the injection, although not uniformly so. In some cases a partial eruption may appear on any portion of the trunk, even farthest away from the site of the injection. These localized eruptions are so common as to be frequently overlooked; and when they occur a few hours after and at the site of the injection they are evidently due to the local irritant effect of the serum. These rarely produce any constitutional disturbances, and are altogether of so little importance that, in making up the number of cases that developed a rash after injection of the serum, I have not taken into account those in which a temporary localized rash appeared at the site of the injection.

The simple erythematous rashes are apt to be localized, although sometimes general. The scarlatiniform and morbilliform rashes, especially the latter, are apt to be more general in their distribution.

The rashes of the urticarial or erythema-multiforme character may be localized or general. Frequently in these cases there are large areas of normal skin, emphasizing the urticarial eruption over the rest of the cutaneous surface. Sometimes the whole body may be affected while one or more extremities are left clear, and *vice versa*. When the rare morbilliform eruption occurs, it is often quite general in its distribution.

The exanthema following injections of antitoxin serum may occur within a few hours after an antitoxin injection, while in other cases several weeks may elapse before an eruption appears. I have seen a typical antitoxin rash of the morbilliform variety appear as late as sixteen days after the injection of the serum. In most of the cases, however, the eruption appears within a few days, and frequently within twenty-four hours after the injection has been made. It sometimes happens that the patient has recovered from a mild diphtheria, membrane having disappeared and the bacilli no longer being present when the rash appears. On the other hand, in severe septic cases of diphtheria in which death occurs early, the rash may not have appeared, owing to there being no time for its development. It follows therefore that the rashes are probably a more frequent sequel of antitoxin injections than is generally supposed. When the exanthema occurs very early, it is apt to be of the simple erythema or erythema-multiforme variety. If it occurs within three to five days, it is apt to be of the scarlatinal or erythema-multiforme variety. Cases in which the morbilliform eruption appears, occur generally in my experience in from nine to fourteen days after the injection. Curiously enough this corresponds with the incubation period of true measles. I have seen a morbilliform eruption occur at the fifth and also at the seventh day after the injection of the serum.

The time during which the eruption persists varies. It may disappear a few hours after it has appeared, while on the other hand it may persist for many days. As a rule it reaches its maximum distribution within one or two days and then rapidly subsides. The morbilliform and scarlatiniform cases rarely follow the well-known duration period of the eruptive disease which they simulate. Frequently after the skin returns to its normal appearance a second eruption occurs. This second rash has not always the clinical character of the first. I have seen a third rash occur in one case. Such a repetition of the rash is more common in cases of diphtheria that are very severe.

The question as to whether these rashes are ever followed by desquamation is an extremely interesting one, chiefly on account of its diagnostic importance.

Some authorities believe that desquamation never occurs. I have seen it frequently after these rashes. When it occurs it generally resembles the desquamation following measles, even if the eruption has simulated scarlet fever. The importance of the differential diagnosis in hospital wards is evident. When the rash resembles a pityriasis rubra, which is rare, the desquamation will be abundant and in large flakes. While I do not consider the occurrence of the desquamation a proof that the rash is not an antitoxin rash, desquamation after these rashes is exceptional.

All of these varieties of rash disappear more or less completely under the pressure of the finger, which simply signifies that the skin lesion is a congestive one, not accompanied by the products of inflammation. Some rare exceptions to this are long-persisting rashes belonging to the erythema-multiforme group, in which the presence of some exudation is shown by the fact

Fig. 1.—Antitoxin Rash (Scarlatiniform).

that the lesion does not disappear entirely upon pressure. Most of these cases suffer more or less from pruritus. In many cases the itching is very severe. In others it is almost entirely absent. It is most apt to be present in the urticarial cases.

The individual groups of these rashes, as classified above, present a clinical appearance resembling more

or less nearly that of the systematic skin diseases after which they have been named.

The cases belonging to the fourth group, erythema multiforme, include many varieties of eruptions generally classed under this head in works on skin diseases. Thus the eruption may be papular, slightly raised, and red, or it may be annular, consisting of circular patches with a depressed centre. Occasionally these circular patches coalesce with one another, forming

Fig. 2.—Antitoxin Rash (Erythema Multiforme).

large, slightly elevated, diffused patches with a scalloped margin, resembling cases described by Fox as erythema marginatum. True urticaria-like wheals are very rare, but these cases of erythema multiforme marginatum are described by some who have studied

Fig. 3.—Antitoxin Rash (Erythema Multiforme Marginatum).

these rashes as urticarial. They differ from these in their greater duration, deeper red color, and above all in the fact that the rash does not appear and disappear at intervals, as true urticaria does (Figs. 1, 2, 3, and 4).

Fig. 4.—Antitoxin Rash (Erythema Multiforme).

Although the appearance of these antitoxin rashes enables one readily to place them in the groups under which I have classified them, the close resemblance of two of these groups to the most common of the acute exanthemata renders it highly important to study the points for differential diagosis.

They are as follows:

Antitoxin Rash (Morbilliform).	*True Measles.*
Prodromal catarrh of conjunctival, nasal, pharyngeal, buccal, and bronchial mucous membranes generally absent. Rash does not appear on face and chest first, but may begin anywhere	Prodromal catarrhal inflammation. Deep red papular eruption on mucous membranes of soft and hard palate and inside of cheeks.
Rash is not uniformly morbilliform over the affected area of skin, but is apt to show a variety of patches of erythema multiforme.	Rash appears on face, neck, and chest first. Uniformly morbilliform, although varying in degree over various portions of body.
Eruption disappears after one or more days, and may return after having disappeared entirely.	Duration of rash four or five days, then gradual disappearance.
Desquamation not the rule. When it does occur, apt to be coarser than after true measles.	Characteristic desquamation always follows.

Some cases of antitoxin rash of this variety, however, do have the various catarrhal prodromal symptoms. By far the greatest reliance should be placed upon the lack of uniformity in the eruption and its irregular distribution.

Scarlatiniform antitoxin rash is far more difficult to differentiate from real scarlet fever than is the case with the morbilliform rashes from measles. This is all the more to be regretted, inasmuch as scarlatiniform antitoxin rashes are very much more frequent than the morbilliform variety. The difficulty of differentiation is enhanced by the presence of diphtheritic manifestations in the throat, particularly when the membrane has disappeared as a result of treatment. It is just this appearance that characterizes the palate and fauces in opening stages of true scarlatina. So difficult is the differential diagnosis in some cases that the most expert are deceived. The points upon which I am accustomed to rely are as follows:

Antitoxin Rash (Scarlatiniform).	*True Scarlatina.*
Vomiting rarely preceding the rash. More or less partial distribution of the eruption. The presence of a non-scarlatiniform eruption, erythema multiforme in character, at isolated areas of skin; frequent disappearance and reappearance of the rash; joint pains early.	Vomiting preceding rash. Eruption much more even, of a uniform character although varying in degree; duration more than three days; no joint pains at beginning. Does not disappear and reappear at irregular intervals; joint pains late, if any.
Duration generally shorter than true scarlatinal rash.	
Desquamation rare, and when it occurs much finer than in true scarlatina.	Desquamation in strips.

The presence of diphtheria prevents the throat and tongue symptoms from being of any value in the differential diagnosis.

The form of erythema (?) known as pityriasis rubra I have seen in a rash following the injection of antitoxin. Here the duration of the desquamation was as marked as in that well-known skin lesion. Its differentiation from scarlet fever should not be difficult. It is proper to speak here of the exanthema which is so frequently present in toxic diphtheria. I do not refer to the petechial eruption consisting of isolated petechiæ scattered through the skin, and due to small extravasations of blood into the superficial layers of the skin. I mean the irregularly distributed reddish-purple, mottled, macular eruption which spreads over the integument in septic forms of diphtheria. It resembles some forms of erythema multiforme, and when it occurs remains until a fatal result has taken place. The spots are irregular in shape, of a deep red color in the centre, and fading toward the periphery. This eruption occurs as a manifestation of the weakening effect of the diphtheria poison upon the heart, causing a slowing of the capillary circulation. The localized congestion of the cutaneous capillaries is the

result. It is apt to occur in some cases of septic diphtheria, whether they have been treated with antitoxin or not, and is not an antitoxin rash. It can be differentiated from such rashes by the fact that it increases in extent and depth of color as the heart becomes weaker. In its final stages the skin, especially about the face and extremities, becomes congested and swollen. It is further contradistinguished from the antitoxin rash in that the maculæ have a general resemblance to each other, while in the antitoxin rash the eruption is apt to be an erythema in one part of the body and erythema multiforme in another. Furthermore, this eruption does not disappear and reappear as do the rashes following antitoxin injection, but is progressive and generally persists until a fatal result occurs.

In some cases of diphtheria, even those that are mild but in which the onset is accompanied by high temperature, an erythematous blush is sometimes seen over the neck and face at the beginning of the disease. This rash, if it may be so called, disappears in a short time, and will not be diagnosticated as an antitoxin rash, inasmuch as it is present before the antitoxin is injected.

Pathology.—There is but little to say concerning the pathology of these eruptions as such. The chief fact to be noted is that all of the varieties of these rashes which I have described are primarily a disturbance of the circulation of the skin. As to whether these disturbances go on to produce the lesions characteristic of true inflammation or do not progress further than a simple hyperæmia, as in the simple erythematous rashes, is only a question of the degree and extent of the circulatory disturbance. Unna says that in toxic erythemas the majority of the cases show as pathological changes hypertrophic changes around the blood-vessels and dilatation of the lymphatics of the skin. Certainly in those cases in which the eruption resembles scarlet fever and measles there is an acute inflammation extending from the capillaries of the skin more or less widely into the epidermis.

The one important point to remember is that the lesion is primarily a lesion of the blood-vessels of the skin.

Pathogenesis.—If we may hope to obviate the occurrence of the rashes which follow the injection of antitoxin serum, it is evident that it becomes a matter of the highest importance to understand the *rationale* of their production. This portion of the subject is the more obscure in that it involves problems of great complexity, for the solution of many of which the data are insufficient. It is evident, however, that the cause of these rashes is the introduction of antitoxic serum into the circulation. This acts as matter foreign to the blood.

Diphtheria antitoxic serum may be said to consist, for our purposes, of horse serum charged with a material known as diphtheria antitoxin.

It is proper to inquire:

1. Is the horse's blood serum as such the irritating cause of these eruptions?

2. Is it the antitoxin which it contains?

3. Is the product which results from the action of the diphtheria antitoxin upon the diphtheria toxin present in the blood of the patient the irritating cause of these eruptions?

To these three questions we can give answers depending for their truth upon reliable observations by competent observers.

It has long been known that when blood serum of an animal of one species is injected into the blood of another it exerts a toxic action. This toxic action depends upon the quantity of blood serum injected. Rumno,[1] who investigated this subject, termed blood serum of animals of the same species "homogeneous blood serum;" that of animals of different species "heterogeneous blood serum." He found that the injection of homogeneous blood serum was less toxic than the injection of heterogeneous blood serum. Rumno thinks that the toxic action of blood serum depends on the action of special toxalbumins. Alexander Schmid believes that this toxic action depends upon the soluble fibrin ferment of one blood serum when injected into the blood of other animals. Rumno found that this toxic action of blood serum is very decidedly lessened by passing the serum through the Chamberland filter. Rumno claims that it is not due to the fibrinogen of the blood causing minute emboli, for the reason that the toxic power of homogeneous blood serum is very much less than that of heterogeneous blood serum.

Bertin[2] injected non-immunized horse serum into children suffering from diphtheria, and found that in three of the patients erythema developed. Sevestre[3] injected four children suffering from ordinary angina with serum of non-immunized horses and observed erythema in all of them.

Finally Johannessen, of the University of Christiania,[3] injected twenty-three individuals not suffering from diphtheria with from two to fifteen cubic centimetres of pure blood serum of a healthy non-immunized horse. Nineteen of the individuals had the serum filtered. In four patients the serum was injected unfiltered. A more or less general erythema occurred in twelve of these twenty-three cases from the first to the eleventh day after the injections. The unfiltered serum produced greater disturbance than the filtered.

I could multiply authorities who can be quoted to prove the same facts. From these experiments we can derive the fact, that pure blood serum of the horse does produce eruptions in a large percentage of cases. 2d. The antitoxin present in the diphtheria antitoxin serum does not add to the frequency with which these eruptions result. 3d. That such erythemas occur after the injection of non-immunized horse's serum into healthy human beings. Furthermore filtering normal horse's serum by passing it through a Chamberland filter diminishes the frequency of the eruptions very much.

Having thus determined that the active factor in the production of these rashes is the horse's serum as such, it becomes a matter for inquiry how this foreign material, horse's serum, when injected into human beings, produces these eruptions.

Behrend, in his works on skin diseases, advocated views with regard to the method of the production of the toxic erythemata which have the support of Unna, Kaposi, and others. Applying his views to such erythemata following injections of antitoxic serum I deduce:

1st. Such serum when injected can exert a direct irritating effect upon the vasomotor nerves and blood-vessels at the site of the injections, thus producing local congestion and dilatation of blood-vessels, *i.e.*, a local rash.

2d. It may, when absorbed into the circulation, affect the vasomotor centres in an irritative or paralytic manner, so as to cause a general cutaneous eruption.

3d. When excreted from the circulation by the capillaries of the skin and sweat glands, it may exercise a direct irritant and paralytic action upon these peripheral capillaries and adjacent tissues, so that exanthemata are developed.

The local rashes, generally simple erythema, occur-

[2] Semaine Medicale, 1895, No. 15, p. 142.

[3] Deutsche med. Wochenschrift, December 19, 1895, No.

ring at the site of the injection and spreading from there over the adjacent areas of skin, are evidently produced in the manner first stated, *i.e.*, by direct local irritation. All the other rashes I have described, partial or general, are either the secondary result of the irritation of the vasomotor centres, or are produced in the process of excretion of the serum from the body by the capillaries of the skin and sweat glands. This last method of production is by far the most frequent. I am led to this conclusion by the study of a very interesting and valuable contribution concerning the mode of excretion of diphtheria antitoxin from the body, by S. Dziergowski, of St. Petersburg.[1] This investigator's experiments and studies were to ascertain the amount of antitoxin contained in the different organs and fluids of the bodies of immunized horses. He found that of the excretory fluids the urine and sweat contained by far the largest amount of antitoxin, and practically it is through the urine and sweat that the antitoxin is gradually excreted from the system. Now we have already seen how probable it is that the "heterogeneous" (horse's) blood serum is the cause of the occasional eruptions. And it is very likely that the irritating elements of this, the carrier of the antitoxin, are excreted in the same manner as it is and with it by the urine and sweat. It is well known that increased activity of a gland causes increased circulation and dilatation of its inherent and surrounding capillaries. That, in itself, would cause an eruption. Further, the sweat which carries these irritating elements would exert a direct irritant or paralytic action upon the cutaneous capillaries. While most of the sweat is secreted by the sweat glands, "some fluid," as M. Foster says, "must pass by simple transudation through the ordinary epidermis of the portion of the skin intervening between the mouths of the glands." The same physiologist further says: "The secreting activity of the skin, like that of the other glands, is usually accompanied and aided by vascular dilatation." Where the injected serum is especially irritating, this vascular dilatation surrounds not only the sweat glands and their ducts but the whole epidermis, giving rise to the scarlatiniform or the various erythema-multiforme eruptions. With an increased degree of irritation in the serum there is even a greater strain placed upon the sweat glands to get rid of the irritant; the vessels around these dilate to an excessive degree and the erythematous rash becomes a morbilliform eruption. In by far the greater number of cases, however, the ordinary exercise of the transudative and perspiratory functions of the skin is sufficient without any exaltation to rid the circulation of the foreign serum, so that by far the larger number of patients treated with antitoxin do not suffer from rashes as a sequence of such treatment.

It appears possible that in a somewhat similar manner the eruptions of the acute infectious diseases, like measles, varicella, variola, scarlet fever, and others, may be produced. It would appear possible that in these diseases the characteristic germs, having gained access to the blood, develop there, during the period of incubation, their toxic products. Every effort is made by the excretory functions of the body to get rid of these toxic agents. The excretory power of the skin, the kidneys, and mucous membranes is brought into play, hence the characteristic manifestation in all of these organs in the course of these diseases; thus the eruption and catarrhal inflammation of the mucous membranes, characteristic of measles, the eruption and characteristic inflammation of the throat and later on of the kidneys in scarlet fever, etc. I recognize readily that this the eliminative theory of the production of the cutaneous manifestations of the acute eruptive diseases does not explain why the eruptions uniformly differ clinically in their appearance in the different diseases. Yet a further inquiry into the pathological anatomy of these skin lesions that is proper in the limits of this paper, devoted to an entirely different subject, would render many of these points less inexplicable.

This paper, upon the eruptions frequently following the injection of antitoxic serum, would be incomplete, did we not attempt by the light of the facts gleaned to indicate possible improvements in diphtheritic antitoxic serums, so that the eruptions should become less frequent.

But first, lest any enthusiastic opponent of the antitoxic treatment of diphtheria should hope to find in the preparation of a paper on serum rashes even slight encouragement for his tottering views, I would here reiterate that it is because of my enthusiastic appreciation of the vast improvement in the treatment of diphtheria which has resulted from the use of the antitoxic serum that I devote this feeble effort to add to the perfection of a remedy which is one of the most marvellously successful therapeutic procedures of the century. We have no longer to establish the beneficent nature of this treatment. That is established beyond question. It is for all of us to improve it and obviate any of its disadvantages. As far as these rashes are concerned, it will appear from what has been said that the inherent cause of their appearance lies in the serum as such, and not in the antitoxin. I will ask pardon therefore for giving here a short *résumé* of methods followed in the production of this serum in the body of the horse, in order that it may be better understood how it may be improved, with a view to diminishing or even preventing these rashes.

A horse is immunized to the toxin of virulent Klebs-Loeffler bacilli by injecting into the animal gradually increasing doses of the poison until the largest possible dose of the toxin no longer serves to produce any rise of temperature or other signs of sickness in the animal. The horse is not very susceptible to the diphtheria poison. An initial dose of 2.5 c.c. of strong toxin often causes but very little fever and very slight local œdema. As a rule, however, a dose of 0.25 c.c. of strong diphtheria toxin is sufficient for an initial dose. The dose is increased with every successive injection, until after two or three months 250 c.c. or more of the strong toxin can be injected without causing any irritation or increase of temperature. The blood serum of an animal thus immunized contains an antitoxin of great protective and curative power. The strength of any given sample of an antitoxin serum varies directly with the virulence and dose of toxin to which the horse from which such blood has been drawn has been immunized. A horse that has been immunized up to a dose of the maximum quantity of the strongest obtainable toxin yields a more potent antitoxin serum than one that has been immunized to an equal quantity of a weaker diphtheria toxin. Thus, while some animals yield a serum of the strength of 50, 100, or 200 antitoxin units to the cubic centimetre, others yield a serum of the strength of 1,000 units to the cubic centimetre. It will readily be seen that, when a given dose of antitoxic serum is to be injected into the patient, the volume of the serum to be injected will be inversely as the antitoxic strength of the antitoxic serum. Thus, while a dose of 1,000 units would mean 10 c.c. of a 100 unit serum, it would require but 2 c.c. of a 500 unit serum to give the said dose. The importance of the volume of serum injected, as far as the antitoxic rashes are concerned, will presently appear. The blood of horses thus immunized to diphtheria and containing the antitoxin is drawn from the jugular, with every antiseptic precaution, into a perfectly sterilized flask, with

[1] Archiv für experimentelle Pathologie und Pharmakologie, 1896–97, xxxviii., pp. 186–214.

a broad base and long neck, the mouth of which is closed by cotton as soon as the flask is about one-third full (Figs. 5, 6, 7) The bottle is then placed on a stand, so arranged that the former lies at an angle of about forty-five degrees. This tilted position is prefered, because in this manner the blood serum which separates after clot-

Fig. 5.—Injecting the Toxin.

ting can be most readily withdrawn. The slow clotting of horse blood is further aided by placing the bottles containing this freshly drawn blood into the refrigerator. The result is a very well-marked "buffy coat." The red blood globules, having had time to fall to the

Fig. 6.—Incision for Inserting Cannula into Vein.

bottom before the clot has become firm, leave a comparatively colorless layer on the top. Clotting under these conditions gives a firm and hard clot, with the largest possible amount of serum (Fig. 8). The serum surrounding the clot which has formed in the flask is

Fig. 7.—Drawing the Blood from the Vein.

withdrawn by means of a tube passing into another bottle, the tube being connected with an air pump. These bottles are permitted to stand in the refrigerator in the upright position. After the antitoxic strength of a given drawing of serum has been tested, the serum is ready for distribution into the small bottles in which it comes to the physician. This transferring of the serum from the large bottles into the small sterilized bottles is accomplished with the strictest precautions for the maintenance of the absolute sterile condition of the serum. It is important here to call attention to the fact that in the large bottles containing the antitoxic serum, if allowed to stand for a time, a more or less dense whitish cloud of flaky material gradually forms at the bottom. This material disappears if the contents of the bottle be subject to slight shaking. It probably consists of the fibrinous constit-

Fig. 8.—Flasks Filled with Antitoxin Serum and Clot (to left). Sterilizer for Flasks to Right.

uents suspended in the blood serum and not included in the clot proper.

This short *résumé* of important steps in the process of the manufacture of diphtheria antitoxic serum is to enable us to appreciate some practical recommendations in the making and use of the serum, with the object of diminishing the frequency with which antitoxin injections are followed by rashes.

It was seen that these exanthemata are not the result of the antitoxin element of the serum, but are rather the effect of the serum itself, irrespective of the antitoxin which it contains. It would therefore commend itself to the most superficial investigator that it is important to give the necessary quantity of antitoxin in the smallest quantity of serum. In other words, it is advisable to use a serum of the greatest antitoxic strength. The health board laboratory has manufactured serum of the strength of one thousand units to the cubic centimetre. This is as strong as any manu-

Fig. 9.—Separating Serum from Clot.

factured. The difficulties in the way of manufacturing this serum are the large dose of toxin to which the animal must become immunized, which presupposes a strong animal and the obtaining of toxins of extraordinary virulence, for upon this even more than the strength of the dose of toxin does the strength of the resulting antitoxin depend.

Another important factor in the production of these rashes was found to be the irritating effect of the "heterogeneous" horse serum upon human blood serum. It is evidently impossible to remedy this

defect, but it is found in practice that a "heterogeneous" serum, obtained from a given individual of a species, is more irritating than the serum from another individual of the same species. It follows that when a particular "drawing" of serum has shown itself to be especially irritating, causing frequent rashes, such a serum should be discarded, while the serum of a horse which has shown itself to be less irritating should be preferred.

Fig. 10.—Filtering Serum.

Finally we come to discuss a very important means of preventing or diminishing the occurrence of these exanthemata. The experiments of Rumno, Johannessen, and others show that while pure horse's serum, non-immunized, produces when injected into the human body rashes such as I have described, with as great frequency as the serum from horses immunized to diphtheria, the number of cases in which rashes occur is very much diminished if the serum be *filtered*. This was shown to be true of the serum from immunized as well as non-immunized horses. It is important, therefore, that the antitoxic serum used in the treatment of diphtheria should be thoroughly filtered by passing through a fine Chamberland filter before injected (Fig. 10). Through the courtesy of Dr. William H. Park, of the bacteriological laboratory of the health board, I was enabled to test this subject thoroughly. During the past six months a portion of the antitoxin used in the Willard Parker Hospital was, at my instance, passed through a Chamberland filter, and a considerable proportion of the cases was treated with filtered antitoxin, while others were treated with unfiltered antitoxin. Two varieties of filter were used. One was a porcelain filter of fine porcelain, through which the antitoxic serum filtered very slowly, even when filtered into a vacuum. Later on, in order to filter more antitoxin, a very much larger and coarser filter was used, through which the antitoxin passed quite readily. When thus filtered, however, the antitoxin did not yield as favorable results as were obtained from that passed through

Fig. 11.—Making an "Antitoxin Injection" upon a Patient.

the fine filter. The serum that passed through the coarse filter was hardly less irritating than that which was unfiltered. But let me give you the figures:

September, October, and November, 1897. Cases treated with antitoxic serum filtered through a fine Chamberland filter. Number of cases, 24. Developed a rash, 4, or 16 per cent. Of the 20 that did not develop rashes 9 cases were under observation less than ten days.

Cases treated with same antitoxic serum unfiltered. Number of cases, 15. Developed a rash, 7, or 46 per cent. Of the eight that did not develop rashes 6 were under observation less than ten days.

Total number of other cases treated during the time of observation with other antitoxic serum than the bleedings under test, 95. Developed a rash, 30, or 31 per cent.

It is seen that the filtered serum caused only a little more than one-third as many rashes as the unfiltered serum, and only about one-half as many rashes as serum of all other bleedings used during the time of test.

So favorably was I impressed by this showing that it was determined to use the filtered antitoxin more extensively. This made the demands upon the laboratory for filtering the antitoxin greater. As I have said, the filtering through a fine filter is extremely slow. A very much larger and coarser filter was therefore substituted, which filtered more serum. Furthermore the resident physicians of the hospital, Drs. Somerset and Poore to whom I owe thanks for invaluable aid in observing and recording these rashes—being desirous to use in the worst cases the serum which would give the best results, used the filtered serum which was furnished almost exclusively upon severe cases, while mild cases were treated with unfiltered serum. I mention this because in severe cases, remaining in the hospital a longer time, a rash could not fail to be observed if it occurred, while the mild cases, being cured and discharged many of them before the tenth day, might develop a rash, which we could not count because we did not see it in the hospital. The figures are as follows:

December, 1897, January and February, 1898. Cases treated with antitoxic serum filtered through a coarse filter, 30. Developed a rash, 13—8 severe, 5 slight—or 43⅓ per cent.

Cases treated with same antitoxic serum unfiltered, mostly mild cases, 60. Developed a rash, 19—10 severe, 9 slight—or 31⅔ per cent.

Finding, as I stated above, that the resident staff was using the limited amount of filtered antitoxin which could be obtained, even with the use of the large filter, upon the severe cases, I asked Dr. Poore to use the antitoxin thus filtered by the coarse filter upon cases of about equal severity with those upon which the unfiltered antitoxin was used. The results thus obtained during March and April were as follows: Cases treated with filtered antitoxic serum (coarse filter), 49. Developed a rash, 13, or 26 per cent.

Cases treated with same antitoxic serum unfiltered, 58. Developed a rash, 15, or 26 per cent.

These latter cases prove that passing the serum through a coarse filter is equivalent to not filtering it. So firmly have I been impressed by the experiments of Rumno, Johannessen, and others which I have cited, that filtered horse serum when injected into human beings produces serum exanthemata less frequently than unfiltered serum; so thoroughly has this favorable impression been fortified by the results obtained in those of my cases treated by antitoxic serum properly filtered through a fine Chamberland filter, as in the cases given in the first group, that it appears to me highly desirable that all horse's serum which is to be used in serum therapy of disease should be carefully filtered through the finest possible Chamberland porcelain filter. I recognize the difficulties connected with filtering antitoxic serum. The maintenance of absolute sterility presupposes the least possible manipulation of the serum in the process of manufacture. But filtering does not necessitate an additional step in

the technique of manufacture, for the filtering could be accomplished directly from the vessel into which the serum is drawn from the bottle containing the clotted blood. The filtering surface can be increased by substituting for the single porcelain candle a number of candles all opening into one central tube, to which the air pump is connected. In this way a very much larger quantity of serum can be filtered.

The antitoxin thus filtered was tested in the laboratory, with the object of determining whether the serum had lost any of its antitoxic strength in the process of filtering. Dr. Park tells me that in every case the serum retained after filtering the same antitoxic strength which it possessed before filtering. It is an interesting question as to what the filter removes from the serum. Rumno[1] thinks that the toxic action of blood serum depends on the action of special toxalbumins, and it is probably these toxalbumins which are separated out of the serum when passed through a filter. The white flaky deposit which I have observed at the bottom of the bottles of unfiltered antitoxic serum which have stood for some time, and which consists for the most part of coagulated fibrin, disappears when the serum is filtered. When it shall be possible to extract the antitoxic principle from antitoxic blood serum and inject the antitoxin in sterilized solution, the ideal aim of removing the irritant effect of the "heterogeneous" animal blood serum will have been attained. Until this is practicable, thorough filtering of the serum should be practised.

I do not think that the agents used to preserve the antitoxic serum from decomposition have any influence in the production of these rashes, for the following reasons: 1st. The quantity of the preservative added is too small to have a deleterious effect. 2d. Antitoxic serums preserved by carbolic acid, terkresol, and camphor, as well as those that have no preservative added, produce the eruptions with about equal frequency when the other factors which I have mentioned remain equal.

I have thus attempted to describe and classify clinically the exanthemata which occur after antitoxin injections. It has been shown also, first, that these eruptions are due for the most part to the animal blood serum as such and not to the antitoxin which it contains; secondly, that the cutaneous manifestations are the result of the excretion of the irritant elements of the blood serum by the sweat glands and blood-vessels of the skin; and finally, that the careful filtering of the serum is apt to be followed by diminution in the frequency of these exanthemata.

ON THE TREATMENT OF CARBUNCLE.[2]

By THOMAS H. MANLEY, M.D.,

Professor of Surgery, New York School of Clinical Medicine.

It is well known that felons, erysipelas, and carbuncle are most commonly observed during the spring and early summer. They all present many features in common, although the clinical distinction is clear enough. They often appear to be aroused into activity by some local change in the tissues, produced and maintained by what we vaguely designate "constitutional disturbances," but of which we certainly know very little.

Carbuncle.—Meredith defines a carbuncle as "a local specific inflammation of the subcutaneous areolar tissues, rapidly leading to sloughing of the deeper and more compact parts; followed by destruction of the skin, the whole of the dead tissues finally separating in the form of a slough."[3]

[1] *Op. cit.*

[2] Read before Society of Medical Progress, New York, March 20, 1898.

[3] Quain's "Dictionary," second edition, p. 275.

Carbuncle is a lesion which presents many very puzzling features. In all of its phases, as a rule, it is a very painful affection, in most instances commencing as a papule with an indurated base, assuming an intense inflammation, finally running into suppuration and gangrene, with later granulation and cicatrization of the ulcer. In this respect it is identical with whitlow. In other more aggravated phases the extent of constitutional disturbance is considerable; bodily strength rapidly fails and well-marked evidence of infection of the circulation is present.

In many cases of this class carbuncle kills. Meredith says that "death may come from exhaustion, which is sometimes aggravated by *hemorrhage, the result of free incision* [italics mine], but the most frequent cause of a fatal termination is pyæmia."

Local Changes in the Parts.—Carbuncle kills, then, by the protracted, agonizing distress it occasions, which racks the system and cripples the vital powers; and by the toxic effects of resorbed dead tissues, ichor, pus, and bacteria. This lesion gives issue to grave symptoms only when certain local pathological changes set in.

How may these be aborted or rendered innocuous, or is either result possible? This brings us to the consideration of treatment.

Treatment: Constitutional or Local, Prophylactic, Palliative, or Radical.—Within the past year two notable essays on the therapy of carbuncle have been contributed by two distinguished members of the medical profession of New York: the first by Dr. L. Duncan Bulkley, and the second by my colleague, Prof. Carl Beck. Both of these contributions are noteworthy because of the extreme tendencies inculcated in each; by the former in the direction of conservatism and palliation, and by the latter in recommending early and complete excision.

Early Excision.—Beck says: "As the infiltrated tissue must be eliminated at all hazards, be it infected by whatever bacteria, it is better to sacrifice it at once and to remove it with its disastrous inhabitants."[1]

Theoretically this position cannot be assailed: *i.e.*, a limited focus of virulent infection of any description, wherever found, should be eradicated. But practically this is often either injudicious or impossible.

Anthrax, although its favorite site is along the lateral areas of the vertebral column, may develop on any part of the cutaneous surface of the face, the trunk, or the extremities. From our experience in excising chancres or buboes, it is well known that before the stages of suppuration or ulceration it is impossible to determine just how wide the limit of invasion is; and, hence, quite in spite of a free dissection, suppuration will invariably follow, with a large, open breach in the tissues, left to heal by granulations. Again at times a wide area is involved by an infiltration which extends deeply into the neighboring parts, so that a free division of important and highly vascular structures will be necessary in excising the indurated parts.

In the incipient or papillary stages of carbuncle, excision affords us a simple means of at once and radically dislodging it, though we may have to repeat the procedure with each eruption of a fresh papule.

Finally, the most cogent objection one can bring against excision is that it may involve an operation requiring the employment of pulmonary anæsthetics, although when the area invaded is of limited dimensions a local analgesic will suffice; but in any event the tissues must be divided with loss of blood. It goes without saying that in carbuncle of huge proportions extending deeply into important structures it is quite

[1] "Radical Treatment of Carbuncle," The Medical Record, January 1, 1898.

impracticable. If anything like an extensive dissection be required, our patient must remain quiet until at least repair is well begun.

Conservative Treatment.—At the late meeting of the British Medical Association in Montreal, Dr. Bulkley, of New York, submitted a somewhat remarkable essay on the treatment of felons, boils, and carbuncles, which, coming from one so well and widely known, must work incalculable mischief.

He begins by saying that "the knife has long been associated in the minds of both the laity and profession with the treatment of boils, felons, and carbuncles, and incision is the recognized treatment on all sides." He declares that he has not incised a carbuncle in fifteen years, and adds that "if others will carefully and intelligently carry out the details in treatment, they will have equally as good results as himself." He advises the same general plan for felons and carbuncles. Now, it certainly would be an enormous gain to medical science if surgery could be dispensed with in a class of cases which practitioners have always regarded with serious apprehension, and which are sometimes a source of terrible torture and even danger to life.

Let us see what this innovation consists in. First, internal medication; the sulphate of calcium for its supposed controlling action on suppuration, purgatives, tonics, etc. Secondly, something locally, of a protecting, soothing, and antiseptic character. The doctor quotes Paget as condemning the incision of carbuncle under all circumstances. It is true that this celebrated surgeon severely criticised the indiscriminate cutting of carbuncles—the deep crucial incision—unless one was certain of deep-seated suppuration; but that was nearly twenty-five years ago, long before the first days of Listerism had flashed on the horizon, and hence principles of treatment regarded as orthodox then are now effete and antiquated.[1]

Kaposi declares that "treatment of carbuncle in its direct sense is almost powerless, as it cannot be cut short by ice, heat, or early incision."[2] Gottheil advises "free and early incision followed by thorough curetting as of benefit in some cases, but complete extirpation is better."[3]

Sulphide of calcium in my own hands has invariably proven inert as a pus destroyer; but what is of vital importance to bear in mind right here is that in the early stages of both felons or carbuncles there is no pus whatever. Several years ago the last phalanx of my little finger (left hand) was the seat of a felon. For three days and nights the agony was something dreadful. In the mean time various local remedies were tried, without the slightest relief. On the fourth day the physician was permitted to do what he wished to do on the first, viz., to sink the blade of a strong bistoury down deeply to the bare bone. The effect was instantaneous, but not a drop of pus escaped. Several times in the early and always the most painful stages of felons have I opened them with the same result. My experience has been that when the pain ceases gangrene has begun, or the bone is necrosed. In genuine felon, true paronychia, which does not early abort of itself, penetration to or destruction of the diseased process beneath the periosteum alone will save the affected joint or cut short the inflammatory changes.

It is inconceivable and contrary to all experience that any oleaginous, impermeable, or antiseptic substance can penetrate through the unbroken derma to reach the seat of disease. In fact, there are but very few medicaments which the skin can absorb at all.

That the constitution is involved in these cases is undoubted, and that bracing reconstructives are sometimes needed is certainly correct. In advanced cases, however, the grave enfeeblement of the vital powers with marked evidence of pyæmic absorption is a consequence and not a cause. That glycosuria is anything more than a coincidence occasionally in carbuncle is by no means proven.

Sir James Paget is the authority for the statement that carbuncles sometimes spontaneously abort early. I have never seen one do so, and the probabilities are that the local induration described by him as carbuncle was some simple form of papillary intumescence. The tendency of unchecked carbuncle is toward progressive destruction of tissue, suppuration, necrosis, and sloughing of tissue, with the great dangers superadded of septic infection, pneumonia, meningitis, etc. To dally with a lesion of such a serious character is, to put it mildly, a grave error. In the remote past, before the days of anæsthetics or antiseptics, we did well to spare our patients the terrors of the blade for whitlow or carbuncle, until every possibility of mistake in diagnosis was eliminated and the thing was "ripe;" but that won't pass for up-to-date surgery in our time; for it may be, and it should be, stated in the most emphatic terms that at the present, in both anthrax and felon, surgical interference must be prompt and radical, though, happily for the poor sufferer now, it may in the former spare him mutilation or the loss of even a single drop of blood.

Potential Cautery.—Moty reports a case of anthrax affecting the lower lip, with secondary foci on the breast, the forearm, and the shoulder, treated by puncture with Paquelin's cautery at each suppurating orifice and subsequent dressing with carbolic acid. In some of the smaller foci the disease was checked at once by the puncture, and no more pus was formed. As for the deep-seated ones, the author remarks that the patient's sensations are the best guide to their situation, for at first they do not betray themselves by physical signs; yet it is of importance to treat them promptly, whether pus has formed or not. The part may be cocainized before the cautery is applied.[1]

In the early stages both of paronychia and anthrax they may be so effectively benumbed with cocaine as to admit of all necessary manipulation. The potential cautery, Paquelin's, or the electro-cautery, may be used with great satisfaction on many types of carbuncle not calling for total eradication and which are easy of access.

Direct, Immediate, and Total Destruction of the Carbuncular Tissue by the Deep or Hypodermic Injection of Pure Carbolic Acid.—Five years ago I commenced the treatment of carbuncle by the injection of pure carbolic acid. I am assured now that this method is simple, safe, and durable in its results. To inject concentrated carbolic acid directly into the living tissues, however, may strike one as a measure fraught with danger, and is a measure which must be exceedingly painful. The first case of carbuncle which I tried it on came under my care in its acute inflammatory stages. It was the source of the most intense pain, with marked constitutional disturbance. The pulse was 116 a minute, the temperature 103° F. Through loss of sleep and appetite my patient was reduced to great weakness. He had delayed professional aid till late, because of his fear of an operation.

In this instance the carbuncle was large, with several openings, lying over the midcervical region of the spine. In this instance the effects of carbolic-acid injection were most extraordinary. Since then I have treated in both sexes more than fifty cases of carbuncle. About three-fourths of my patients were in hospital and dispensary practice. Five were physicians and three physicians' wives. There was no mortality, and in no

[1] Paget's work appeared in 1875.
[2] Kaposi: "Skin Diseases," p. 217, vol. i.
[3] Gottheil: "Illustrated Skin Diseases," p. 176.

[1] The Indian Medical Record, February 17, 1898.

single instance was there protracted delay in repair, except in those which came under my care late. Without exception when employed early this method arrested the advance of the boil, nipped it in the bud, so to speak, destroyed it root and branch, and, what is an enormous gain under these circumstances, permitted the afflicted to continue with comfort their ordinary occupations. Crocker in his work on skin diseases notes that "it is said that a one to ten per cent. hypodermic injection of carbolic acid will abort carbuncles." He does not appear to have had any experience with it himself.

Local and Constitutional Effects of the Deep Injections.—The first sensation the patient experiences after the needle is deeply lodged is a burning heat from the crude acid. This is quickly followed by an immediate loss of all pain. The acid in places when it issues up blanches and chars the tissues, coagulates and destroys the purulent foci over a wide area. In the diminutive inital papule it also at once numbs all pain and stamps it out. The relief is so prompt and the destruction of infective spread so decisive, that the suffering patient again enjoys his unbroken sleep and recovers his appetite. And in this procedure we have an illustration of just the reverse of what is promised through constitutional measures, demonstrating as it does that the *fons et origo* of all the distressing and grave systemic disturbances of carbuncles are entirely dependent on a most virulent local septic process—a process which, if left undisturbed, proceeds to the total death of all the tissues invaded. In no instance in which I have employed these injections has there been any evidence of toxic effects on the system through absorption by the circulation, although it is possible that some of the salutary effects resulting may depend on the phenic elements acting on the system. This view derives some support from the interesting case recently reported by G. Scott Jackson, M.D., of Glasgow.[1] His patient had an anthrax, resulting from an infection of a sore on a sheep. The sore on the arm having attained great proportions, the whole limb being enormously swollen, Jackson cut deeply down through the infiltrated mass, and then mopped the divided surfaces with pure carbolic acid. Besides, he immediately placed his patient on carbolic acid and iron internally, ten grains of the acid and ten of ferric tincture. From a desperate condition his patient was immediately relieved, with a subsidence of all the symptoms and rapid recovery. The writer believed the satisfactory result was attributable to the loss of blood after incision and the large doses of carbolic acid.

Technique.—Before describing the details of the phenic injections for virulent abscess it is necessary to state that they must be modified to meet the requirements of the various stages and types of the lesion. It may be well to bear in mind also that when utilized late their most precious value is lost. The time for prevention, prophylaxis, has passed, and dead tissues cannot be recalled to life; but even when utilized in the advanced stages of the malady their value is infinite in arresting pain and checking the farther advance of disintegrating processes.

In employing this powerful agent let us be quite certain that we are dealing with a genuine anthrax, in order not needlessly to subject our patient to such heroic treatment for, perchance, an innocuous transient papule. Before we proceed to inject the fluid acid it is necessary first to carefully cleanse the surface, and then spray with ethyl chloride the part about to be punctured.

In my early experience I used the pure dissolved crystals of carbolic acid for injections, but later it was found that an eighty or ninety per cent. solution answered equally well. In all cases it is necessary to have a long and strong hypodermic needle, as the tissues are sclerosed and very resistant.

When an injection is made into a carbuncle in its early papillary stage, before extensive infiltration has set in, not more than from one to three drops are necessary. In all these cases, however insignificant the papule, after the acid has penetrated its base, coagulated pus will well up through its centre. Care should always be observed that the surrounding integument be protected against the corrosive effects of the escaping fluid. Quite generally for small undeveloped carbuncles one injection will suffice; but, as we may miss the central "core," or infective focus, the first time, it may be necessary to repeat it once or twice, although this is unusual.

Carbuncle in the Suppurative Stages.—After the multiple pustules of a large carbuncle have opened, its surface is raised high, and a wide-reaching, deeply inflamed zone surrounds it; the phenic-acid injection entirely dispenses with the need of incisions for the relief of tension and for drainage, as it totally destroys the imprisoned pus and the pyogenic bacteria which produce it. Pyogenic action extinguished, pain ceases and resolution begins.

In this class the acid must be injected with a free hand. In one case of a most aggravated description in the wife of a physician, into the enormous mass over her back I repeatedly injected as much as thirty drops each time. In carbuncle of massive proportions or great depth the fluid must be sent in to the base.

Here caution must be observed, if we are operating over vascular areas, not to pierce the walls of a vessel and send the toxic charge into the general circulation. It is equally important to clear the large nerve trunks.

In most ordinary cases in this suppurating stage from fifteen to thirty drops are ample completely to destroy all purulent foci. But one needle puncture is needed through the integument. After a few drops are deposited at one point, the needle is partly withdrawn, to be sent in again in a different radius after being turned on its axis. This is repeated until the whole base is thoroughly cauterized.

After-Treatment.—When this method is employed as a prophylactic early, there is practically nothing further to do other than to keep the surface protected until the charred centre, the slough, is detached and thrown off, when complete healing quickly follows.

In large suppurating anthrax carbolization stays its progress only; the extensive gangrenous sloughs must be thrown off by a slow process of ulceration. At times a large hiatus is left to close in by granulation. Here complete cicatrization is sometimes very tedious because of the septic state of the system and want of plasticity in the blood. During the separation of the slough the patient should be freely stimulated and strengthened by the bitter tonics, iron, etc., conjoined with nourishing food. In severe cases the heavy wines and malted liquors are highly useful.

Types of Carbuncles Not Calling for Active Surgical Measures.—Sir James Paget pointed out two very important features of carbuncles which it is well carefully to bear in mind when radical measures of treatment are being contemplated: 1st, that heavy carbuncles tend to spontaneous disappearance in their early stages; and 2d, that many do equally as well without the incision as with it, although he did not deny that the scalpel has a place in all deep-seated suppurating cases.

And so would my experience lead me to advise nothing other than palliative measures in any instance when there is absence of pain; but pain is an essential clinical constituent of any true carbuncle. If it be but transient and trivial, the sore should be let alone, or treated by simple measures; certainly by no

[1] Lancet, March 5, 1898.

aggressive surgery. Such a case I lately saw in the sister of a physician. The carbuncle was situated on the buttock; though freely suppurating, it was quite painless. With moist dressings and compression repair was quite rapid and complete.

Cases Suitable for Conservative or Non-Operative Treatment.—Pseudo-furuncle or carbuncle, those painless papillary projections from the cutaneous surface which occasion no inconvenience and make no impression on the system, should be treated with placebos or simple remedies.

For some reason, yet a mystery, even a malignant ulcer may continue its ravages without any pain; and so sometimes one may resolutely convince himself that he has no severe injury, though the head of a bone is luxated or a shaft sundered, because he endures no sufferings. In certain individuals a suppurating, sloughing carbuncle causes no pain or marked soreness. Generally with this class there is but little if any severe constitutional disturbance.

With the above class Dr. Bulkley's line of treatment may be adopted with advantage, because it obviates mutilation and seeks to eliminate the *materies morbi* from the system. As between excision and phenic congelation, for reasons set forth, the painless mummification should be quite generally adopted.

MIDDLE MENINGEAL HEMORRHAGE IN A WOMAN, SIXTY-NINE YEARS OLD: OPERATION; RECOVERY.

By CHARLES L. SCUDDER, M.D.,

ASSISTANT IN OPERATIVE AND CLINICAL SURGERY, HARVARD UNIVERSITY; SURGEON TO OUT-PATIENTS, MASSACHUSETTS GENERAL HOSPITAL, BOSTON, MASS.

M. A. B——, sixty-nine years old, a spinster, was brought to the accident room of the Massachusetts General Hospital at about 10:30 P.M., with a history of having fallen one and one-half hours previously, upon being struck by a coasting-sled.

Examination: She does not know of the accident which has befallen her, nor why she is at the hospital. She talks coherently. She recognizes her sister. There is slight shock. The pulse is 64 and of fair strength; the respiration is 16; the temperature is 97.5° F. There is bleeding from the right ear. There is some dry blood about the nostrils. There is no visible external injury. There is no paralysis. All the superficial reflexes are present. The pupils are contracted equally and react to light. The patient is not very restless, although she talks considerably and affirms again and again that she is not hurt.

The ears were washed out carefully and treated antiseptically.

She vomited two or three times during the night. She was quite restless, moving and turning in bed. She slept two or three hours altogether. There were no evidences of intracranial pressure in the morning. At about noon of the second day she talked a little incoherently. She did not answer questions as readily as in the morning.

At 3 o'clock in the afternoon examination finds the pupils equal and reacting to light. She understands what is said to her, but does not talk coherently or distinctly. There is almost complete paralysis of the right arm. There is paresis of the right leg. The face is not paralyzed. The pulse has increased in rate to 85, is now particularly full and bounding. The knee jerk is much less active upon the right side than upon the left side.

At 4:30 P.M., one and one-half hours after the previous observation, all the symptoms were considerably intensified. The face was uneven, the wrinkles being most marked on the left. The breathing was becoming labored and almost stertorous. It was hard to arouse the woman. She moved the left arm freely. The right arm she moved slightly or not at all. There were no abdominal reflexes active. Bleeding from the right ear continued to a slight extent all day.

A diagnosis of middle meningeal hemorrhage on the left side was made.

At 5 o'clock that same afternoon Dr. J. J. Putnam saw the patient in consultation. He agreeing in the diagnosis, it was thought wise to operate at once.

At 6:15 o'clock, under ether anæsthesia, an elliptical incision was made upon the left side of the head, beginning just in front of the ear, and was carried up across the temporal muscle and down to the zygoma of the same side. A quarter-inch trephine was used (see Fig. 1). The hemorrhage was from a branch of

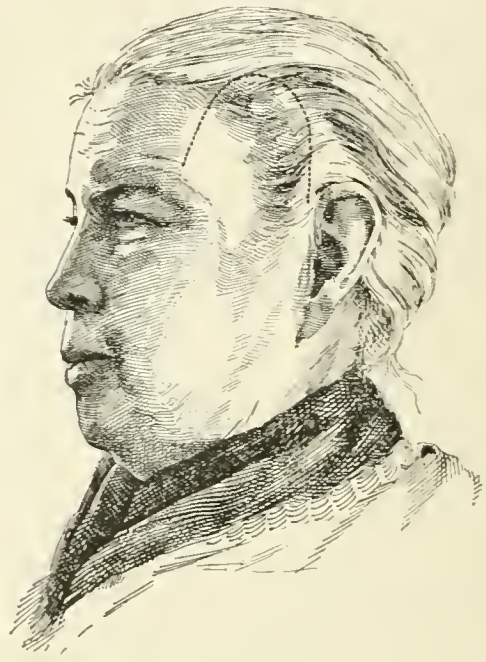

FIG. 1.

the middle meningeal artery, and from within the dura, which was found lacerated. A large clot and much fresh blood were found lying over the temporal and parietal regions. This blood was carefully sponged out. The middle meningeal branch was tied with a silk ligature. Gauze wicks were placed well down deep toward the base of the skull. The dura was not sutured. The bleeding vessels of the diploe were stopped with wax. The skin flap was replaced and sutured, leaving a small gauze drain down to the dura.

The pulse was poor and there was evidence of considerable shock at the conclusion of the operation. Proper stimulation with strychnine and enemata of salt solution and brandy had a good effect. The temperature rose to 110° F. during the night, but dropped immediately and gradually came to normal.

The following day unconsciousness was present, the paralysis was unrelieved, the breathing was stertorous and puffing.

The second day after the operation the gauze drain was removed and two smaller gauze drains were replaced. Some signs of consciousness appear. She takes notice of people coming into the room.

The fifth day following the operation she notices friends. The paralysis is still present.

The sixth day after the operation she moves the right leg a little. No articulate speech is present. Understands questions and grunts in answer to all questions. She can express no idea in words.

The tenth day after the operation she moves the right arm. The mental condition is clearer.

On the eighteenth day she moves the leg, and the arm has some power.

The thirtieth day was an important one for the patient. She walked alone for the first time since the accident. She left the hospital at this time.

One year after the accident the patient is found to be having occasional attacks of dizziness, accompanied by "falling-fits." She is perfectly sane, and talks, often very well; then there come times of difficulty in talking, when she can't find the right word to express herself. Just after one of these attacks of fainting, etc., talking is less easy.

Three years after the operation the following examination was made, Dr. Putnam again seeing the patient in consultation: The speech is thick, slow, and with effort. The facial muscles of the left side are stiff and slightly drawn; they do not move so well as on the right side. The left nasolabial fold is more accentuated than the right. The left eyebrow is lower than the right. The patient thinks that she can hear better with the right ear than with the left. The right hand gets cold "and does not look natural." The right forefinger is often whiter than the other fingers of the right hand. It is difficult to pick up needles or pins with the fingers of the right hand. There is no increase in the wrist jerks. The knee jerk is slightly greater on the right side than on the left.

The patient says she is enjoying excellent health, eats and sleeps well, and is out of doors much of the time. She is taking bromide of potassium regularly once a day in small doses. About once a month she has a fainting or "weak spell." These attacks are growing less pronounced and less frequent.

This case illustrates the important fact that after a severe head injury with almost no external visible sign, the patient should be kept under very careful observation through the hours immediately succeeding the accident. Relative symptoms are of far greater importance in head injuries than isolated observations. Bleeding from the ear as a symptom in head injuries does not necessarily imply fracture of the petrous portion of the temporal bone. Rupture of the tympanum may cause bleeding from the ear. There was no fracture of the skull detected after careful examination in this case.

The interval of consciousness in this case was a somewhat short and hazy one. Immediately after the accident the woman was dazed, and at no time was she herself mentally. It is to be remembered in this connection that the interval of clear consciousness may be so masked by the symptoms of concussion as to be completely overlooked.

NEGLECTED POINTS IN PHTHISIS.

By HENRY H. STONE, M.D.,

ONEIDA, N. Y.

After several seasons passed in the Adirondacks and in the South at resorts frequented by patients afflicted with tuberculous troubles, and coming in contact with them socially, a desire to note with what regularity the importance of diet and exercise had been impressed upon the mind of each individual by the physician previous to departure from home led me to propound the question.

In some instances it had not been mentioned; in most it had been considered but not thoroughly; while in some every phase had been considered and gone into in detail. This apparent neglect so impressed me that surely I am "in order" in calling attention to the fact. I am now speaking of the class of cases which are in the incipient stages, when the chances of recovery are good, and not of the second and third stage cases. In all of our institutions in the North and South, especially directed to the treatment of this malady, the greatest care in detail follows upon these two points; and especially so as to out-door exercise. Numberless patients have I seen who were on the "express for eternity," who had received no instructions; had only been told they would better go to the "Adirondacks" or the "South," as the case might be. These patients were in the habit of remaining up at night as long as they had any one to talk to, and were so tired by that time they could scarcely reach their rooms. The result was coughing and a restless night. With the appearance of morning they were exhausted; they breakfasted in their room, got up for luncheon, took a little walk in the afternoon, and in the evening —a repetition of the night before. This was the usual routine with occasional variation.

What are we to expect from such procedures as I have related? A rapid decline and death, and this in cases in which we might reasonably expect cures. Should we not then be very careful to give explicit instructions, and, when necessary, written ones?

After we have decided upon the locality (my observations have led me to believe that an altitude of from seventeen hundred and fifty to two thousand feet is the proper one for the early stages), then we should go into the details, impressing upon the patients the importance of exercise—not to the point of fatigue—in the open air, frequent walks, deep breathing, etc.; a tent for their siesta; careful attention to the skin. Add then the diet, its great importance, one selected for the case; for without proper assimilation of food the most favorable cases will go down, and with proper assimilation the most unfavorable cases will advance to recovery. To the above more could be added, but such is not the intent of this paper. If I have succeeded in impressing upon the profession the importance of being careful in the future in these cases, I have attained my object; for surely we have not so many means at our command to combat with that we can afford to lose sight of or neglect any one of them.

A New Method of Skin Grafting. — Dr. George T. Doolittle (*The Journal of the American Medical Association*, March 26, 1898) summarizes as follows: 1. With the use of the safety razor any physician can easily obtain large uniform grafts. 2. By the use of large grafts we have little or no contraction of tissue, and the work of covering a large denuded surface is greatly hastened. 3. Where there is a granular surface without ulceration, it is not necessary, in preparatory treatment, to freshen the granulations by scraping; neither is a protective necessary in dressing the surface—it only sweats and softens the grafts. A few words are necessary in regard to the razor. Set the blade forward to about the edge of the guard. Grasp the razor between the thumb and first and second fingers, thumb at the front of the razor and the first and second fingers pressed firmly against the back of the blade to keep it from slipping. With the left hand hold the skin tight just back of where you begin to cut; hold the blade at an angle of about 45° with the skin surface; cut toward you and against the grain; do not be afraid to bear down until you feel the blade taking hold of the skin, which will roll up on the blade as it is cut. After a little practice a strip six or eight inches long can be cut if necessary. Remove the blade and the skin will be found gathered up and the upper surface ready to spread, which is done by placing the blade flat on the granulations, holding down the last cut edge of the skin with some light instrument and withdrawing the blade. The skin will readily spread evenly over the granular surface.

Clinical Department.

FLOATING KIDNEYS.

By FREDERICK CLEVELAND TEST, A.M., M.D.,
CHICAGO,
INSTRUCTOR IN ORTHOPÆDIC SURGERY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL AND WOMEN'S MEDICAL COLLEGE.

The recent perusal of two or three short clinical articles on this condition leads me to offer, as a slight contribution to the literature of the subject, some brief notes on nine cases. As an illustration of the saying that "cases of a kind flock together," five of these presented in two months, and two of them on the same day.

The patients considered comprise a variety of nationalities—a matter of possible interest as indicating a widespread tendency to the condition. Seven of the nine can trace their trouble to traumatism, but the history of the other two is indefinite. In four of the seven the loosening of the kidney was brought about by undue strain in lifting heavy weights, while in three it was due to violent falls. It will be noticed that the cases are almost equally divided between the two kidneys, there being five of the right and four of the left. Again, all of the patients are women, and with two exceptions all are young, the ages of the seven younger averaging twenty-four years.

The authors of the articles referred to seem still to regard loose kidneys as of rare occurrence, but I am becoming more and more convinced of the soundness of the proposition advanced a few years since, that loose kidneys in women are much more common than has been formerly suspected, and am making a search for such a condition a routine part of my physical examinations. Indeed, these notes are intended as a testimony to the frequency of the condition, rather than as an attempt to advance new ideas of pathology or treatment. Whether the increased frequency of finding loose kidneys is due to more careful searching for the condition, or whether loose kidneys are a by-product of our modern civilization, is a query. That seven out of my nine cases were in young women might suggest the latter view, but it is palpably unsafe to theorize from so short a series. It must be also borne in mind that the older generations of women, through prudish reasons, are more reluctant to seek medical advice in regard to lesser and chronic ailments when a physical examination would be necessary.

In examining, the standing position has been usually employed, the patient leaning slightly forward and toward the side to be examined, thus relaxing the abdominal muscles. With the fingers of one hand laid on the abdomen, well up toward the ribs, just external to the rectus muscle, and the other in the same position relative to the quadratus lumborum, the location of the kidney can be mapped out perhaps more satisfactorily than if the patient were lying down. A normal kidney is almost or quite beyond reach of the fingers, but even a slight laxity of the attachments brings the lower border within touch. The contour, and the fact that replacing upward brings instant relief from pain and dragging sensations, are prominent proofs of a correct diagnosis.

In my cases the symptoms most complained of have been more or less definite pains and dragging sensations in the side, together with disturbances of alimentation in almost every instance. In one or two of the cases there have been nervous symptoms, referable to the loose kidneys, in so far as they ceased with the remedying of the latter difficulty.

The treatment has been with pads and bandages, or abdominal supporters, for holding the kidneys in place, although nephrorrhaphy will probably be required in Cases I. and V. to bring about complete relief. Massage and electricity have not been employed.

So far I have been unable to learn of a recorded instance of an actual cure of a floating kidney by the pad-and-bandage method, so that the kidney permanently retained its position on removal of the bandage, but my second case seems to merit the distinction. As it was seen when the lesion was only a few hours old, all circumstances were in favor of the torn attachments reuniting and producing a physiological cure.

Case I.—Miss C——, American, stenographer, aged twenty; seen December 10, 1895. History: Three years previous, while lifting an invalid, the patient had felt "something give way" within her. Symptoms: General weakness and nervousness; frequent attacks of indigestion and flatulence; more or less constant dull ache and dragging sensation on the right side, with occasional throbbing or palpitation in the abdomen, probably due to the kidney pressing on the right common iliac. The right kidney was found very movable. Replacing the kidney, with the patient lying on the back, and maintaining it with pad and bandage, gave immediate relief. Later an abdominal supporter and pad were worn, but the kidney showed a constant tendency to slip down. Operation was refused. On one occasion, in August, 1896, when I was called after the patient had taken a serious "header" down a hillside during a bicycle ride, the kidney was found in the left hypogastrium, and replaced with great difficulty and pain after half an hour's taxis. Through change of residence the patient is no longer under observation, but by long-continued wearing of a snugly fitting supporter and pad has become more comfortable, although an operation probably will be eventually required.

Case II.—Mrs. J——, colored, servant, aged forty; seen February 15, 1896. History: The day before, while lifting a heavy scuttle of coal, the patient had felt a sudden tearing sensation on the right side, immediately and continuously followed by acute abdominal pain. Hernia and uterine prolapse were excluded by examination, and then an ovoid tumor was felt in the right inguinal region. Floating kidney being suspected, this was gradually pushed upward, with moderate ease, when it suddenly slipped away and into the normal kidney position, with instant relief from pain, to the patient's great surprise. A pad and bandage were applied, and rest on the back was enjoined. The patient disobeyed to the extent of doing the family washing, with the result that by evening the kidney had again slipped down and the patient was once more writhing with agony. Replacement was more difficult, but relief just as complete. The bandage was readjusted and the patient kept in bed six or seven days, an abdominal supporter being applied quite tightly on the second day. No urinary or other disturbing symptoms were present. The patient did light housekeeping for three or four weeks, with no trouble from the kidney, and then returned to service. Two months after the injury examination failed to find the kidney out of place, and all inflammation had subsided. In May, after three months, the patient ceased wearing a supporter, against advice, but up to September, when she passed from under observation, seven months after the injury, the kidney had remained in place and the trouble was apparently completely cured. In this case the prompt replacing of the kidney brought about a readjustment of the torn areolar tissues, and the retention by means of bandaging resulted in a reunion, or else the formation of new adhesion bands, by which the kidney was retained in its proper position.

Case III.—Mrs. S——, German, housewife, aged

fifty-four; seen August 21, 1897. History: The patient had been under treatment for complete uterine prolapse of thirty-three years' standing, accompanied of late by cystocele and extensive enteroptosis. The inflammation had been improved, and the uterus and cystocele held up by pessary, when one day the patient asked for relief from a dragging pain on the right side, that had been gradually increasing for three weeks. At this time the patient was unable to lie down, the attempt to do so causing her to scream with the increased pain, so that she had had little sleep for three nights. There were extensive flatulence and constipation, and the urine was diminished about one-half in quantity and very high colored. Examination showed an extremely sensitive kidney that had dropped as low as the umbilicus. Replacement was difficult and painful, but gave prompt relief, although bandages failed to hold the kidney up for more than a few hours. An abdominal supporter and pad, applied a few days later, held the kidney up perfectly; all dragging sensations and tenderness promptly disappeared, the urine cleared, and flatulence vanished. At present the patient expresses herself as being more comfortable than for many years, and performs with ease ordinary household duties. The supporter, by holding up the pendulous abdomen, serves a double purpose: that of affording a support of intestines for the kidney, and that of relieving pressure from above on the uterus, thus lessening its tendency to descend. No history of sudden traumatism could be elicited, and it seems likely that in this case the enteroptosis had some effect in producing the loose kidney, through depriving it of the normal intestinal support.

Case IV.—Miss B——, English, medical student, aged twenty-two; seen August 26, 1897. History: Two years previous, while assisting to move a stove, the patient had felt a "giving away" on the left side, and ever since, at intervals varying from a few weeks to a few months, had had more or less severe pain on the left side, always commencing suddenly—"as if something slipped"—and lasting from a few hours to a couple of days. The pain was worse on walking, and final disappearance usually took place at night, while she was lying down. The left kidney was found to have dropped four or five inches, but was easily replaced, with instant relief. A temporary bandage and pad were applied, and an abdominal supporter was adjusted snugly on the second day, since which time the kidney has continuously remained in position. No flatulence, constipation, or any symptoms other than the dragging pain were noticed.

Case V.—Miss G——, German, factory girl, aged eighteen; seen October 21, 1897. History: After recovery from an attack of peritonitis the patient called attention to a "stitch" in her left side, that had troubled her intermittently for about two years, and which now seemed accompanied by an area of tenderness. The left kidney was found movable about three and one-half or four inches; it was easily replaced, with relief from dragging sensations, but quickly slipped down again. Wearing a supporter and pad gives temporary relief, but the kidney slips down during the day, as the patient's work requires her frequently to stoop and lift heavy trays of condensed-milk cans from the floor to tables. This labor probably induced the displacement. The peritonitis had been ascribed to colonic fæcal impaction, but it is possible that the loose kidney also was a causative agent, to a greater or less degree.

Case VI.—Mrs. H——, American, housewife, aged thirty-three; seen October 25, 1897. History: For three years the patient had suffered with occasional dragging pain on the left side. When the pain was most severe, irregular heart action accompanied it. Indigestion, with intestinal fermentation and constipation, was frequent. The left kidney was found movable about two inches. No history of traumatism could be obtained. Application of bandage and pad gave relief, but the patient is not at present under observation.

Case VII.—Mrs. S——, Irish, housewife, aged twenty-seven; seen October 25, 1897. History: Two years previous, when six months pregnant, the patient had experienced a severe fall while attempting to enter a room through a transom. Miscarriage followed, and since that time there has been increasing pain on the left side—at first an occasional dull ache, but now almost constant and frequently changing to sharp pain. There were some digestive disorders, with flatulence and constipation. No urinary symptoms were noticed. Examination showed the left kidney to be movable about three inches. Relief was afforded by application of a bandage and pad, but the patient, as in the last dispensary case, has not been seen of late.

Case VIII.—Miss S——, American, restaurant cashier, aged nineteen; seen December 24, 1897. History: Five months before, while bicycling, the patient had had a severe fall, the wheel and another rider falling upon her. This was followed by pain and tenderness in the right side for some weeks. Since then there have been intermittent sharp and dragging pains. Some slight digestive disturbances were complained of, although no flatulence or constipation presented. The patient was rather nervous and easily excitable. The right kidney was found dropped about three and one-half inches, and replacement was quite painful. Present treatment of any kind was declined, but the nervous symptoms have lessened with a knowledge of the true condition.

Case IX.—Mrs. L——, German, housewife, aged twenty-eight; seen January 6, 1898. History: Five years previous the patient had been thrown from a buggy, since which time at intervals she experienced peculiar aches and pains on the right side. The right kidney was found movable about five and one-half or six inches, and usually lying at the lower limit of its motion, in the lower lumbar region, where it could be easily felt and the contour plainly mapped out. Replacement was easy, with disappearance of dragging sensations, but the patient objected to the retaining bandage, on account of stomach tenderness, which was accompanied by excessive flatulence and constipation. Incidentally it may be stated that the patient was just convalescing from an attack of exophthalmic goitre, of six years' standing, and was in a very neurasthenic condition. Further attention to the kidney was declined for the present.

404 Indiana Avenue.

AN UNUSUAL CONDITION OF THE ARTERIES OF THE FOREARM.

By EDWARD JUDSON WYNKOOP, M.D.,
SYRACUSE, N. Y.,
ATTENDING PHYSICIAN TO THE WOMEN AND CHILDREN'S HOSPITAL AND TO THE SYRACUSE FREE DISPENSARY; FIRST TOPE OF THE ANATOMICAL LABORATORY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

Though variations in the normal distribution of the arteries are quite common, especially in the arm, yet the following condition is worthy of notice.

In a male subject the brachial artery divided just opposite the elbow-joint into the radial and ulnar arteries. The ulnar artery passed downward and inward, resting upon the pronator radii teres and flexor carpi radialis muscles, till it reached the muscular body of the palmaris longus muscle. Passing under this muscle and partly covered by it, it coursed well over to the ulnar side of the forearm, being covered in the upper part of its course by the flexor carpi ulnaris. It then descended the forearm to the hand, forming the super-

ficial palmar arch. In most of its course this artery was covered only by skin and fascia. Instead of passing below the common origin of the superficial flexor group of muscles, it passed superficial to all except the palmaris longus and flexor carpi ulnaris. The anterior and posterior ulnar recurrent and a few small muscular branches were the only ones given off from the ulnar artery.

The radial artery occupied its normal position. About two and one-half inches below its origin a large branch was given off and passed inward and downward. This branch, about two inches in length, divided into two terminal arteries—one passing down the forearm anterior to the anterior interosseous membrane and forming the anterior interosseous artery; the other passing through the membrane and then down posteriorly to it, becoming the posterior interosseous artery. Just before the common interosseous artery divided a small branch was given off, forming the radial recurrent artery.

The common interosseous artery finding its origin from the radial is quite unusual.

Another condition noted in another male subject, not so unusual, was division of the brachial artery two inches below the axilla. In one arm the inner division of the artery passed outward and downward over the other division and median nerve, and passed down the forearm to become the radial artery; the other division passed to its inner side and formed the ulnar. In the other arm the division occurred high up, but there was no crossing of the arteries.

CASE OF DIFFUSE SYMMETRICAL SCLERODERMA WITH MARKED MUSCULAR ATROPHY.[1]

By JAMES C. McGUIRE, M.D.,

PROFESSOR OF DERMATOLOGY, GEORGETOWN UNIVERSITY; DERMOTOLOGIST, GARFIELD HOSPITAL, ETC.

The peculiar condition of the skin characterized by induration, rigidity, and subsequent atrophy was first described by Curcio in 1752. Gintrac in 1847 applied to it the name scleroderma.

Briefly described, the malady presents itself first as a firm symmetrical œdema involving the subcutaneous tissue, pitting under pressure, but soon becoming tense and hard. The surface of the skin over the affected area is smooth, shiny, waxy, or mottled, and deeply pigmented, usually on a level with the surrounding parts. Rheumatic pains may precede the outbreak, but it may make its appearance so insidiously that the patient is unaware of its occurrence till there is well-marked induration. The integument cannot be pinched up into folds or moved over the deeper structures. Sensibility is in time impaired; later the skin becomes tightly stretched over the underlying parts, and atrophy of the cuticle and muscles may be marked. The contraction of the skin causes pseudo-ankylosis, so that the fingers are flexed on the hands, the forearms on the arms, and from lack of nutrition ulcerations over the bony prominences frequently occur. Though the general health may remain good for years, marasmus frequently supervenes, which sooner or later terminates in death.

As to the cause of the malady but little is known. Like that of most other cutaneous disorders, the etiology is very obscure. Rheumatism has been mentioned as a predisposing cause, but the generally accepted idea is that the changes in the skin are due to some disorder of the nervous system. According to Heller's statistics, only fifty-two cases had appeared in literature previous to 1873, and probably twice as many more in the following ten years. In this country in 1894 the returns of the American Dermatological Association show 24,321 cases of skin disease; eleven of these were reported to be scleroderma. Returns from the same source, from June, 1878, to January, 1893, give eighty-five cases of the disease in 204,866 cases of cutaneous maladies. So it would seem that in this country there is about one example in every twenty-five hundred cases of skin diseases.

The disease is therefore sufficiently uncommon to make the report of the following case of some interest:

B. K——, seventeen years of age, a well-developed, intelligent mulatto girl. Her father died some years ago of pneumonia; the mother is a strong, robust woman, who has seldom had a day's sickness. The patient states that some years ago while attending school she began to suffer from rheumatic pains, loss of appetite, and general debility. Though she had been strong and was well developed for her age and capable of doing as much work as her mother, she now had to leave school, remain at home, and, to use her own expression, was "absolutely good for nothing." In a short time the joints began to swell and became so stiff she could not extend the arms or fingers. At first the swelling was soft and pitted on pressure, but it soon extended along the arms, forearms, and thighs, and became hard and unyielding. Two years ago she first noticed that the limbs were shrunken and as hard and unyielding as stiff leather. She entered a hospital and was there treated for progressive muscular atrophy. Receiving no benefit, she came to this city a year ago. October 1st she presented herself at my office for treatment. Dark pigmentations irregular in outline, from a pinhead to the palm of the hand in size, were scattered over the surface of the skin; the arms were reduced very much in circumference; the muscles were so much atrophied that the skin seemed to be almost in contact with the periosteum, with the exception of longitudinal ridges of muscles that extended the full length of the arm, and were as hard as wood. The arms could not be lifted above the shoulders nor could the fingers be fully extended. The thighs also were much reduced in size; on the inner part of the left thigh, just below the groin, was a distinct swelling of about the size of an egg. The ankles were much swollen, firm pressure causing some pain. About the right buttock was a subcutaneous tumor, of the size and shape of a small saucer, and, though the skin was firmly attached to it, the tumor was freely movable on the parts beneath. The integument of the arms, thighs, and legs felt cold and hard to the touch. Sensation was unimpaired. Two small ulcerations were seen on the right elbow. The face was much swollen. The eyelids were œdematous and covered with a reddish papular rash; though red and looking like a papular eczema, the condition has lasted without change for two years. There were no pruritus and no history of moisture about the parts. The skin in this situation was not bound down, but felt rough, dry, and unyielding. The integument about the lower jaw was hard and smooth, could not be pinched up into folds. Except for the general weakness, the patient did not complain.

From a clinical standpoint the case is of interest, on account of the excessive muscular atrophy, the very large and peculiar-shaped subcutaneous tumors, and the non-inflammatory papular eruption.

When first seen the patient was given a generous diet, with cod-liver oil and iron; locally salicylic-acid ointment and massage, combined with inunctions of cod-liver oil and occasional Turkish baths. The galvanic current was applied twice a week over the region of the spine. At the present time the patient declares that she is feeling better in every way, except for periodical pains extending along the limbs. The skin lesions have changed but little in appearance.

New York, June 18, 1898.

CLIMATES OF CUBA AND MANILA.

CUBA is to a great extent an unknown land; her forests alone are estimated to occupy no less than 13,000,000 acres, and are said to be so dense as to be almost impenetrable. But perhaps the most extraordinary feature in regard to this general ignorance concerning that island is the lack of exact knowledge of the climate. Pessimists contend that it is in a high degree deadly to the white man, while optimists are as strenuous in asserting that, provided needful precautions are taken, the air is quite salubrious. We have always been of the opinion that the climate of the island, at least on the coast and in the lowlands, during the wet season from May to October, is decidedly unhealthy. Certain it is that its effects on the Spanish soldiery have been most disastrous, although, as we pointed out in a late number of the MEDICAL RECORD, much of this excessive rate of mortality has been due to the inefficient system of hygiene, to bad diet, unsuitable clothing, and the carelessness universally prevailing among the military authorities with regard to the health of the rank and file of the army. However, there is no evading the fact that the landing of a large body of more or less raw, unacclimatized men in the lowlands of a reputed unhealthy coast at the beginning of the rainy season is an experiment that must from the very nature of things be attended with much risk. Therefore any accurate information on the subject is both apropos and welcome. A pamphlet has recently been issued by the weather bureau of the United States department of agriculture, prepared from information collected by W. F. R. Phillips, in charge of the section of climatology, and which contains in its pages all that is at present known concerning the climates of Cuba and Manila. Mr. Phillips says: "Ramon de la Sagra, in his 'Histoire Physique de Cuba,' quotes as the earliest record he had consulted a year's observations of the barometer and thermometer made in Havana in 1794. The thermometer readings, however, appeared to be in error from some cause or other not known, and were considered too inaccurate to use. At only one station have systematic meteorological observations been made and published for any considerable time, and that is at the observatory of Belen College, Havana. . . . The climate of the West Indies presents, with respect to both temperature and rainfall, considerable variations from the generally conceived idea of tropical uniformity. These variations are largely, if not entirely, caused by differences in altitude and position with respect to the prevailing winds of the zone. . . . The average annual temperature of Havana, as determined from the observations at Belen College, made during the decennium 1888–1897 may be stated in round numbers as 77° F. In this decennium the highest annual temperature was 77.2° F., and this occurred upon three occasions; and the lowest annual temperature was 76.1° F., and happened upon only one occasion, showing in the ten years an extreme range in annual averages of but 1.1 degrees. It would therefore seem probable that the mean temperature for the decennial period 1888–1897 is about a true average for Havana for any long period. The warmest month at Havana is July, with an average temperature of 82.4° F. The coldest month is January, with an average temperature of 70.3° F. The highest temperature recorded was 100.6° F., in July, 1891, and the lowest 49.6° F., in February, 1896. For Matanzas, on the coast about fifty miles east of Havana, there is a record for two years. From this the mean annual temperature at Matanzas appears to be about 78° F. At Santiago it is apparently higher than on the northern and western coasts, and from the meagre data available appears to be about 80° F. . . . The relative humidity of the atmosphere appears to be fairly constant, as far as can be determined from the observations available, and averages about seventy-five per cent. of saturation. . . . The absolute humidity is very great. At Havana the average is about 7.5 grains of vapor to the cubic foot of air. The average rainfall for Havana is about sixty-two inches for the year. On an average the greatest rainfall occurs in October and the next greatest in June. The description of the rainfall of Cuba virtually resolves itself, so far as present information goes, into that of rainfall at Havana. The number of days on which rain falls is upon the whole considerable, about one day out of three at Havana. The prevailing winds of the West Indies are the 'northeast trades.' The average velocity of the wind at Havana is about 7.5 miles an hour. In climates having such high temperatures and humidities as shown for the West Indies, the velocity of the wind and its constancy are of the greatest importance to both comfort and health." As may be gathered from the portions quoted, Mr. Phillips' report is highly interesting, and should serve to remove certain misapprehensions which now exist respecting the temperature and rainfall of Cuba. The belief is widespread that the heat and rainfall are infinitely greater than in any part of this country; whereas in reality, the average summer temperature of Havana is but little higher than that of New Orleans, while its rainfall is actually less. The climate of the low coast lands of Cuba is that of the torrid zone, and in the rainy seasons doubtless exercises a pernicious effect upon the health of unacclimatized white men. The higher interior of the island enjoys a more temperate atmosphere. The average temperature of Manila is 80° F. The months of April, May, and June are the hottest part of the year. May, with an average temperature of

84° F., is the hottest of the three. The highest thermometer reading recorded is 100° F.; this was observed in May. The average relative humidity is seventy-eight per cent. The average absolute humidity is 8.75 grains in a cubic foot. The average rainfall is 75.43 inches, of which 43.69 inches, more than fifty-seven per cent., fall during the month of July.

SHOES FOR THE TROOPS.

A CONSIDERABLE amount of dissatisfaction continues to exist on account of the failure of the contractors to supply with shoes with a desirable degree of alacrity the men now in camp. Some of the troops are said to be barefooted, while many are the possessors of footgear alleged to be unserviceable. It is also reported in some of the journals that cheapness rather than quality has entered somewhat largely into the question of the shoe supply. If such be the case, it may be taken for granted that the proceeding is one of false economy and will assuredly in the long run be a matter for repentance. Shoes have often been a stumbling-block with army authorities. In the campaign recently undertaken by Great Britain in the Soudan, bitter complaints were made by the British soldiers with regard to the ineffectiveness of their shoes; indeed, so much bad feeling was evoked that the secretary of state for war made it his business, on the first convenient opportunity, to deliver himself of a public apology and to explain as well as he was able the cause of the defective shoes. Dr. A. C. Girard, U. S. A., in May, last year, said that he considered that some of the bad results following the use of ill-fitting shoes were in many instances the fault of the men themselves, who selected them so short as often to cause ingrowing toenails and inflamed corns. He suggested that the footwear of the men be under the personal supervision of company commanders. On the enlistment of a man the company shoemaker should measure the man's foot and a record be kept of this measurement, and in drawing shoes this measure should be adhered to. Commenting on this, Colonel Woodhull, chief surgeon of the department, remarked: "The action recommended in relation to shoes is both wise and important. An infantry officer should take the same care of his men's feet that a cavalry officer does of his horse's feet; but generally the men's feet are neglected and the results described follow."

"AMERICAN WOMEN AND WAR."

THE above is the title of an article which appeared in a recent number of the *Hospital Mirror*, and which highly praises the work done by American women in war. The following are some of the writer's remarks: "It may be interesting at the present time to recall a few facts with reference to the noble part played by American women in the civil war. Now that the United States are at war with Spain, there is no question that they are in a position to make their nursing and hospital arrangements on a scale of perfection never before equalled in the war of nations. So far back as 1861 the Americans were able to equip their field service and various agencies for giving 'first aid' to the wounded in battle in an admirable manner, which has served as a pattern to every other country. And the nursing-service at that time, it must be remembered, was largely the work of amateurs. To-day the United States army possesses a vast force of skilled and efficient nurses, who can and will be put into action in a few days." After referring in the most complimentary terms to the work of the women throughout the Civil War, the *Hospital Mirror* ends its article thus: "Of the devotion of nurses and amateurs who went through a hurried training of a few weeks in order to qualify for posts in the military hospitals, it is impossible to speak, for whole volumes might be written of the heroism and self-sacrifice displayed by the women of the civil war. With such examples before us of what has been accomplished by American women in time of war, it is quite safe to predict, now that an outbreak of war has occurred between the United States and Spain, that the trained nurses of the former country will show themselves second to none in bravery and devotion to duty." The above panegyric should be very gratifying to the American *amour propre*, and is in addition on the whole true. Certainly that part which refers to the conduct of the American women in the civil war is true to the letter. Whether, however, we possess at the present time a vast body of skilled and efficient army nurses is somewhat open to question. There is no doubt that the ones we do possess are equal to those of any nation, and it is equally certain that we have an immense reserve from which to draw those only who require a little training to render them competent to fulfil the duties of soldiers' nurses. The latter are to be equipped for immediate service through the agency of the civil branch of the American National Red Cross, and promise from present indications to fulfil the most sanguine anticipations of what American nursing can accomplish.

A Painful Accident to a Surgeon.—We regret to learn of a very serious and strange accident which befell Dr. Simmons, surgeon to the Polyclinic Hospital, while operating there on Saturday last. According to the account given in the daily papers, Dr. Simmons was amputating the leg of a man who had been injured in a cable-car accident. A number of students were watching the operation, and the leg was hanging only by the soft parts, when Dr. Simmons took up the knife to sever the leg from the body. The assistant who had hold of the leg suddenly slipped and fell against Dr. Simmons. His weight pushed the knife against the left wrist of the surgeon, and the hand was nearly cut off. The loss of blood was excessive and Dr. Simmons is now reported to be in a very serious condition. We earnestly turst that the account first given of the accident was exaggerated, and that the accomplished surgeon will be spared for yet many years of useful activity.

News of the Week.

The Naval Hospital Corps.—The house bill to organize a hospital corps of the United States navy, to define its duties, and regulate its pay has passed the senate. Under the bill the pay of hospital stewards is to be $60 a month; hospital apprentices (first-class), $30 a month; and hospital apprentices, $20 a month, with such increase on account of length of service as is now, or may hereafter be, allowed by law to other enlisted men in the navy.

Obituary Notes.—Dr. Louis E. Bertine, of Mount Vernon, N. Y., died recently of injuries inflicted by an unknown assailant on the evening of June 4th. He was returning to his home when he was suddenly set upon and stunned by a blow on the head, apparently from a sandbag. His skull was fractured and he never recovered consciousness after reaching his house. Dr. Bertine was a graduate of the Bellevue Hospital Medical College in 1881, and was city physician and president of the Mount Vernon board of health.—Dr. Louis Michel, of West Hoboken, N. J., died on June 9th, at his home in Summit Avenue. He was seventy-two years old, and was a graduate of the New York Medical College in 1852. He served as surgeon in the navy during the civil war, and was city physician in West Hoboken from 1892 to 1896.—Dr. Porteous C. Gilbert, of Saratoga, died on June 11th, at the age of fifty-seven years. He served during the civil war as captain in the New York volunteers for two years, and then resigned and re-enlisted as surgeon and served as such to the close of the war. He was a pension examiner at the time of his death.—Dr. John A. Larrabee, of Louisville, Ky., died at his home in that city on June 12th, of chronic nephritis. He was born in Maine fifty-eight years ago, and was graduated in medicine from Bowdoin College in 1864.

The Hospital Ship "Solace," during her recent visit to this port, bringing fifty-four sick and wounded sailors from Admiral Sampson's fleet, was inspected by Surgeon-General Van Reypen. The patients were doing well and all are expected to recover. The jackies have named the *Solace* the "ice-cream ship," because the ice-making machine aboard has enabled the nurses to add ice cream to the other delicacies supplied to the inmates of the hospital. All the necessaries in the way of diet are furnished, of course, by the navy department, but the delicacies, such as oranges, lemons, jellies, chickens, etc., have been provided by private subscription.

Dr. Sternberg on the Danger from Yellow Fever.—In a recent number of the *Army and Navy Journal* it was said that Surgeon-General Sternberg had expressed himself as having little fear that yellow fever would prove more harmful to the troops in Cuba and Porto Rico than are ordinarily the diseases common in northern latitudes. Dr. Sternberg, however, disclaims making any such prophecy, in the following communication to that journal: "I have not expressed any such optimistic opinion, and regret to say that it is not justified either by my studies relating to yellow fever or by my personal experience. History teaches that when a considerable number of unprotected persons are exposed in a yellow-fever-infected locality during the months when this disease is most prevalent (May 1st to November 1st, in the latitude of Havana) an epidemic almost infallibly results. In the last week of April of last year there were seventeen deaths and seventy new cases of yellow fever in the city of Havana. Now, suppose that we had a similar number of cases at the same season in New Orleans, and that twenty thousand strangers from the North should go there to spend the summer, what would be the result? All past experience supports the belief that a majority of them would have yellow fever, and that from twenty to forty per cent. of those taken sick would die. This is what I anticipate would happen if we should send an army to occupy Havana, or any other infected seaport on the coast of Cuba during the summer months. If, however, these troops could be camped upon high land in the interior, and circumstances were such as to enable them to comply with all of the exactions of modern sanitary science, I am of the opinion that our loss from yellow fever would not be serious. But in time of war military commanders are expected to take their troops to the points occupied by the enemy, and a picnic in the interior with frequent changes of camp, etc., is perhaps not exactly what we may expect."

Yellow Fever on the Gulf Coast.—Several cases of yellow fever have occurred at McHenry, a small town in Mississippi, on the Gulf of Mexico. The town was visited by the epidemic last year. Some apprehension is felt lest the disease reappear in other places visited by it last summer and fall, especially in view of the fact that the winter has been so mild. The Marine Hospital Service has taken the matter in charge, and Dr. R. D. Geddings, now stationed at Tampa, has been ordered to proceed to McHenry and take charge of Camp Fontainebleau, the yellow-fever camp put in operation during the last year, and which is now in readiness for present cases.

The American Association for the Advancement of Science.—The fiftieth annual meeting of this association will be held in Boston in August. The city has appropriated $2,500 for the entertainment of the members, but the State legislature has voted against an appropriation of a like amount, on the ground that it would establish a dangerous precedent. The committee on arrangements will need $10,000, so $7,500 will have to be raised by private subscription, as it should be.

St. Vincent's Hospital.—At the annual meeting of the hospital the following appointments were made: Assistant visiting surgeons, Dr. Joseph B. Bissell, Dr. George D. Stewart; assistant visiting physicians, Dr. Charles H. Lewis, Dr. Jose M. Ferrer.

Disinfection of the Transports.—Among other measures to prevent the introduction of yellow fever into this country from Cuba or Porto Rico, Surgeon-General Wyman has recommended that the transports engaged in carrying troops and munitions of war to those islands be disinfected at the end of each round

trip, and that nothing be carried in them except troops and supplies, and that refugees and others from Cuba and Porto Rico be not permitted to occupy the boats.

The British Medical Association.—The sixty-seventh annual meeting of this association will be held in Edinburgh during the last week in July, under the presidency of Sir Thomas Grainger Stewart.

Examination for the Marine Hospital Service.—A board of officers will be convened at Washington, July 6, 1898, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine Hospital service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1, physical; 2, written; 3, oral; 4, clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and, when practicable, candidates are required to perform surgical operations on the cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per cent. in addition to the regular salary for every five years' service up to forty per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. Invitation to appear before the board of examiners may be obtained from the supervising surgeon-general, United States Marine Hospital service, Washington, D. C.

Medical Education in France.—Frenchmen who find fault with us because most of our medical schools require only four years of study, conveniently overlook the fact that they themselves devote less than half of each year of their student days to work. The *British Medical Journal* says that the students of the University of Paris are not likely to suffer from intellectual overpressure, if one may judge from the number of holidays which they enjoy. One of the students has used some of the abundant spare time which the bounty of his alma mater in the matter of "free days" leaves him to compile the following list of holidays: The great summer vacation, 64 days; All Saints' holidays, 3; Christmas and New Year, 10; St. Charlemagne, 2; free days in Lent, 2; the Easter vacation, 15; Whitsuntide, 3; the National Festival, 3; Sundays, 52; Thursdays, 52; memorial days of great men, 10; total, 216 days. Thus it is seen that the future doctors of France devote only 149 days out of the 365 to the business of their education.

The California State Medical Society.—At the recent turbulent meeting of this society at Fresno, the following officers were elected for the ensuing year: Dr. William Watt Kerr, *President;* Dr. A. J. Pedlar, *First Vice-President;* Dr. George L. Cole, *Second Vice-President;* Dr. D. A. Hodgehead, *Secretary;* Dr. Thomas Ross, *Treasurer.* The next annual meeting will be held at Monterey.

The Ontario Medical Association.—The eighteenth annual meeting of this association was held in Toronto on June 1st and 2d. The following officers were elected for the ensuing year: *President,* W. J. Gibson, Belleville, Ontario; *First Vice-President,* J. F. W. Ross, Toronto; *Second Vice-President,* I. Olmstead, Hamilton; *Third Vice-President,* W. J. Rowe, Georgetown; *Fourth Vice-President,* Neil McCrimmon, Kincardine; *Secretary,* John N. E. Brown, Toronto; *Treasurer,* George H. Carveth, Toronto. The next meeting will be held at Toronto on the first Wednesday and Thursday in June, 1899.

Obituary.

JOHN BLAIR GIBBS, M.D.,

ASSISTANT SURGEON, U. S. NAVY.

Dr. John Blair Gibbs, the first medical victim of the present conflict with Spain, was a practising physician in this city up to the beginning of the war. He was the son of an officer in the United States army, who was killed in the Custer massacre by the Indians. He was born at an army post in the West in 1858. He was a graduate in arts of Rutgers College in 1878, and in medicine of the College of Physicians and Surgeons, New York, in 1882. He served in the surgical interne staff at Bellevue and afterward at Roosevelt Hospital. After studying abroad for a while, he returned to New York and entered upon practice. He was an attending surgeon to the Demilt Dispensary and assistant attending surgeon to the Lebanon Hospital.

When war was declared, Dr. Gibbs volunteered at once for service in the navy, and, after passing his examination and receiving his commission, was the first of the New York volunteer naval surgeons to be assigned to duty. He was ordered at first to the *Miantonomoh*, but was later transferred to the *Panther.* When the marines from the latter were landed on the shores of Guantanamo Bay he was sent with them. He was killed by a stray bullet, just after leaving the hospital tent, at one o'clock on the morning of June 12th, during an attack on the camp by a Spanish guerrilla troup.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 19, 1898.

EDWARD G. JANEWAY, M.D., PRESIDENT.

The Serum Exanthemata Observed in the Antitoxin Treatment of Diphtheria.—DR. HENRY W. BERG read a paper on this subject (see page 865) and illustrated it with lantern slides.

Nature of Rashes.—DR. H. G. PIFFARD spoke of the nature of these rashes, particularly those of an acute character. It was well known, he said, that many of the eruptions on the skin were clearly due to local causes, such as croton oil, poison ivy, etc., resulting in an inflammatory reaction against the attack—the irritant—but when the irritant was applied from within instead of from without, the nature of the process was not so clear. Some years ago it was the fashion among dermatologists to speak of many of the common eruptions as neuroses of the skin. There could not be any eruption without a neurosis, in one sense, *i.e.*, that there was a change in the calibre of the vessels brought about by nerve influence. In the case of eruptions observed in connection with disturbances of the stomach, it certainly seemed plausible to suppose that the eruption was a reflex phenomenon. It was assumed, but had not been proved, that the eruption seen in connection with the use of antitoxic serum was the result of the effort to eliminate the poison through the skin. It was a reasonable hypothesis because it was known to be the explanation in the case of other toxic substances, such as iodide of potassium. As the diphtheria antitoxin had not been isolated, there was no proof that the eruption was due to the antitoxin itself.

Individual Variations in Horse Serum.—DR. W. H. PARK said that he had been intensely interested in this work of Dr. Berg, because it would have a bearing not only on diphtheria antitoxin, but on other antitoxic serums. It was not rare that the physician was unable to differentiate between scarlet fever and the eruption produced by diphtheria antitoxin. In work at the laboratory it had been found that there were great differences in the serum from different horses regarding the production of rashes, and even a difference in serum taken from the same horse at different times. Thus, one of the best serum horses at the laboratory suddenly began to produce a serum which gave such a large proportion of eruptions that it was necessary to stop taking serum from him. The horse was sent to the country to recuperate for a few weeks, and on his return it was found that the serum taken from him no longer produced such an unusual proportion of rashes.

The Rashes Not Altogether Harmless.—He agreed entirely with Dr. Berg that these rashes were at times quite serious. In some cases the mucous membrane was involved, and in these there seemed to be a special tendency to bronchitis and pneumonia.

Effect of Dosage.—Where immunizing doses were given, the rashes would not be seen in more than about two per cent. of the cases, and the rashes would be very mild, as a rule. However, there were marked individual differences exhibited, even with these small doses. In a general way, however, it was true that the larger the dose, the more frequent the development of rashes and the greater their severity. It seemed to him hard to believe that antitoxin rashes were even largely the result of an effort to eliminate the poison through the skin. The time of the appearance of the eruption was exceedingly variable, as was also the type of the eruption, and the eruptions showed a remarkable disposition to come and go.

Filtration of the Serum.—The filters spoken of in the paper as "fine" filter so slowly that only about ten or fifteen cubic centimetres are obtained in a day; the filter denominated "coarse" in the paper was really a moderately fine filter, as it was capable of taking out all bacteria. It should not be forgotten that rashes were occasionally observed, even with serum that had been passed through the fine filter. As there was no effect observed with the so-called coarse filter, and as the number of cases was really quite small, he did not feel that any very definite conclusions could be drawn regarding the effect of filtration of the serum on the production of rashes.

Heating of the Serum.—One observer had just made the statement that by heating the serum up to a certain point the rashes could be prevented, and it had been ascertained that such heating did not injure the antitoxin. Antitoxin had not yet been obtained in even an approximately pure state in a form in which it could be preserved for any length of time.

Maximum Concentration.—About eight hundred to one thousand units to the cubic centimetre was as high as it was practicable to get a horse serum, although it might be run up to twelve hundred or fifteen hundred units under exceptional circumstances.

Observations on the Dosage in Relation to Rashes.—DR. W. P. NORTHRUP thought that with our present knowledge it was almost hopeless to attempt to explain the etiology of these rashes. Although the eruption of typhoid fever was practically an erythema, and the germ of the disease was known and had been abundantly investigated, there had been no definite explanation as yet given of the occurrence of this eruption. Moreover, in typhoid fever the eruption was so scanty that the eliminative theory hardly seemed to apply. He had recently had an opportunity of observing some of these cases in connection with an epidemic of measles at the New York Foundling Asylum. In previous epidemics the measles had usually been complicated with diphtheria or pneumonia. All of the cases were accordingly immunized with diphtheria antitoxin, and there was an unusually small percentage of eruptions observed. Such as did occur were very mild and very transient. This would seem to argue in favor of the view that the size of the dose of serum had much to do with the frequency of these erythemata. This experience was especially interesting when compared with the previous one in the same institution at the time when very large doses of antitoxin serum were in use. At that time rashes had been very frequent and very severe.

Serum itself Dangerous.—DR. HENRY DWIGHT CHAPIN said that the greatest improvement in the diphtheria antitoxin serum was in its greater concentration. He had not been able to convince himself that large quantities of serum were harmless, because in a series of experiments with large doses of sterilized horse serum in the treatment of marasmus he had found that all of the cases did very badly. The rashes were not so frequently observed now that a more concentrated antitoxic serum was used—in other words, when less serum was given with each dose of antitoxin.

Various Kinds of Eruptions Compared.—DR. A. JACOBI said that not long ago, when it was found that the antitoxin serum would cause eruptions, this in itself constituted a great objection to the use of the remedy, but that feeling had passed off. The eruption was not always characteristic. There were two principal forms observed, viz.: (1) erythema; and (2) urticaria. The same eruptions were observed after the administration of such medicines as the bromides, arsenic, quinine, and the coal-tar products, notably antipyrin. A number of different eruptions also were associated with rheumatism, *e.g.*, erythema, urticaria, and petechiæ. It was not surprising when one con-

sidered the great extent of the cutaneous surface that eruptions appeared on this surface rather than on the internal integuments and organs.

Albumose Appears in the Urine.—He had noticed that the injection of diphtheria antitoxin was frequently followed by the appearance of peptones or albumose in the urine. This usually disappeared in from five to ten days. In this respect also the diphtheria antitoxin acted only as did the various infectious diseases.

It is an Eliminative Rash.—Dr. Berg closed the discussion. He said that there was considerable proof that the antitoxin rashes were of an eliminative character and not of neurotic origin. One of the best of these proofs was that a Russian observer, who had tested all the secretions and excretions of the body in connection with the use of antitoxin, had found that about eighty per cent. of the antitoxin was excreted from the body by the sweat glands. The speaker said that he firmly believed that the acute exanthemata produce their skin manifestations by the effort of the skin to excrete the poison of these infectious diseases. The skin being an important channel of elimination, it endeavored to eliminate this poison, and it was this great effort that led to the production of the eruption. No one had claimed that the rashes could be entirely prevented. It was not only his small number of cases that he offered as proof of the good effect of filtering the antitoxin serum, but a large number of experiments made by several foreign authorities on the effect of injections of normal horse serum, both filtered and unfiltered.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, May 26, 1898.

Edwin B. Cragin, M.D., Chairman.

A Case of Intra-Uterine and Tubo-Interstitial Gestation.—Dr. Brooks H. Wells reported the following case of this kind: Mrs. X——, twenty-seven years of age, married, had had one child, five years ago. Last October he had curetted her uterus because of hemorrhage following an incomplete abortion. The uterus was extremely retroverted and non-adherent; the appendages were normal, and there was no history of previous pelvic disease. She ceased menstruating March 20th, and when she was seen by him on April 19th pregnancy was diagnosed. There were appreciable softening and enlargement of the uterine fundus, and she presented some of the subjective signs of pregnancy. On April 24th she complained of nausea, and the examination showed the uterus to be slightly enlarged and elastic, the enlargement being rather greater on the right side. There was no tenderness. She returned on May 1st, complaining that for the past two days she had had some pain in the upper sacral region and over McBurney's point, but examination failed to show evidence of appendicitis. The uterus was rather large for a six weeks' pregnancy, and the right cornu was quite tender and decidedly more bulging than before. The appendages were apparently normal. That evening she again complained of the "pinching" pain in the right side, and after a while the pain suddenly became severe and was accompanied by faintness and nausea. A neighboring physician insisted that she was only suffering from colic, and gave some codeine. When seen by the speaker the following morning, she was pale, the skin was moist, and the pulse was 120, soft, and weak. There were slight tenderness over the right inguinal region, decided tenderness about the right uterine cornu, and a slight feeling of resistance over the entire vaginal fornix. The existence of internal hemorrhage being recognized, hasty preparations were made for abdominal section; but before it could be performed she became pulseless, pale, and cyanosed, and the sensorium was blunted. A large quantity of freshly clotted and fluid blood was found in the peritoneal cavity, and the tube was discovered to have been entirely torn off from the uterine cornu, while the remains of the ovum projected from the cornu. The rent in the cornu, about one inch in length, was sewed up with chromicized catgut, and the dangling tube and ovary were ligated and removed. The clots were turned out of the abdomen, and, after the peritoneal cavity had been flushed with saline solution at a temperature of 110° F., the abdominal wound was closed. Hypodermic injections of strychnine and whiskey and hot saline injections into the rectum were also required to keep alive the spark of life during the operation. Six hours after operation her pulse was 120. Her temperature reached 101.4° F. on the evening of the second day, and dropped to the normal on the fourth day. On the twenty-fourth day, by the aid of a curette and without anæsthesia, the intra-uterine ovum was removed. It had evidently been dead for some time, but caused no symptoms other than an offensive discharge for a few days. The patient was now steadily recovering, though still very anæmic. The special points of interest in this case were: (1) The combination of uterine and ectopic gestation; (2) the situation of the ectopic pregnancy in the interstitial portion of the tube; (3) the complete absence of symptoms until within a few hours of the rupture; (4) the normal condition of the tube: and (5) the question of operation in the face of such desperate conditions.

Dr. H. J. Boldt congratulated Dr. Wells on the excellent result obtained in this desperate case. The first interesting feature to him was the difficulty of making the diagnosis prior to rupture. He contended that the statement made by many, that it was easy to diagnose ectopic gestation before the occurrence of rupture, was erroneous. It was easy in a typical case, especially after slight intraperitoneal hemorrhage. Another point of interest was the uncommon site of the impregnation. In a large number of cases seen by him he had met with only one instance of interstitial pregnancy. This likewise ruptured at an early stage. He called attention to the moderate elevation of temperature that occurred after operation, which, he said, was common, and he attributed it to the absorption of water and blood left in the abdomen. He said that impregnated Fallopian tubes which were non-adherent were especially dangerous to the patient, because they gave rise to such free hemorrhage when they ruptured, and because of the difficulties of previously recognizing the condition. The case reported was an additional instance, and a very impressive one, of the fact that, no matter how desperate the condition of the patient, prompt action should be taken.

Dr. E. B. Cragin said that the text-books usually stated that interstitial pregnancies ruptured at a late period of gestation.

Dr. S. Marx observed that it was by no means rare to find in text-books statements which were not borne out by facts.

Dr. H. N. Vineberg called attention to the necessity of operating without delay, no matter how apparently desperate the condition of the patient.

A Third Successful Case of Abdominal Hysterectomy for Acute Puerperal Sepsis.—Dr. Hiram N. Vineberg reported the following case, and presented the specimen: Mrs. S——, twenty years of age, married ten months, had been delivered by another physician with forceps on April 17, 1898. On April 19th her temperature was 102° F., and the next day it was 104° F. He then used the dull curette without anæsthesia. As the temperature remained the same, she was again curetted and the uterus irrigated. On April

26th a consultant vigorously used a sharp curette on the uterus, with temporary improvement in the symptoms. When the patient was seen by him on the morning of May 1st, her temperature was 103 F., the pulse 120 and fairly good; the tongue was coated, the mucous membranes were livid, and the abdomen and uterus were flabby. Two fingers could be easily passed up to the fundus of the uterus, and, while nothing was found in the interior of the uterus, one point of the wall of the fundus was suspiciously thin. There was a boggy mass in Douglas' cul-de-sac. At 9 P.M. her temperature was 106 F. and the pulse 130. It being suspected that the posterior mass was an abscess, an incision was made in the posterior vaginal vault. This disclosed the fact that the mass was the posterior portion of the very flabby uterus. On May 3d her condition was very critical, and she was taken to St. Mark's Hospital for a hysterectomy. This was done in the afternoon, after an attempt to remove the uterus per vaginam had failed because of the great friability of the former. On the second day after the operation a septic pneumonia developed, which gradually spread over both lungs, and, until lysis occurred, between the tenth and twelfth days, her condition was extremely critical. For over a week past she had been entirely free from fever and was convalescing satisfactorily.

The uterus from this case was presented. It was very soft and flabby, and over the interior of the fundus was an area, about the size of a silver dollar, from which all the muscular wall had been scraped away. The exterior of the uterus was riddled with small abscesses, varying in size from that of a pea to that of a kidney bean. One abscess, situated on the anterior wall, just below the uterine end of the tube, was about the size of an almond, and the peritoneum covering it was very much thinned. In a very short time this would have ruptured and a *foudroyant* septic peritonitis would have resulted. This case, the speaker said, although belonging to a different class from his two successful cases, emphasized the surgical principle which should guide one in the treatment of these desperate cases. If it was concluded that the uterus was the gross source of infection, and that curettage, irrigations, and similar palliative measures were ineffective in controlling the sepsis, extirpation of the uterus should be done as a *dernier ressort*; but by that it was not meant that one should wait until the patient was moribund before instituting this treatment.

Case of Renal Calculus Simulating Tuberculosis.—Dr. H. N. Vineberg reported also the following case: Mrs. F—— was operated upon for right pyosalpinx at the Woman's Hospital in March, 1894. In October, 1895, he had operated upon her for a very large ovarian cyst, with extensive adhesions to the intestine, uterus, and pelvic floor, and had found it necessary to remove the uterus also. She recovered and enjoyed good health up to last summer, when she began to have chills and fever, which seemed to yield to quinine. In December she again had some fever, and this time it was associated with vague pains in the left lumbar region. He saw her in consultation, diagnosed a pyelitis, and advised cystoscopy, but this was not performed. She did fairly well until March of the present year, when she developed an irregular fever and complained of pain in the right lumbar region. After this had lasted about a fortnight, he saw her again, and was struck by the great emaciation. The cystoscope now showed an intensely inflamed bladder, and, two drachms of urine being drawn from the left ureter, it was found to contain a little muco-pus. The urine from the right ureter contained about fifty per cent. of pus. Palpation revealed some enlargement of the right kidney. In a consultation with Dr. F. Lange, a few days later, these points were confirmed, and it was concluded that there was a double pyelitis, with a large pus collection in the right kidney, and that the left kidney was functionating fairly well. Evacuation of the pus on the right side was advised. A second cystoscopic examination on the following day gave the same result, and about a drachm of pus which drained from the right ureter was examined for tubercle bacilli, with negative result. Two days later the right kidney was exposed by an incision, and was found to be considerably enlarged, but not fluctuating. Exploration with an aspirating needle finally located a small collection of pus near the centre of the kidney, and exploration of the interior of the organ showed that its whole pelvis was occupied by a hard calculus, which ramified into the pyramids. The calculus was broken up and removed, and was found to weigh forty-eight grains. As its removal caused quite free bleeding, the cavity was packed with iodoform gauze, and, after the arrest of the hemorrhage, the wound in the loin was partially sutured, leaving a large space for the gauze drain. The patient did well for about twenty hours; then she gradually passed into collapse, and died thirty hours after the operation. During this time there was an abundant secretion of turbid urine. An autopsy was not permitted, but Dr. Vineberg said it was reasonable to suppose that the left kidney also contained a calculus.

The following features were especially interesting: (1) The absence of hæmaturia; and (2) the absence of any well-marked renal colic. The elements favoring the diagnosis of tuberculosis were: (1) the progressive character of the disease; (2) the irregular fever; (3) the great emaciation and weakness; (4) the kidney lesions being double; and (5) the large quantity of pus coming from the kidney. That death was not the result of the impairment of the other kidney was proved by the abundant secretion of urine after operation; it was really due to delay in operating and the inability of the patient's debilitated system to resist the shock. The loss of blood contributed largely to the fatal result, as septic patients readily succumbed to any decided loss of blood.

Acute Inversion of the Uterus, with Report of a Case.—Dr. William S. Stone read a paper on this subject. He said that the first extensive description of this rare and serious complication had been given by Crosse, of England, who in 1846 found four hundred cases in the literature, three hundred and fifty of which had followed pregnancy. The present paper was limited to a consideration of the parturient inversions. The rarity of the condition was well shown by the fact that in 190,000 deliveries at the Dublin Lying-in Rotunda it occurred only once. He had been able to collect from the literature of the last five years about forty cases, twenty of which had been reported in America. Dr. Stone said that formerly precipitate or very slow labors, and traction on the cord, were considered to be the chief etiological factors; but, as Emmet had well said, if traction on the cord was such an important cause, these cases should have been more frequent in the days when obstetrics was less developed and more cases were entrusted to midwives, which was not so. According to Crosse, the predisposing causes were: (1) All general diseases which relaxed and enfeebled the system; (2) the erect position during labor; (3) partial inertia of the uterus; and (4) attachment of the placenta to the fundus. The exciting causes he stated to be: (1) Such as were situated in the uterine tissue itself; (2) such as acted on the outer surface of the uterus, pressing it down; and (3) such as acted on its internal surface, pulling it down. After referring to the views of Tyler Smith and Matthews Duncan, the speaker quoted from a review of two hundred and twenty-six cases, collected and published by Dr. H. E. Crampton in 1885. According to this report, inversion was preceded by paresis of some

portion of the uterine muscle, caused by too frequent childbearing, tedious labor, previous miscarriages, traumatism, emotional excitement, or too rapid labor. In its inception, it was a pure neurosis. It was more apt to occur in primiparæ, probably owing to the peculiar emotional excitement attendant upon a first labor, which was reflected upon the exhausted uterine muscle, called for the first time into unusual action. Under such conditions a slight degree of depression of any portion of the uterine body became a source of danger. In ten of Crampton's cases there was a very short cord. Beckman, in a paper published in 1895, drew the conclusion that spontaneous origin was more frequent than previous writers had supposed. In fifty-four of his one hundred cases reported, this was considered to be the origin; in twenty-one the inversion was due to violent procedure, and in twenty-five the description was too meagre to allow assigning any cause. Frequent mention, the speaker said, was made of the fact that inversion of the uterus was associated with adherent placenta, but it seemed very probable that the frequent presence of true adherent placenta was not the cause of the inversion, but that the lack of contraction at the placental site caused both the adherent placenta and the inversion. Abdominal pressure and the improper application of the Credé method of expelling the placenta must also be put down as causes, and it was interesting to note that inversion had been recorded as having taken place after death.

The following was the report of his own case: The patient was a primipara, twenty-two years of age, who had been married three years. She had always been delicate and of an extremely nervous temperament, and had suffered much from dysmenorrhœa, and, after marriage, from vaginismus. She had been very nervous and apprehensive during her pregnancy. He was called because of the early rupture of the membranes. Examination showed the membranes to have ruptured and the os to be about three-fourths dilated, although the patient insisted that she had had no pain whatever. After some hours she began to have pains, and the head reached the pelvic floor. They then ceased, and delivery was effected with forceps. The cord was wrapped once around the neck of the child. The delivery was immediately followed by a gush of blood. Before the placenta could be expressed the patient became pale and the pulse rapid and feeble. The placenta was found in the vagina, firmly adherent to the inverted uterus. The cord was of the average length. The hemorrhage ceased and did not recur. Pending the arrival of a consultant, measures were taken to revive the patient from her condition of profound shock, but when the consultant arrived, one hour after delivery, she was almost moribund. She died in half an hour.

It should be noted that most of the cases collected by him occurred in primiparæ; this was the fact in regard to sixteen. Twenty-two of the labors were abnormal; in two there were very short cords; in eight cases traction was used; in ten the placenta was said to have been adherent; one was a case of placenta prævia; and two were cases of placenta succenturiata, one of which occurred seventeen days after labor, while the patient was at stool.

Symptoms.—The ordinary symptoms were sudden and severe pain, with more or less hemorrhage and shock. However, in a number of cases on record the symptoms had been so slight that the lesion was not recognized. The shock was out of all proportion to the hemorrhage. It most commonly occurred between the birth of the child and the delivery of the placenta. This was the time of its occurrence in thirteen of the cases collected in the paper.

Prognosis.—The prognosis was almost always serious, threatening the life of the patient within a few hours. The mortality given was quite variable—all the way from thirty to fifty per cent. There were six deaths in the collected cases. Occasionally spontaneous reduction occurred after a considerable time. There seemed to be little tendency for the uterus to invert a second time.

Treatment.—The chief obstacle to reduction was the constricting ring. Prolonged continuous pressure on the fundus and constriction by means of the hand were perhaps the best measures. The placenta should be removed before reduction was attempted. An important part was the treatment of the severe shock.

Dr. S. Marx said that the symptoms were very much like those of an accidental hemorrhage, except the hemorrhage. Apparently a sudden and profound irritation was brought to bear on the splanchnic plexus. He had operated in five cases, in four of which he had seen the patients during life. Of these four, he had been able to save three. One case was extremely interesting, because it occurred three weeks after an absolutely normal labor in a flabby multipara. The exciting cause was a large organized blood clot which simulated a fibroid. This was removed, the uterus was replaced, and the woman died of some intercurrent disease a few weeks later.

Dr. H. E. Crampton said that about sixteen years ago he had collected two hundred and twenty-six cases, occurring between 1840 and 1880. It was interesting to hear further testimony regarding the frequency of this complication in primiparæ. In his cases many of the primiparæ were unmarried, and this gave rise to special emotional excitement and a neurotic condition favorable to such an occurrence.

Dr. Leonard S. Rau said that in 1890 he had had a case of inversion of the uterus. He had been called to see a woman who had first been attended by a midwife, and then by a neighboring physician before his arrival. This physician applied forceps, which produced a severe hemorrhage. It was at this juncture that the speaker had arrived and had found a placenta prævia. He accordingly performed version and delivered a dead child. The woman then suddenly went into collapse, and examination revealed an inversion of the uterus. The patient was inverted, and then by prolonged manipulation the uterine inversion was reduced and a gauze packing inserted. The woman made an uneventful recovery.

Clinical Report of Five Cases of Appendicitis in Pregnancy and the Puerperal State.—Dr. S. Marx presented this report. He said that he was of the opinion that appendical inflammation occurred in connection with pregnancy more often than had been supposed. Indeed, there was reason to think that the congestion of the system and the vicious condition of the blood associated with pregnancy acted as a predisposing cause of appendicitis. In most cases the diagnosis was difficult, but this was fortunately not of much importance, because if the symptoms were sufficiently severe the treatment was operative, whether the appendix or the uterine appendage was the seat of the inflammation.

In his first case there was no definite history of prior attacks. Six hours after a perfectly normal labor the patient had a severe chill, accompanied by pain, fever, and abdominal tenderness. This tenderness gradually became localized over the caput coli. She slowly recovered, but had two or three slight attacks subsequently, and finally Dr. Willy Meyer performed an "interval" operation, and removed an appendix which measured eight inches in length.

The second case occurred in a primipara, who had had attacks of appendicitis prior to her marriage. Dr. Gerster operated upon her for appendicitis when she was four months advanced in pregnancy, and she made

a satisfactory recovery. She was delivered without difficulty, but forceps were used with the idea of taking the strain of the second stage off the recent abdominal scar. A few hours later she experienced much pain about the scar, apparently from the rupture of an abdominal adhesion band.

The third patient was in confinement with the third child, two months and a half after a suppurating ovarian dermoid had been removed. After labor the patient developed a rapid pulse with increased temperature and pain localized in the caput coli. She gradually recovered, operation being refused. Subsequently the symptoms became so urgent that an operation was performed at night. The appendix was firmly embedded in the posterior wall of the suppurating mass. She was now fully convalescent.

Serum Therapy in Puerperal Cases. The fourth patient was a primipara in the Maternity Hospital, who had had an attack of peritonitis three years before. At the seventh month of pregnancy she began to complain of pain over the appendix, but the pulse and temperature were normal. The treatment consisted in catharsis, the use of the ice bag, and rest in bed. After six days the temperature rose, the pulse became rapid, and there was abdominal tenderness, but no tumor could be detected. At the time of the operation the pulse was 124 and the temperature 101.5° F. The right tube and ovary constituted part of the abscess sac, and the appendix was necrotic. About four ounces of fetid pus was evacuated. Twenty-four hours after operation labor pains set in, and the woman was delivered of a living child. The temperature and pulse rose rapidly, and, general septicæmia being apprehended, she was given ten cubic centimetres of Gibier's antistreptococcus serum, with the happiest result. The appendix came away on the fifth day. On the twelfth day she began to have chills and fever, and to develop a sero-purulent peritonitis. After an extensive operation convalescence was slowly established. Meanwhile the serum was continued in small doses.

Hasten Labor when Uterus and Abscess Sac are Adherent.—Dr. Marx said that in cases in which the uterus formed an anatomical part of the wall of the abscess cavity, when the uterus contracted it was liable to cause rupture of fresh adhesions and produce infection of the peritoneal cavity. It was therefore his rule in such cases to deliver the woman at the beginning of labor by manual dilatation of the cervix, version, or forceps delivery, and immediately tampon the utero-vaginal tract.

The fifth case was that of a woman four and a half months pregnant, who had been in good health previously. Her present attack began with vomiting and pain, with but little fever. When he saw the case on the fourth day the temperature was 100 F. and the pulse 130. The abdomen was moderately distended and painful, and there was tumefaction over the caput coli. Rectal and vaginal examinations were negative. An incision was made high up in the loin, and about half a pint of pus escaped. The abscess cavity was encapsulated. The parts were thoroughly washed with pyrozone and a gauze drain was inserted. All of the symptoms were improved at once. On the sixth day it was decided to suture the wound. She suddenly developed symptoms of intestinal obstruction, and exploration under ether revealed an obstruction in the ascending colon, due to a constricting band. Pus was found coming from the general peritoneal cavity, so multiple incisions were made, a gauze drain was inserted, and doses of Marmorek's streptococcus serum were administered. The patient died in forty-eight hours.

Dr. Marx said that in his puerperal streptococcus cases the serum had invariably failed. When it acted well the effect was observed quickly. Large doses of the serum produced headache, nausea, and vomiting, with rise of temperature.

Dr. Boldt said that he had once had a case of appendicitis complicating extra-uterine pregnancy. In this instance the diagnosis of appendicitis was not made until operation for the ectopic gestation. His experience with the serum therapy in puerperal streptococcus cases had been like that of the reader of the paper.

Dr. Vineberg said the idea of delivering the pregnant uterus at full term by manual dilatation and other methods calculated to hasten labor seemed strange to him, because when this was done the anatomical relations of the uterus to the abscess cavity must be changed, especially when the uterus was packed with gauze. It seemed to him a dangerous teaching in such cases. He also questioned very much whether it was necessary to hasten or aid delivery simply because there was a recent abdominal scar, as many women with separated recti muscles and pendulous bellies were easily delivered without interference, and without any further damage to the abdominal wall. His experience with serum therapy had been entirely negative, both as to good and bad effects.

Dr. Wells said that he had used the serum in only two cases, but in these he had been unable to observe any effect from it. He did not think it was at all necessary to assist delivery in cases in which there was a recent abdominal scar, unless there was reason to believe that the scar was especially weak. He had had occasion to deliver three women at intervals varying from six weeks to four months after abdominal section, and the labor had had no injurious effect upon the scar in any of these cases.

Dr. Marx said that in cases in which he had interfered to hasten labor and avoid rupture of the contiguous abscess cavity, his idea had been to permit a minimum of uterine contraction, and then after delivery to support the uterine side of the abscess sac by a temporary gauze packing, the manipulations being, of course, done under deep chloroform narcosis.

AMERICAN MEDICAL ASSOCIATION.

Forty-Ninth Annual Meeting, Held in Denver, Col., June 7, 8, 9, and 10, 1898.

(Continued from page 852.)

GENERAL SESSION.

Third Day—Thursday, June 9th.

Report of Trustees.—Dr. Alonzo Garcelon reported that the board of trustees had become an incorporated body during the past year, and that the financial condition of the association was very satisfactory. The total receipts for the year ending December 31, 1897, were $64,522.72, and the expenditures, $25,637.67.

Report of Special Committee on Department of Public Health. Dr. U. O. B. Wingate, the chairman of the committee, presented a report of the work done by the committee, and offered the following resolutions, which were adopted by the association:

"*Resolved*, That the committee on department of public health be continued; that the bill as now perfected and before Congress, and which is submitted with this report (the Spooner bill), be and hereby is approved, and that the committee be authorized to use their best endeavors to have it passed by the Congress of the United States, at such time as in their judgment it seems proper and wise.

"*Resolved*, That the members of this association

do all in their power by urging upon their representative members of Congress to have this bill passed."

President's Address.—Regarding the suggestion in the address of Dr. Sternberg, that reputable physicians who were willing to subscribe to the regulations of the association be admitted to membership without regard to whether or not their State, county, or district association subscribed to the code of ethics, the executive committee reported that, while in sympathy with the view expressed by the president, it did not feel that action could be taken on it under the existing laws of the association. The report of the committee was unanimously adopted.

Rush Monument Committee.—Dr. H. G. Holton, of Burlington, Vt., was elected treasurer of this committee.

Medical Education and Membership in the Association.—On the recommendation of the executive committee, the following resolution offered by Dr. Reynolds, of Kentucky, was adopted:

"*Resolved*, That the American Medical Association gives notice that no professor or teacher in, or any graduate of any medical college of the United States which shall after January 1, 1899, confer the degree of doctor of medicine, or receive such degree on any condition below the published standard of the Association of American Medical Colleges, shall be allowed to register as delegate or permanent member of this association."

New York Physician and the American Medical Association.—Dr. Hobart A. Hare, of Philadelphia, at the general session held Wednesday, introduced the following resolutions, which he explained had been offered at the meeting in Baltimore two years ago, and had, under the rules, been laid over for one year, and for some unknown reason had not then been acted upon.

"*Resolved*, That the American Medical Association invites the New York State Medical Society, the Medical Society of the County of New York, the New York Academy of Medicine, and other good societies in good and regular standing, to send delegates to this association, who will be received and accredited on proper credentials from the officers of such societies; and

"*Resolved*, That all acts or ordinances contrary in spirit or letter are hereby rescinded."

These resolutions were referred to the business committee after a struggle, and at the present session that committee reported that, while it unanimously indorsed the idea, the members of the committee felt that the resolutions involved questions which did not properly come within the province of the committee, but of the association at large, and consequently the resolutions were referred back to the association. On motion, the report was received.

Dr. Hare then explained his reason for offering the resolutions. He said that it was unknown to many members that in New York State there existed two State and in New York county two county medical societies. One of these State and one of the county societies had a right in the association by the rules of that body, and it possessed that right at the present moment by inheritance. The other association—the other county society—a much younger organization, but nevertheless a very much more powerful one, both in numbers and in the large amount of scientific work contributed each year, had not been admitted. It was true that these two organizations had not adopted in their constitutions and bylaws a rigid code of ethics which governed the entire body, and which brought each individual member under the care of their censors or judicial councils. Each member did what he believed to be right. This association—the Society of the County of New York—numbered thirteen hundred, while the New York County Association numbered about nine hundred members. Dr. Hare said that it was with the object of admitting, under certain restrictions, these thirteen hundred members of the Medical Society of the County of New York to the meetings of the American Medical Association that these resolutions were offered. He would not counsel that those who consult with irregular practitioners should be admitted; each member coming from the County Society should sign the code of ethics of the association. Attention was called to the fact that the judicial council was empowered to state what societies should come in, and hence there was no danger of the association being "snowed under," as some feared, by irregular practitioners. It was simply his wish that the members of this prominent and scientific society, who might not agree on minor points regarding the code of ethics, should have the privileges of the American Medical Association. We had heard much about the unity of the country: that there were no North and no South; that the different sections of this country were welded together; and yet there were one American Medical Association and one medical profession in America, and there was no irregular medical profession. Dr. Hare concluded his remarks by immediately moving the previous question, and requesting that the roll be called and the ayes and nays recorded on that motion.

The chairman, Dr. T. J. Happel, of Tennessee, said that he would not have heard Dr. Hare's statement if he had known that he was going to move the previous question; he had allowed him to speak because he had been under the impression that Dr. Hare wished a full and free discussion of the matter, and he had thought in this way it might be settled once and for all time.

Dr. Hare then withdrew his motion until Dr. Scott, of Ohio, might have an opportunity to present the other side.

Dr. Scott said that there was a history connected with this question. The New York State Society, he declared, was no young society, but was formerly a constituent of this body. In 1881 it passed a resolution that it would have no code, and that its members could consult with whomever they pleased. In 1882, at St. Paul, its delegates were refused admission by the judicial council. The matter then rested until 1891. Some members of the New York State Medical Society had come back and had been admitted to membership. Finally, in 1892, the council decided that they could not be admitted, but, upon the representations of the members of the New York State Society who were present in Detroit, a committee was appointed by this organization to confer with a committee from the New York State Society. The result was that in 1893 the American Medical Association was informed that a union could be brought about only by acceding to the terms of the former. The association then passed a resolution that it would never consider this question. (Applause.) The speaker, continuing, said that this question did not come from the New York State Medical Society asking for proper qualifications, but from gentlemen entirely outside of that society. He thought it was time when that society made the request for the members of this association to consider the matter; any other plan would only stultify the association.

Dr. I. N. Love, of St. Louis, said that he had studied this question carefully from the various standpoints, and he thought the resolutions offered by Dr. Hare would permit many able and scientific members of the profession in New York county to enter this association. They were in the minority, and they could do nothing, as their hands were tied. They could, however, by this resolution enter the association individually, as others did. Dr. Scott had made the point that members of the State and county societies had presented no request, and that it had been done by

outside parties. How could they present any request when they could not get in? If they individually joined the association by signing the rules and regulations and the code of ethics, just as the rest did, as individuals, he certainly would favor the resolution offered by Dr. Hare.

Dr. E. D. Ferguson, of Troy, said that Dr. Scott had practically covered the field, and had been accurate except as to two or three minor dates. Dr. Ferguson said that to the profession in the State of New York this was a very tender and a very serious question. The members of the New York State Association regretted as much as did Dr. Hare that all the members of the medical profession in New York State were not entitled to representation in the American Medical Association, but it was their own fault. They deliberately cut themselves off from that association, although warned what the result would be. They replied that they were the high scientific body of the State of New York, that the American Medical Association was nothing but a junketing association any way, and that it would come to them in due time. That was fifteen years ago. But the American Medical Association had grown, and it was now desirable for these men to come into the association. As the secretary of the New York State Association since its organization, he had been repeatedly asked if there was not some way by which these men might be entitled to the privileges of this floor. They had never as a body given any sign of their desire to return to the American Medical Association. At the time of the appointment of the committee at the Detroit meeting, the New York State Society said that it saw no occasion to appoint a committee. The New York State Medical Society was not a young body; it was the pioneer body in the organization of the American Medical Association. Now, in the face of all sorts of official ways of rejecting proposed methods by which its members might reinstate themselves, a resolution was now introduced, inviting them to become members. It had been said that these gentlemen would be pure and holy because they could subscribe to the code of ethics. If they could do that, the door was open for them, for they could join their local association in New York and come here as delegates. It was now stated that these men should come here and be received as delegates. Delegates from what? Delegates from a body which had spat contumely upon the association, and had never withdrawn these insults! Were the members of this association to ask and beg the New York State Medical Society to some back into the fold of the American Medical Ascociation? (Cries of "No! No!" "Not much!")

Dr. W. P. Munn, of Denver, said that these resolutions were the inoculated scalpel by which it was proposed to introduce the sepsis of commercialism into the American Medical Association. (Loud cheers, and cries of "Good!" "Good!") Dr. Hare, the speaker said, was a delegate from Pennsylvania, and, although it was now eight years since he had left his home in that State, he knew from his many visits among the practitioners in that State that he could to-day voice their sentiments more faithfully, more accurately, and more truthfully than could Dr. Hare. These resolutions were the resolutions of Dr. Hare, and they could not carry for one instant before the State Medical Society of Pennsylvania. In this Western country the profession had had all it could do to uphold the code of ethics of the American Medical Association, but it had been done. Were they now to be trodden down by this derelict, dead, rotten society from New York—(stopped by hisses).

Dr. Jackson, of Philadelphia, said that he had sincerely hoped that this question could be decided once for all. The question was: Shall the American Medical Association be a representative body, representative of the local organizations of the profession throughout the country, or shall it consist of individual members attracted to its meetings, who represent themselves?

Dr. Hare said that he had had no intention of making any erroneous statements, if he had done so, and he had withdrawn temporarily his motion of the previous question as a matter of courtesy. Although in his remarks he had endeavored to be courteous, others had been guilty of using very offensive language. He would only add that in New York State there was an organization which had made a mistake, and its members desired to come back. (Derisive laughter.)

Dr. Hare then insisted in renewing his motion of the previous question.

Dr. W. T. Bishop, of Harrisburg, raised the point of order that if these resolutions were adopted the organic law of the association would be contravened. The organic law provided that there should be but one State medical society and but one county society in a county.

The Chairman sustained the point of order. The regular order of business was then proceeded with.

Address on Surgery.—This was delivered by Dr. John B. Murphy, of Chicago, who selected for his subject, "The Surgery of the Lung." He stated that an analysis of the accomplishments in this special line of work was of great interest, the advancements having been made by individual and unsupported efforts. The profession at large had never entered into these fields with the enthusiasm, persistency, and energy with which it had invaded other fields, as the peritoneum, the genito-urinary, the osseous, and the nervous systems. The speaker then considered at great length the early history of lung surgery, after which he discussed the anatomy of the lung, the lymphatics, and the physiology of respiration.

Operations upon the Lung.—In considering this subject, he said that several questions arose: (1) Was the lung, situated in its bone-bound cavity, accessible to surgical manipulation? (2) What were the difficulties and dangers encountered in entering this bony cavity? (3) To what extent might this wall be removed and replaced, and what latitude of manipulation was permitted within the chest? (4) What would be the effect of opening the pleura of pneumothorax in cases of adhesions, and without adhesions? (5) How could its dangers be avoided or lessened? (6) Should the pleura be closed or drained? (7) Could the lung be incised, excised, or defunctionatized? (8) In pneumotomy, what were the dangers and limitations? They were hemorrhage from the opening in the chest, and pneumothorax from the opening in the bronchi; also pleuritis of the same and the opposite sides, and traumatic pneumonia and sepsis. (9) What were the pathological conditions of the lung requiring excision? They were hernia, infected injuries, abscesses, bronchiectasis, gangrene, the removal of foreign bodies, tuberculous cavities, hydatids, and actinomycosis. (10) In pneumotomy, what were the dangers and limitations? In answer to this last question, he said that the immediate dangers were hemorrhage, pneumothorax, and dyspnœa, and the secondary ones, shock, dyspnœa, hemorrhage, sepsis, pleuritis and pneumonia on the opposite side. Dr. Murphy then dwelt upon the best method of treating the intrathoracic stump, and of drainage and closure, and expatiated upon the pathological histology of repair of the stump, etc. (11) How was the chest filled after excision? What were the pathological conditions in which excision was desirable or required? These were neoplasms of the chest wall involving the lungs; circumscribed tuberculosis. (12) How could the lung be defunctionatized artificially and quiescence maintained? By

injections into the pleural cavity and by resection of the ribs, which allowed the chest wall to collapse; and thoracotomy with separation of pleural adhesions and compression of the lung. (13) What were the technical difficulties of intrapleural injection? They were adhesions and consolidations. What were its technical dangers? They were air embolism, subpleural emphysema, pulmonary emphysema, dyspnœa, and sepsis.

The following questions were also propounded: How could we determine that the injected material was passing into the pleural cavity and not into the lung tissue, or bronchus? What was the most desirable material to use for injections? What were the effects of this pulmonary quiescence on the healthy lung? What were the effects of this pulmonary quiescence on the diseased lung, particularly in tuberculosis? How long must the lung remain functionless that the process of repair in tuberculosis might be complete? Were pleuritic effusions beneficial or prejudicial to the repair of tuberculosis of the lung?

Pathology, he said, indicated, and clinical experience justified, resection of ribs to allow collapse of the lung. The same conditions demanded thoracotomy with separation of adhesions and compression of the lung. The dangers of operation on and injuries to the chest wall were shock, hemorrhage, pneumothorax, and sepsis. These three dangers were then taken up seriatim by the author and considered at length, after which followed extensive observations on the action of the lung in the human subject.

Dr. Murphy next considered the diagnosis of pneumothorax and its treatment, and afterward the following subjects: Hernia of the lung and its treatment; wounds of the lung; infective lesions of the lung, their etiology and treatment; abscess of the lung, and its treatment; bronchiectasis; gangrene of the lung; foreign bodies in the lung; tuberculosis of the lung; incision and drainage of the tuberculous cavities; hydatid cysts; actinomycosis of the lung; neoplasms of the chest wall, and lung requiring pneumectomy. In conclusion, the speaker gave an exhaustive numerical summary of the cases operated on, both by himself and by other eminent surgeons, as collected from the literature of the subject, for the following conditions: Gangrene of the lung, abscess of the lung, bronchiectasis, tuberculosis of the lung, foreign bodies in the lung, and neoplasms of the lung. This included the results, favorable or unfavorable, of the various operations.

Dr. Murphy said that pulmonary surgery had ever been hampered by that nightmare—pneumothorax. Different views had been held regarding the cause of the dyspnœa in pneumothorax, but from considerable study and experimentation he had concluded that it was the result of vibration of the mediastinal septum, which thereby nullified the piston action of the diaphragm. If, therefore, the mediastinal septum could be immobilized, the great danger from this complication would cease to exist. Pulmonary tuberculosis was cured by surrounding the focus of infection by connective tissue. More cases, he asserted, of cured tuberculosis were found at autopsies on persons dead of other diseases than cases of death from pulmonary tuberculosis. This connective-tissue formation was favored in the lung as elsewhere by immobilization of the part. In one hundred and sixty-four collected cases of empyema four patients died, seven had fistula, and one hundred and sixty recovered. This seemed to him very good treatment for pulmonary tuberculosis. In at least eighty-three per cent. of cases of pleurisy the disease was tuberculous in origin. It should not be forgotten that plastic pleurisy was curative of tuberculosis of the lung. The method of treating tuberculosis of the lung by compression was a very old one. It was well known that the lung could be compressed for a long time, and that it would expand again when freed from pressure. He had injected into the pleural cavity large quantities of nitrogen gas, as this gas was the least active, and was very slowly absorbed. It might be allowed to remain for a number of months, and the lung be permitted to perform its function. In one case one hundred and forty cubic inches of nitrogen gas was injected. This was followed by slight dyspnœa, lasting, however, only a few minutes. Skiagraphs were taken at intervals for five weeks, and these showed that the gas was slowly removed. Prior to the injection the patient's cough had been very harassing, but on the night following the injection he slept the entire night. Dr. Murphy said that he had tried the method on other patients, and they were anxious for it, as it was simple and free from discomfort. As long as the chest was not opened and the vibration of the diaphragm was prevented, there was no danger of pneumothorax, but there was a possibility of air embolism occurring from injury of a vein by the trocar. Again, in cases of adhesions the trocar might not enter the lung unless special precautions were taken. This method of treatment was applicable to the earliest stage of tuberculosis of the lung, when there was only a small superficial cavity in the apex.

By a rising vote the association tendered its thanks to Dr. Murphy for the address.

SECTION ON SURGERY AND ANATOMY.

W. L. Rodman, of Louisville, Chairman.

First Day—Tuesday, June 7th.

Address of the Chairman: The Influence of Age, Sex, and Race in Surgical Affections.—Dr. W. L. Rodman delivered an address on this topic. He said that the negro was an entirely different being now from what he was in *ante-bellum* days; he was less resistant, and gave a larger mortality in both medical and surgical affections than the Caucasian. It was no wonder that some claimed that in time the negro would become extinct.

Malignant Disease.—Malignant disease was certainly increasing in the black in greater ratio than in the white race. The negro was relatively somewhat more prone to sarcoma than to cancer. From the statistics he had been able to collect it seemed fair to conclude that the negro suffered from cancer one-half as often as the white, although malignant disease of the mammary gland was as frequent in the negro as in the white. He had not seen cancer of the penis, larynx, or tongue in negroes, although rectal cancer was comparatively common. Cancer was pre-eminently an affection which increased in frequency with the advance of civilization. Women were twice as liable to malignant tumors as men, because of the proneness to malignant disease of the breast and uterus. Infancy and childhood were practically exempt from cancer; it was rare prior to thirty, and after this age was more and more frequent. During the second decennium the long bones were the usual site of sarcoma. After forty years and before sixty sarcoma was less common. Like cancer it was a common senescent change, but, unlike cancer, was more destructive in early life.

Tuberculosis.—Pulmonary tuberculosis was practically unknown among the negroes several generations ago; now it was more than twice as common as among the whites, and was still more common in the American Indian. Local tuberculosis of the joints, lymphatic glands, and serous membranes also showed a marked increase. An enormous percentage of Indian boys and girls developed surgical tuberculosis when taken

from their native out-door life to that of the school-room.

Varicocele.—Dr. Rodman said that in his two hundred and fifteen operative cases he had never known varicocele to begin before puberty, and rarely after thirty. Most of the cases occurred between the ages of fifteen and twenty-five years. As a rule, it was cured by marriage, although he had operated upon many married men, and in one instance upon a man over fifty years of age. In six hundred cases operated upon by the surgeons in Louisville, not once was it seen in the negro and only once in the mulatto. This had been the experience of many surgeons in other parts of the country. Anatomically, the testicles of the negro did not hang so low as in the white, and they were not so large, although the penis was larger. Moreover, the scrotum fitted more closely, and gave better support to the veins. Physiologically, the negro began his sexual life at puberty, and thereafter did not know what sexual continence was.

Enlarged Prostate.—According to his own experience it was common to find enlarged prostate in the white race after the age of fifty, but it was rarely seen in the negro, and this had been the experience of many other surgeons. Dr. H. H. Mudd's supposed case of hypertrophy of the prostate in the negro had often been cited, but Dr. Mudd had recently stated that the case had turned out to be one of malignant disease.

Gall Stones.—Cases of gall stone were infrequent after thirty years, and became progressively more frequent as age advanced. The condition was very much more common in women, probably owing to their sedentary habits and bowel and stomach troubles. It was exceedingly rare in negroes, probably owing to their more active life, better teeth, and stronger digestion, together with their diminished liability to malaria and other affections associated with torpid liver.

Aneurism.—According to the records of the Louisville Hospital, aneurism was a little over three times as frequent in negroes as in the white, although the proportion of colored to white was three to one. It was more than three times more frequent in males, owing to the greater tendency to arterial degeneration and the effect of habits of life and occupations.

Tetanus.—This affection was more common in subjects living in hot climates and having dark skins. In this country the negro was unquestionably more obnoxious, especially in infancy. This was partly due to racial predisposition, and to carelessness and ignorance. Persons from five to fifteen showed the highest death rate, and it was five times higher in boys than in girls, apparently largely owing to toy-pistol accidents. Sudden variations in temperature and the depression following upon defeat had always been noted to increase the number of cases of tetanus in military practice. Tetanus was much too common in connection with ritual circumcision among the Hebrews, owing to unsurgical methods.

Ovarian Tumors.—These occurred at all ages and in every race, the cystic and dermoid varieties being the most common. They were frequently congenital, and were stimulated to activity at puberty. Ovarian tumors were less frequent in the negro than in the white, but the negro was far from immune to such growths. The largest tumor of this kind removed by operation weighed two hundred and forty-five pounds. Malignant disease of the ovary was four times more frequent before the age of fifteen than afterward.

Surgical Anatomy of the Bile Tracts.—Dr. A. D. Bevan, of Chicago, read a paper with this title. He said that the modern surgery of this region dated back to the operation of cholecystotomy performed by Sims in 1878. The usual incisions employed in these operations did not give sufficient room, unless made very long, and if this was done there was liability of hernia. The vertical incision along the outer border of the rectus was objectionable because it cut off a large part of the nerve supply of the abdominal muscles, and weakened the abdominal wall. The T-shaped incision was difficult to suture so as to secure primary union, and it was prone to be followed by hernia. The incision in the upper half of the linea alba did not give free access to the gall bladder. An incision which was suitable both for exploration and extensive operation, Dr. Bevan said, was made as follows: It consisted of an outer or primary part, and an extended part. The former was shaped like an italic letter "S," and passed through the outer border of the rectus muscle. It was about three or four inches in length. The extended portions were added when required. They could be made from one inch to three inches in length. The upper extension should not completely divide the entire thickness of the rectus. When complete the incision furnished much freer access to the gall bladder than could be secured by any other incision. Considering its length it injured a minimum amount of nerve supply, and the danger of hernia was likewise reduced to a minimum, the incision being in close contact with the costal arch. At no point should this incision come within three-fourths of an inch of the costal arch. The gall bladder might be conveniently located by the junction of the costal arch with the anterior border of the rectus muscle. At the junction of the neck of the gall bladder with the duct was an S-shaped curve which could be straightened out by division of the peritoneum and connective tissue covering the neck of the gall bladder. The speaker called attention to the close relations between the common duct, the pyloric vein, the portal vein, and the gastro-duodenal artery.

Dr. John B. Hamilton, of Chicago, said that about two years ago he had become interested in this subject, and had examined into the position of the gall bladder in about twenty-five cadavers. By drawing a line from the ensiform appendix to the superior spine of the ilium and another from the umbilicus to the tenth costal junction, it would be found that the gall bladder was situated at a point about half to three-fourths of an inch above the intersection of these lines.

Dr. Harris, of Chicago, said he had made a number of dissections of this region, and had been able to confirm the statements made regarding the relations between the ducts and the portal vein—a point that had been a subject of contention. He had used on several occasions the incision recommended in the paper, and could testify to the very excellent access which it afforded to the bile tracts. In the extension of the incision downward and outward the external oblique was divided at right angles to its fibres, thus causing this portion of the wound to gape. It could be obviated by very accurate suturing at this point.

Intestinal Obstruction from Gall Stones.—Dr. J. P. Lord, of Omaha, read this paper and reported a case in which he had removed, because of intestinal obstruction, a stone of large size from the bowel of a woman of seventy years. The stone was about the size of a hen's egg, and had a gall stone for a nucleus. As there was no history of biliary colic, it had probably ulcerated through the gall bladder into the bowel. It was probable that its size had been considerably augmented after it reached the intestine. In these cases the abdominal distention was not usually marked; the greatest abdominal distention was observed in cases in which the obstruction was in the rectum, sigmoid, or some portion of the large intestine. From fifty to eighty per cent. of these patients should be saved by operation, yet the mortality from operation hitherto had been almost equal to this percentage. He thought it probable that if all cases were operated upon in the

first twenty-four hours, the mortality would be reduced to a point which would be creditable to the surgeon. Fæcal vomiting should be an indication for immediate interference in intestinal obstruction from gall stones. It was his practice to precede operations in cases of intestinal obstruction by lavage of the stomach, because he had seen patients nearly killed during operation by the vomited matter choking them.

Removal of the Stomach.—Dr. P. S. Connor, of Cincinnati, said that fifteen years ago it had occurred to him to remove the whole stomach, and he had done it, but the patient had died on the table just at the completion of the operation. Because of this, only an informal report had been published about a year later. He had been exceedingly gratified to learn that the stomach had been successfully removed, and that the patient had recovered completely from the operation. He had long maintained that such an operation was perfectly feasible. Of course, an operation of this kind would be required only in very rare instances, and certainly it would not be appropriate as long as any portion of the stomach was still functionally active. The trouble was that in those cases in which the conditions were such as to warrant this operation, the difficulties and risks were very great. Greig Smith, in the first edition of his book on abdominal surgery, had called attention to the difficulty of maintaining the circulation in the walls of the colon, but this view he had never shared, as it did not seem to have an anatomical basis. This operation had been called foolhardy, but no operation should be so designated which was based on physiological or anatomical grounds and good surgical reasons. The operation would usually be done for carcinoma, and only in those cases in which the walls of the stomach had become so extensively infiltrated that the organ was functionally dead. It was still an open question whether the removal of the stomach would be proper in other conditions than carcinoma. If the stomach was simply a receptacle and had no physiological function, it might very properly be taken out, and there was no operative reason why this should not be done.

Dr. Kiefer, of St. Louis, said that it was absolutely impossible to remove the stomach, necessitating as it did the severing of the lesser omentum, without severing the fibres of the pneumogastric nerve leading to the liver. He was anxious to know what the liver would do when this nerve was cut.

Dr. Harris, of Chicago, said that a year ago he had removed the stomach entirely for carcinoma in a man, seventy-two years of age. There was no difficulty in securing the œsophagus to the duodenum. The difficulty encountered would depend upon the amount of obstruction existing prior to the operation and upon the degree of mobility of the duodenum. In regard to the pneumogastric nerve he would say that the right pneumogastric nerve passed high up, so that the stomach could be removed without injuring it, provided one kept in the omentum near the stomach.

Dr. Connor, in closing, said that under certain circumstances it would be difficult to make an attachment to the ileum, but not usually to the duodenum. Regarding the effect upon the liver from interference with the pneumogastric nerve, he would only say that the subject of the first successful operation was still alive, and so far no deleterious effect on the function of the liver had been noted. He doubted very much if many cases would be reported in which this bold operation had been done for non-malignant disease.

Diagnosis and Surgical Treatment of Malignant Obstruction of the Pylorus.—Dr. W. J. Mayo, of Rochester, Minn., read a paper on this subject, in which he reported three pylorectomies and four gastro-enterostomies. He said that the one successful case of Schlatter was hardly sufficient to give a substantial basis to the operation for the removal of the entire stomach. He had met with one example of extensive fibrous obstruction of the pylorus, and, believing pylorectomy indicated, had done the operation. In these cases of obstruction of the pylorus it was well to pass a stomach tube and inflate the stomach with air by means of an ordinary syringe, which would enable one to map out the position of the organ. In pyloric obstruction from cicatricial contraction there were commonly a history of early vomiting, especially after the taking of food, and a previous history pointing to ulceration. In the existence of a tumor with a short history, accompanied by cachexia, it should be looked upon as probably malignant. In cancer the absence of free hydrochloric acid had been the rule, but, on the whole, the chemical tests had been disappointing. The gastroscope and the gastro-diaphanoscope did not give encouraging results, even in the hands of their advocates. Under any circumstances, when there was a marked pyloric obstruction, a surgical operation was indicated, and consequently an accurate diagnosis from the symptoms was not essential. An early diagnostic incision should be made. Tait long ago called attention to the good effect on intra-abdominal disease of merely opening the abdomen. The extent and character of the disease, the adhesions to the viscera, and the condition of the glands would determine whether or not the operation should be extended further. Pylorectomy, based on the hope of a possible cure, and gastro-enterostomy, as a palliative measure, were the only two operations deserving of serious consideration. Pylorectomy had not been a popular operation, owing to the mortality attending it being between forty and seventy per cent., but recently Kocher had had seven recoveries in nine cases, and it was probable that the mortality would be greatly reduced by improved technique. Gastro-duodenostomy should be the operation of choice, as distinguished from gastro-jejunostomy. Dr. Mayo then described in detail the method he employed in doing pylorectomy, a modification of that published by Dr. J. B. Murphy in 1895. His operations of gastro-enterostomy had all been done with the Murphy button. The stomach wall should be cut to the mucous coat, he said, before the puckering string was put in, and the bite of the suture should not be too deep. He believed the results, both immediate and remote, were better with the button than with the suture. The preliminary cleansing and emptying of the stomach in his experience had been less perfect than had been expected prior to operation. Great care was necessary upon the part of the anæsthetizer in these cases to prevent fatal septic pneumonia from aspiration of vomited matter.

Dr. J. B. Murphy, of Chicago, expressed his gratification at the emphasis placed by the reader of the paper on the importance of early exploratory operation. Good results in this class of cases seemed to him perfectly within the grasp of the surgeon, but only by early exploratory incision. This operation involved a risk of less than one per cent. He had adopted the plan of separating the omentum, so as to throw the pylorus outside of the abdomen in the early stage of the operation, and had found that it materially reduced the difficulties of the operation.

Dr. McArthur, of Chicago, thought it advantageous to reverse the procedure and make the gastro-enterostomy prior to the operation for plyoric stenosis. The object of this was to re-establish a proper state of nutrition before the pyloric operation, which was at best but poorly borne.

Dr. Hamilton said that about three years ago he had done an exploratory operation on a woman of thirty, who was suffering from regurgitant vomiting, and who had become greatly emaciated. There had been no hemorrhage. Finding no glandular involve-

ment of the mesentery, he had passed his finger into the pylorus, and, this yielding, he had dilated it according to the method of Loretta. The case was apparently one of non-malignant disease.

Intestinal Anastomosis by a New Method.—Dr. William F. Metcalf, of Detroit, said that any device for facilitating this operation should possess the following qualifications, viz.: (1) It should be rigid; (2) as soon as possible after its object had been accomplished it should pass away, leaving the lumen of the gut free; (3) it should be easy of introduction. He had found these indications met by cylinders of hard sugar, in different sizes, and with smooth grooves made in them by a hot iron. A spiral suture of carbolized catgut should be passed so as to bring all of the coats of the bowel together at the bottom of the groove. The size of the "sugar approximator" should be such as slightly to stretch the gut. The groove should be shallow to allow placing the first line of suture as nearly as possible to the edge of the serous coat. Care should be taken to avoid puckering, and the operation should be completed by folding a portion of the omentum around the line of sutures. The operation could be done very quickly and easily.

Dr. H. H. Grant, of Louisville, said that in his experiments and observations he had found that he got along just as well without any artificial aid as with it. The method just described was really only a modification of the old potato method. He questioned very much if it could be done more quickly than direct anastomosis in skilled hands. Of the various known devices, the best seemed to him to be the Murphy button, and with it sutures would be very rarely required if the serous surfaces were properly approximated. The application of the omental graft added to the length of the operation. If the graft was not severed, a loop was left which might cause intestinal obstruction, and if it was detached there was danger of hemorrhage, both immediate and secondary.

New Method of Performing Intestinal Anastomosis and Enterorrhaphy.—Dr. Ernest Laplace, of Philadelphia, described a method of performing intestinal anastomosis by the aid of a specially constructed forceps. This instrument consisted of two rings introduced into the two openings to be anastomosed, and they served as supports during the suturing. The rings of the forceps were separable into halves. These could be withdrawn through the small aperture not yet sutured, and the suturing could then be completed. This left no foreign substance in the gut. The serous surfaces were held together by this clamp in the hands of an assistant during the process of suturing. The forceps having been removed piecemeal, as already described, one stitch sufficed to complete the operation. In a lateral anastomosis the suturing was facilitated by the use of special invagination forceps.

Dr. MacRae, of Atlanta, highly commended the operation. He said it was not always possible to regulate the pressure necrosis or be absolutely sure of the approximation of the serous surfaces with the Murphy button unless sutures were used.

Aneurism of the Aortic Arch; Surgical Treatment by Ligation of the Right Carotid and Subclavian Arteries.—Dr. B. Merrill Ricketts, of Cincinnati, reported a case in which he had ligated these arteries for aneurism with most excellent result, and called attention to the suggestion of Bernays and other surgeons as to the possible advantages of turning back a portion of the sternum like a flap.

Second Day—Wednesday, June 8th.

Penetrating Wounds of the Popliteal Artery.—Dr. George W. Miel, of Denver, in a paper on this subject, recommended double ligation and extirpation of the intervening part in all cases of incised wounds which are more than one-eighth of an inch in length. In every instance the external wound should be loosely closed.

Dr. B. Merrill Ricketts, of Cincinnati, said that Dr. George W. Crile, of Cleveland, had demonstrated that the common carotid artery could be closed with a clamp for a period of from twelve to twenty-four hours without any serious results. Dr. Ricketts said that in a recent operation he had accidentally torn off the external iliac vein, and had ligated it without any unpleasant results. He referred to a case in which the deep profunda had been shut off close to the femoral, and the limb was cold. An amputation was performed at the hip-joint, according to the methods of that time, and the patient had died a few hours later. At the present time he thought it would be better to divide the artery and make an anastomosis, or sew it up with fine silk.

Dr. Oliver, of Cincinnati, said that he had recently been called upon to attend a boy with a compound fracture of the femur at the epiphyseal line. The lower end of the fragment protruded through the popliteal region, and the pulsations of the popliteal artery could be distinctly felt in the wound. The dislocation of the fragment was reduced, but after forty-eight hours symptoms of obstruction to the circulation appeared, and on the ninth day it was thought best to amputate the limb. In the subsequent dissection of the limb it was found that there was a good deal of effusion under the deep fascia, and that this had apparently caused sufficient obstruction to the collateral circulation to give rise to the gangrene. It was also discovered that about two inches of the popliteal artery had been destroyed. In another case of this kind he would open the parts freely and sew up the deep fascia, thus converting the operation practically into a simple ligation of the popliteal artery.

Dr. Tinker, of Philadelphia, alluded to an experiment on an animal in which a Frenchman had succeeded in successfully performing an end-to-end anastomosis of one of the large arteries in an ass.

Primary Carcinoma of the Axilla.—Dr. D. W. Graham, of Chicago, read this paper. He said that primary carcinoma of the skin of the axilla was rare. In seventeen hundred and ninety-seven reported cases of primary carcinoma, five hundred and seventy-one were of the skin, but of these only three were axillary. He had been able to find but eighteen well authenticated cases of primary carcinoma of the axilla recorded, and to this he added two from his own experience. In the treatment of these cases one should be governed largely by general surgical principles, but it was more difficult to decide as to the removal of the mammary gland than when the disease originates in this gland. The liability to infection of this gland from the axilla was not so great as infection of the axillary glands from the mammary gland. The author drew the following conclusions: (1) Primary carcinoma was probably more frequent than the records would lead one to infer; (2) when present it originated first in large tubular convoluted sweat glands peculiar to this region, or in the more or less rudimentary glands, or in the true skin; (3) when the disease appeared first in the axilla, and later in the mammary gland, the most logical explanation was that there had been a retrograde infection through the lymphatics from the axilla to the breast; (4) when the tissues between the axilla and the mammary gland were at all infected, they should be removed along with the mammary gland; (5) when the breast was not removed, it should be examined at short intervals in order to detect the first evidence of the presence of the disease.

Dr. Charles A. Powers, of Denver, said that it

should be an absolute rule to subject every tumor in the mammary gland to the closest scrutiny, for only by early and radical excision could we hope to cure carcinoma of the breast. He had during the past year removed a nodule which could not be distinguished clinically from the malignant growth. After its removal the pathologist reported the tumor to be a supernumerary mammary gland.

Dr. Ochsner, of Chicago, said that at the inner portion of the axilla and at the lower edge of the pectoralis major he had in three instances observed the origin of a carcinoma. In each instance the growth had been movable under the skin, and consequently it could not have originated in the sweat glands. The only other glandular tissue here was a portion of the mammary gland—a supernumerary gland. He had frequently found extensions of the mammary gland to a considerable distance from the gland proper, and there seemed to be no reason why there should not be an extension in this as well as in other directions.

Dr. Bevan spoke of the occurrence of a very small primary focus, overshadowed by a larger secondary mass, which might be between the mammary gland and the axilla.

Dr. J. B. Murphy, of Chicago, asked Dr. Graham if in his cases the tumor was situated deeply or superficially primarily, and also as to whether the skin moved with the tumor in the early stage. He said that every surgeon operating in the axilla had noticed suppurating foci and collections of sebaceous material. This indicated that they were invaginated portions of the epiblast. They were not connected with the skin.

Dr. W. L. Rodman, of Kentucky, said he was able to add another case of this interesting affection. The patient was a male, about sixty years of age, who had an undoubted scirrhous carcinoma of the axilla. This diagnosis was confirmed by microscopical examination after its extirpation. He had carefully followed this case up to the time of the man's death. It was not probable that there was an outlying portion of the mammary gland in the male. Most of the cases that had been reported were sarcomata rather than carcinoma, but there could be no doubt that primary carcinoma in the axilla was occasionally met with as a primary growth. He had more than once had his attention called to what appeared at first to be primary growths in the axilla, but careful examination would show a small primary focus in the mammary gland. Owing to the danger of infection of the lesser pectoral, the speaker said, the Halsted operation was even more suitable than for the ordinary cases of mammary carcinoma.

Dr. Graham, in closing, said that many cases of fibro-adenoma originated in these sweat glands. The areola of the mammary gland had been shown to have these same large, convoluted sweat glands beneath the skin and running down into the mammary tumor. It was possible to have a supernumerary nodule in the male.

Clinical Results Obtained by the Use of the Harris Instrument for Securing the Urine Separately from the Two Kidneys.—Dr. M. L. Harris, of Chicago, presented a communication with this title, and related four illustrative cases. He had used his instrument in examining forty cases. The fourth case, one of hæmaturia, was a complete demonstration of the perfect action of the septum in the bladder. The instrument was not difficult to use, and he felt that it would make Edebohls' proposed operation of taking out and inspecting both kidneys entirely unnecessary.

Dr. McArthur, of Chicago, testified from personal experience to the great value of this instrument.

Splint for Fracture of the Leg.—Dr. Macbeth, of Denver, exhibited a splint, which he highly recommended for the treatment of fractures of the lower part of the leg, near the ankle. It consisted, he said, of two parallel strips, or side-pieces of wood, and of a footboard and of means for suspending the limb and heel in the splint. The length of the splint and the degree of extension exerted were adjusted by a thumb-screw device attached to the footboard. The foot was secured by adhesive plaster and the limb by a two-tailed bandage.

Use of Mixed Toxins of Erysipelas and Bacillus Prodigiosus in Treatment of Inoperable Sarcoma, with Immediate and Final Results, Based upon a Personal Experience of Six Years.—Dr. William B. Coley, of New York, read a paper with this title. He said that in the meeting at Baltimore one of the speakers had ventured the prediction that another year would see the method consigned to oblivion, but he had continued his observations in spite of this statement, in the belief that that prediction would not be verified. He emphasized the fact that the treatment should be restricted to inoperable sarcoma. In cases of rapidly growing round-cell sarcoma of the bone he would not advise the toxins. He had used the treatment in a few cases after operation to prevent recurrence, and, while the outlook in this particular field was hopeful, he was not yet ready to draw any conclusions. The toxins had been prepared for his use in the Loomis Laboratory. He had never claimed to be the first to substitute the toxins for the living cultures. In all his successful cases the combined toxins had been used, and so far as he knew, no one had reported a successful result from the use of the toxins of erysipelas alone. He was confident that the degeneration of tumor tissue was decidedly increased by the addition of the toxins of the bacillus prodigiosus. The theory generally accepted regarding the treatment was, that it was a process of necrosis—a local process—but this was certainly far from the truth. A number of cases of sarcoma had disappeared entirely by absorption without breaking down. The toxins probably acted through the blood serum, causing coagulation necrosis with breaking down of the tumor cells. In the spindle-cell variety absorption without breaking down was more common, whereas in the round-cell variety the reverse was true. A much larger quantity of the remedy could be given subcutaneously remote from the tumor than when injected into the tumor—a point of no little importance. The rule should be to begin with a minimum dose, and gradually increase it, and if this rule was followed the risk of the treatment was almost nothing. Toxins produced from very virulent cultures should never be given in larger initial doses than half a minim, boiled water being used to obtain the requisite dilution. If the injections were given subcutaneously at a point remote from the tumor, a dose of one minim might be used. If the temperature following the chill reached 104° or 105° F., stimulations with whiskey and strychnine might be indicated. Usually after one or two hours the temperature began to fall; it should reach the normal after twenty-four hours. It was not necessary to produce a chill by each injection—indeed, some of the best results were obtained when only two or three chills occurred altogether. If the treatment was judiciously carried out, the patients did not usually lose flesh. The first change in the tumor was a marked decrease in vascularity; next loss of the glossy appearance of the overlying skin; then the tumor became more mobile, and a visible reduction in the size was observed. In most cases, if no marked improvement was observed within three weeks, it was useless to continue the treatment. Out of his eighty cases of round-cell sarcoma thirty-five were more or less improved, and in two the tumor disappeared entirely. One of these latter patients was well after three years, and one after a year and a half. Of the twenty spindle-cell sarco-

mata, ten disappeared entirely and all showed great improvement. Seven patients had now been well over three years, eight from one to three years, and four others from six months to one year. The paper contained a detailed report of eight cases of sarcoma successfully treated since the meeting of 1895. All save two were considered inoperable, and in both of these patients the disease had rapidly recurred. In seven of these cases the diagnosis was confirmed by microscopical examination, and in the eighth the clinical diagnosis was beyond a reasonable doubt. It had been objected that the number of cases benefited was a very small proportion of the total, but this was an argument which was unworthy of the physician, in view of the desperate condition of these unfortunates.

Dr. McArthur, of Chicago, said that he had had six cases under careful observation and treatment by this method. In one case of recurrent sarcoma of the arm, in which further operation had been refused, the toxins had been used, and the patient had now remained well for three years. According to his experience it was almost useless to use the treatment in melanotic sarcoma.

Dr. Harrison, of Colorado, asked why the toxins were not recommended in carcinoma.

Dr. Lewis, of Topeka, said that he had had one cure from the use of the toxins. The case was one of sarcoma of the angle of the jaw on the right side, in which an operation had already been done. The disease extended, necessitating the removal of the clavicle, and later of a portion of the tibia. About a year later the patient had had an attack of erysipelas of the face, which had so improved her condition that he had decided to resort to Coley's mixture. The result had been most satisfactory.

Dr. Bevan related an experience that he had had with the toxins, as he thought it threw some light on their action in sarcoma, or pathological conditions at present confounded with sarcoma. The case was one of large gumma of the thigh coming under his observation in the past year. His original diagnosis had been sarcoma, and a very radical operation had been advised. As the patient objected to operation, the toxins were used for a time, and caused some diminution in the size of the growth. Subsequently he performed an exploratory operation, and removed a section of the tissue, which appeared both macroscopically and microscopically to be gummatous. The patient was then put upon iodide of potassium, and the growth entirely disappeared. The patient then admitted that, although the father of four healthy children, he had been infected with syphilis some years before. In view of the almost unanimous opinion of foreign surgeons that no results had been obtained in pure sarcoma, he thought it possible that the successful cases had been examples of that class described some years ago by Esmarch, which could hardly be differentiated from sarcoma even by histological appearances.

Dr. Coley, in closing the discussion, said that he had treated nine cases of melanotic sarcoma, and in only two of these had there been even temporary improvement. He did not recommend the treatment in carcinoma, because up to the present time the results had not been sufficiently good to warrant its use. In one case of epithelioma of the chin, floor of the mouth, and lower jaw, in which even extensive operation seemed of doubtful propriety, the treatment had been tried, and the patient had remained well three years, but one case was not sufficient evidence. In his cases the cures had not been in round-cell sarcoma—the only variety of sarcoma which it was possible to confound with syphilitic lesions, according to the eminent pathologist, Dr. William H. Welch. Inasmuch as in fifty per cent. of the spindle-cell cases a cure had been effected, it did not seem that the diagnosis could fairly be doubted.

On the Advantages of a Permanent Artificial Anus and of Total Closure of the Sacral End of the Rectum in Operations for Cancer of the Rectum.—Dr. W. W. Keen, of Philadelphia, read this paper. He said that cases of cancer of the rectum had become now so amenable to treatment that physicians were derelict in their duty to their patients if they did not recommend operation, even when the disease is high up. He had now done the Kraske operation in seventeen cases, of which fourteen had ended in recovery, giving a mortality of a little over seventeen per cent. Two patients were well after five and one-half years, both being men who had been deprived of the coccyx and a portion of the sacrum, and yet they habitually rode bicycles. Six had passed the three-year limit, so that he claimed that one half had been permanently cured. When the sacral anus was made, as was usually requisite, the difficulties were threefold, viz.: (1) Very great liability to infection; (2) the patient must always wear a napkin because of the discharge of mucus from the lower portion of the bowel—that part below the inguinal colostomy; and (3) there was a certain degree of prolapse of the bowel. To obviate these difficulties he resected the bowel, and instead of bringing it out at the sacrum he treated it just as he would when doing a lateral anastomosis—invaginating and inserting one row of Lembert's sutures. This ordinarily avoided infection, and as it closed the anus entirely there would be no discharge of mucus. The only openings left were the two colostomy wounds. Two illustrative cases were reported by Dr. Keen.

Dr. Bevan asked why it would not be desirable to remove the entire lower segment.

Dr. William M. Harshaw, of Chicago, suggested that in case of closure of the anus, the lower segment of the bowel would assume the position of a vestigial organ, and might, therefore, favor the recurrence of the malignant growth.

Dr. Keen said that the lower segment was really a long part, which would require an abdominal section and an unnecessarily increased risk. It should be remembered that vestigial organs did not develop in the individual, but required several thousand years.

A Large Coccygeal Tumor.—Dr. Charles A. Powers, of Denver, exhibited the following clinical cases. The first one was that of a little child of ten months presenting a coccygeal tumor of unusual size. He had first seen the infant when it was at the age of three months, and then the tumor had been decidedly cystic. He believed it to be a coccygeal tubulo-dermoid. It had no communication with the gut, and apparently none with the spinal canal.

Value of the Murphy Button.—The second case, that of a young man, illustrated in a striking way the value of the Murphy button under the most adverse circumstances. There was a history of an ordinary appendicitis, and when the patient was first seen there were a large tumor in the median line and an absolute intestinal obstruction for four days. His condition was precarious. At the operation a large quantity of fetid pus was evacuated, necessarily through the free abdominal cavity. Nearly two hours were occupied in liberating the extensive adhesions and washing out the belly. A large piece of rubber tubing was passed down behind the pubis into the abscess cavity. After twenty-four hours a fæcal fistula formed, and all the faeces were passed through this for a few days. Last January the operation was attempted for the cure of this fistula, the Murphy button being used. The button was passed from the bowel on the thirtieth day. The intestinal fistula was cured. Just as the patient was thought to be well, he developed another attack of appendicitis, as the appendix had not been found and

removed at the first operation. He was operated upon through Kammerer's incision, and a perforative appendicitis found. The patient then made an uneventful recovery.

Treatment of Fracture at the Elbow-Joint.—Dr. Powers also presented two cases of T-shaped fracture at the elbow-joint, because they illustrated the results usually obtained from a method of treatment which he had adopted at the Chambers Street Hospital, New York City, some years ago. He said that much had been written upon the value of extended position in the treatment of these fractures, but he believed it to be wrong. If ankylosis should take place, the position was the worst possible. He recommended that, with or without ether, with the arm slightly abducted and in a position of semiflexion (140 to 150 degrees) a plaster-of-Paris bandage should be applied. At the end of a week the arm should be flexed a little more and again put up in plaster. After still another week the arm should be put up at right angles and left so for two or three weeks, when all bandages were to be removed.

Dr. J. P. Lord, of Nebraska, said that he thought the indication for the treatment of these cases was to prevent the filling in of the olecranon fossa with the callus. This could not be avoided if the treatment was carried out in the flexed position. Flexion should be begun very early after using the extended position, perhaps after one week. In his opinion, the extended position had a distinct place.

Dr. McArthur said that in those cases in which it was impossible to get good motion at the elbow-joint, neither the extended nor the flexed position seemed to him so desirable as wiring of the bones under strict asepsis.

Dr. MacRae, of Atlanta, said that the case of appendicitis illustrated the necessity of not doing ideal surgery at one sitting. There could be no question that this patient's life had been saved by doing three operations instead of one.

Medical Aspect of Appendicitis. — Dr. H. A. Hare, of Philadelphia, presented this paper. He said he believed that in some cases of appendicitis operation was indicated, and that in others it was not indicated. Appendicitis was often insidious and provocative of aberrant symptoms which masked the real trouble. He reported two cases, one of what appeared to be a slight typhoid infection of the appendix, and another in which a typhoid fever was complicated by an appendicitis so severe as to demand operation. In the making of the diagnosis rigidity of the abdominal walls was of the greatest importance, and should be an indication for the necessity of having a consultation with some broad-minded surgeon. All cases of appendicitis, he said, could be divided into three classes, viz.: (1) Those which should be undoubtedly subjected to operation at once; (2) those about which doubt existed; and (3) a certain number of cases of appendicitis in which the patients recovered from moderate attacks, and had no more. There were many cases of the last class which could easily be cited. When dogmatic surgeons ceased to combat dogmatic physicians, the best statistics would be obtained. Opium should be used very cautiously, and only to the extent of slightly mitigating the patient's suffering.

Time to Operate in Appendicitis. — Dr. H. D. Niles, of Salt Lake City, read this paper. He said that the chief reasons for operating promptly in appendicitis were: (1) Such a course was in harmony with the generally recognized law that the presence of infected devitalized tissue was an indication for the removal of pus by the most direct and safest route; (2) as extensive adhesions might interrupt the functional activity of neighboring organs, this process of repair should be interrupted early: (3) if this was done the mortality in the hands of experienced operators should not be over two per cent.; (4) prompt operation was attended with less immediate danger and gave better ultimate results; (5) even if certain stages of the morbid process were known to present favorable conditions for operative procedures, there was no means of accurately determining the exact pathological changes taking place within the abdomen. The death rate of the delayed operations, it should be remembered, could not be exactly computed; it was admitted, however, that seventy-five per cent. of these cases ended in imperfect recovery. The condition present in appendicitis was one of local infection, giving in the first attack a mortality of ten per cent. and an ultimate mortality of twenty-five per cent.

Early Treatment and Indications for Operation in Appendicitis.—Dr. William M. Harsha, of Chicago, discussed this subject. He said that the number of those who favored operation in non-fulminant cases, immediately upon making the diagnosis, was small compared with those who preferred to wait a period of about twenty-four hours for purposes of observation. As in many cases the first attack subsided or was aborted, it seemed to him preferable to delay operation for this brief period; moreover, it could not be denied that a great many patients recovered and did not have a second attack. Rest in bed, abstinence from food, and hot or cold local applications constituted the chief measures to be employed. Failure to relieve pain by these means naturally suggested the use of some anodyne, and, while there was a great difference of opinion regarding the use of opium, the majority seemed to favor its judicious and moderate use, especially when the case was under the constant observation of a skilful nurse. Codeine was the best preparation to use. The cautious administration of an opiate relieved the pain and diminished shock. There was the same diversity of opinion regarding the use of cathartics. Thus, McBurney advised against their use, but the majority of both physicians and surgeons seemed to admit the value of such eliminative treatment. A free serous depletion of the intestinal tract might sometimes relieve the stenosis, which constituted one important factor in appendicitis. In the early stage, the increased peristalsis thus produced should not be dangerous, as at this time the wall of the appendix was not greatly weakened. In some cases it would be found desirable to administer a saturated solution of sulphate of magnesium by the subcutaneous method. The dose varied from 1.86 to 4.5 grains. Veterinary surgeons were in the habit of injecting eserine, and he had tried this remedy in three cases, using in one case $\frac{1}{50}$ gr. of eserine combined with two grains of sulphate of magnesium in two-per-cent. solution. The result was catharsis in three hours. The foregoing treatment constituted all that was usually required or indicated in the twenty-four hours of observation. In the later stages the indications for treatment were less clear. There was an overwhelming opinion in favor of leaving the appendix, for the adhesions must be broken up in order to effect its removal. He believed that the following out of the principles laid down in the paper would reduce the mortality to less than five per cent.

Dr. W. W. Keen said he believed that appendicitis was a medico-surgical disease, and that, therefore, the physician should, as soon as he made the diagnosis, call a surgeon immediately in consultation. He was of the opinion that the majority of cases of appendicitis, at least after the first attack, demanded surgical operation, but at the same time he would be loath to have the two last papers go forth as the opinion of the surgical section without protest. He protested against the position taken by Dr. Harsha regarding the use of opium. One dose, or possibly a second dose of one-

fourth of a grain of morphine hypodermically might be proper, but after that, to the winds with it. He protested with equal vehemence against Dr. Nile's position, that every case of appendicitis should be subjected to immediate operation, and also that the appendix must be taken out, no matter how extensive the adhesions. Dr. Niles had appealed to pathology, and so did he, for Hektoen, of Chicago, had examined three hundred cases of persons dying after diseases other than appendicitis, and in one hundred of these had found evidence of a previous appendicitis that had been recovered from. Nor could he accept the statement that the mortality could be reduced to two per cent. He challenged all the surgeons present to deny that, if they operated upon one hundred well persons, they would not kill more than two. Even in the hands of the most skilled surgeons asepsis not infrequently failed. It was, of course, not ideal and complete work to leave the appendix behind, but it did not follow from this that such a procedure was safe and proper in every instance. It was much better to have a live patient with an appendix inside of him than to have a corpse without an appendix; he was not like the French school, which believed that a case was not complete without an autopsy. Regarding the time of operating, the speaker said that if a patient with a first attack was not getting any better, after twenty-four or forty-eight hours—if one could wait so long with any degree of safety—or was getting worse, he would say, operate. The rule would probably hold true in the second attack, but he never allowed his patient to have a third attack if he could possibly avoid it.

Dr. J. Ransohof, of Cincinnati, said regarding immediate operation that in one instance, in which the diagnosis had been made of appendicitis, the case proved to be one of stone in the bladder. In another case, seen in consultation, there was a history pointing to appendicitis. He operated immediately, but to his intense chagrin he found a large malignant gland in the right iliac fossa, and further examination showed sarcoma of the testicle, with secondary deposits within the abdomen. He had seen only two cases in which the opening of an abscess had necessitated later on removal of the appendix. These abscess cases seemed to be very rarely subject to subsequent attacks of appendicitis.

Dr. MacRae said that Dr. Niles' mythical percentage of ninety-eight seemed absurd to every right-thinking physician and surgeon, for there was absolutely nothing upon which such a statement could be based. He had seen eight cases of appendicitis in children under twelve years of age. In seven of these cases death occurred from septic peritonitis without operation. Children did not bear this disease well, and the mortality was heavy unless the operation was undertaken very early.

Dr. J. E. Moore, of Minneapolis, said that neither physicians nor surgeons should be dogmatic, but should draw conclusions only after earnest, careful, and scientific study and observation. This could be best done by consultations between physician and surgeon. At one time he had held the opinion that no great effort should be made to remove the appendix, but more recently he had broken down adhesions when necessary and had removed the appendix, with a successful issue in every instance.

Dr. Grant, of Louisville, said that this unfortunate diversity of opinion in the profession was apparently responsible for many deaths. It was because the surgeons lacked confidence among themselves that many cases did not come to them until it was too late. It seemed to him infinitely better for the surgeons to perfect their diagnostic resources than to study special methods of operation.

Dr. Porter, of Fort Wayne, said that to carry the argument of Dr. Niles to a logical conclusion meant that an ulcerated ileum infected with typhoid bacilli must be removed because it was incapable of recovery. In many instances it was far better not to do a complete operation. In an experience comprising over one hundred cases he had not seen a recurrence from leaving the appendix behind. The chief guide in the treatment of this, as of other conditions, should be common-sense.

Dr. Coley said that the tendency, in New York City at least, was to do the complete operation, carefully dissecting away the adhesions and removing the appendix. He had personally operated upon two cases for recurrent attacks after the appendix had been left behind at the first operation. These infections varied in character; at one time it was a virulent streptococcus infection; at another time it was a mild staphylococcus infection, and never gave rise to another attack.

Dr. J. B. Murphy said that the diversity of opinion was due to lack of knowledge regarding a number of important factors. In a case of general fulminating streptococcus peritonitis, we should not operate, for it was useless and surgery got the credit for the death. He was willing to admit that in a large number of cases of appendicitis patients did recover, but, on the other hand, a large number of patients died because they were not operated upon in time. Was this serious question to be left to the patient to decide? No; whenever this was done it was because the attendant was a moral coward. His duty was not performed until he had properly advised the patient. In cases of staphylococcus peritonitis, when the infection was limited by the formation of adhesions, it was often possible to secure recovery without operation. The time to operate was when the surgeon had made a correct diagnosis. The speaker said that he thought he now got better results from opening into the free peritoneal cavity; he endeavored never to open into the abscess. He built up a good firm cofferdam with gauze, and felt secure. The presence of pus in the peritoneum for a short time conferred a certain immunity, so that the operative manipulations were not so dangerous as in other cases. Many more lives, in his opinion, were sacrificed by small openings than by large ones. The opening should be large enough to admit of doing the work well, and then the size of the wound should be reduced as much as possible without interfering with the action of the drain.

Dr. W. W. Grant, of Denver, said that the experience of all surgeons who operated early in this disease was that the mortality was insignificant; it did not exceed more than one or two per cent. The only way to reduce the mortality was to operate early in all cases. The surgeon usually explained his fatal results by the statement that he was called too late. If Dr. Hare had operated upon his case early there would have been no abscess.

Dr. Conner, of Chicago, cited two cases illustrating the non-operative side of the question.

Dr. Reed, of Wyoming, said that the experience of over fifteen years in operating upon appendicitis showed him that the fatal cases were those in which operation had been delayed.

Dr. Eagleson said that one of the great disadvantages of late operation was the presence of adhesions.

Dr. Ochsner, of Chicago, thought enough stress had not been laid upon the very different results obtained by competent and by incompetent surgeons. It was absurd to lay down rigid rules for all operators. In appendicitis the ileum and the cæcum were also inflamed. It was a well established rule that an inflamed part should be put at rest, and hence in appendicitis no food of any kind should be given by mouth.

This was his practice and his results seemed to justify the wisdom of it.

Dr. Keen said that he had understood Dr. Niles to say that, regardless of the stage of the disease and the condition of the patient, every case of appendicitis should be operated upon, and against this he had protested. In first attacks a large number of patients would recover without operation, and, if these were all operated upon by the average operator, he was of the opinion that the mortality would be much greater than if they had not been subjected to operation.

Dr. Murphy said he had paid so heavily for the position he took that he now felt that if he saw a case of appendicitis and put off operating, and that patient should die, he would be personally and morally responsible for that death. It was not a mythical statement that only two per cent. of the cases would be lost in early operations; on the contrary, he believed that this was the maximum that should be lost in the hands of a competent surgeon. He said this because the pathological conditions in the first twelve hours of appendicitis were such that the disease was confined—except in primary perforative appendicitis, which occurred only once in about one hundred cases. After the first thirty-six hours, in seven out of ten cases there was pus in the free peritoneal cavity from streptococcus infection without perforation of the wall. He knew this to be a fact because he had seen it; then why should he take the chances of that pus doing any harm? If he was suffering from appendicitis he would want to be operated upon just as soon as he was convinced of the correctness of the diagnosis.

Dr. Niles, in closing the discussion, said he saw no reason for establishing rules of treatment for children different from those accepted for adults. The speakers who advocated the use of cathartics failed to show how infection imprisoned in a closed tube like the appendix could be influenced in this manner. In view of the utter unreliability of the signs and symptoms he saw no escape from the conclusion that the only safe plan was to operate in all cases of infective appendicitis. Some of the speakers had made a personal matter of this question; so had he, and had operated upon his own son for appendicitis just as soon as he had made the diagnosis.

Dr. Harshaw closed the discussion. He said he believed it had not been gainsaid that the majority of cases which aborted or spontaneously subsided did so in the first twenty-four hours. He did not believe it was safe to wait longer than this. In fulminating cases the operation should, of course, be done without any delay.

Third Day—Thursday, June 9th.

Course and Treatment of Injuries to the Peripheral Nerves.—Dr. A. H. Levings, of Milwaukee, read a paper with this title. He said that if the divided ends of the nerve were immediately sutured, or the gap was immediately bridged with suitable material, under aseptic precautions, it would be found that but slight degenerative changes would take place in the nerve. On the other hand, if these measures were not taken, or if suppuration occurred, there would be pronounced degeneration in the ends of the nerve. In many cases the function of the nerve, both motor and sensory, had been established in a few days, entirely too soon to have been accomplished by regenerative changes. An examination of his specimens had convinced him that the neurilemma with its nuclei played an important part in the restoration of the divided nerve. Both the central and the peripheral parts seemed to take an active part in the projection of the neurilemma threads. The essentials for success in uniting divided nerves were: (1) Absolute asepsis; (2) the nerve should not be separated from its connective-tissue surroundings; (3) the nerve should be approximated evenly and without tension; (4) if an inch or more of the continuity of a nerve was lost, the gap should be bridged with some material having longitudinal fibres or strands; (5) contrary to the prevailing belief, absolute rest of the limb was not imperatively necessary. The nerve ends should be allowed just to touch each other; if the tension was greater the ends of the nerve fibres would be bent and the restoration of the function would be much slower and more imperfect. He had practised the flap method, he said, in a few instances, but with poor results. Bridging the gap with a piece of nerve taken from an animal was an excellent method, but had the objection that it was complicated and required two operations instead of one. Experience had shown that when the gap was not over three inches long, six strands of silk constituted an excellent bridge between the divided ends of the nerve. In one case the function was restored in twelve days, and in the others in varying periods up to forty-six days. Dr. Levings reported a recent case in which he had used pieces of muscle for the bridging material. The nerve had been injured in 1869. At the operation it was found that there was a gap of more than one inch in the radial and three inches in the ulnar. After four months sensation was now almost normal, but the muscular function had not yet been noticeably improved.

Dr. C. A. Powers briefly reported a case bearing on this subject. A man, about twenty years of age, had been admitted to his hospital service about two years ago, with a compound comminuted fracture of the head of the fibula, with laceration of the external popliteal nerve as it wound around the head. The wound was filled with coal and other dirt. After thorough cleansing and trimming of the wound, there was still so much infection present that it seemed best to do a secondary operation. After six weeks this was done, the interval between the divided ends of the nerve being bridged with a piece from the great sciatic nerve of a dog. The interval was a little over four inches in length. The nerve was united with fine black silk threads passed through the sheath, care being taken that the sharply cut ends of the nerve just touched each other. Primary union occurred and sensation began to return in six or seven days. After three or four weeks sensation was complete, but up to the present time function had not been restored. He had been under the impression that nerve tissue was the best material for bridging the gap, and hence he was delighted to learn that Dr. Levings had found that such an easily procured material as muscle was excellent for this purpose.

Dr. R. Harvey Reed, of Wyoming, said that in cases in which the interval between the divided ends was considerable, and the bridge could not therefore be used, he had found, both by animal experiments and by clinical observation, that by neural infixation the desired object could be achieved. By this was meant that the divided ends of the injured nerve were fixed into a neighboring nerve. One of the first, if not the first, to call attention to this valuable procedure was Dr. Galbraith, of Omaha, who infixed the musculospiral nerve in this way. He had known the function of the nerve to be re-established in from ten to thirty days.

Dr. Levings said that it was not uncommon for sensation to be restored without restoration of motor function. He believed this occurred almost entirely from anastomosis of the collateral branches. In the cases in which he had used catgut, failures had been much more frequent than when silk had been employed. The bridge of silk simply afforded a scaffolding,

which favored the regeneration of the nerve. When the gap did not exceed three inches he had found no difficulty in securing restoration of function. The method of infixation was a useful one, but was not feasible in many instances, because of the great distance of the uninjured from the injured nerve.

Post-Operative Insanity.— Dr. R. Harvey Reed, of Rock Springs, Wyo., read this paper. He said that the literature of the subject was unfortunately exceedingly meagre. He reported six cases occurring in females and two in males. One of these latter was a healthy man who developed mania nine days after an operation on a fractured patella. The wound had been healthy up to that time, but the violent movements of the patient led to rupture of some of the tissues, and this was followed by sepsis and suppuration, and, in spite of free drainage, eventually by death. A circular letter of inquiry had elicited further experience with these peculiar cases. Some surgeons of large experience stated that they had never met with a case of insanity after operation in a person who had been mentally sound up to the time of the surgical interference. Dr. Reed said that in only one of his cases of post-operative insanity had iodoform been used in the dressings, and there seemed to be no evidence of septicæmia or pyæmia. Since he had been located in Wyoming, nearly a mile and a half above the sea level, he had not met with a single case of this kind, although he had done some formidable operations.

Dr. George W. Johnson, of Illinois, said that Dr. Wagner, of Leipsic, had reported six cases of bilateral castration, with four deaths from acute mania. In his own experience there had also been cases of this kind.

Dr. Davis, of Omaha, said that in two cases of post-operative mania he had been impressed with the idea that the mania was often what might be expected as a result of mental and physical depression. His patients had been in rather unstable mental condition prior to operation. He was of the opinion that surgeons should never operate upon the pelvic organs of insane women for conditions for which they would not operate in a sane woman. In a case of depressed fracture of the skull, insanity came on about eleven months after the injury. The girl had not been considered severely injured at the time, but when she was seen by him in consultation a depressed fracture had been detected and operated upon. The patient was restored to robust health, both mentally and physically.

Dr. Ochsner reported several cases bearing on this subject. The first case was one of general infective peritonitis. The abdomen was opened, and drained only, yet immediately on awakening from the anæsthetic the patient was violently insane. She remained so for two years. Subsequently he had removed the uterus and again drained the abdomen with the idea of removing all infection. She once more exhibited symptoms of insanity, but by means of "suggestion" she was enabled to control her nervous condition, and as a result had been perfectly well ever since.

Dr. Moore, of Oregon, remarked that there did not seem to be any particular pathological connection between an operation and insanity, but the operation sometimes caused just that perturbation which was all that was requisite to overturn the mental balance.

Tendon Suture: Its Preparation and Uses.— Dr. H. O. Marcy, in a paper with this title, referred to the important investigations made as long ago as 1829 by Dr. Jamieson, of Baltimore, and stated that, so far as he knew, Mr. Lister was entirely ignorant of these researches. At one time he had himself made a comparative study of the various animal ligatures, and had discovered that when aseptic ligatures of this kind were buried in the tissues they were surrounded by leucocytes which, little by little, invaded the sutures and ligatures, and that the material of these was eventually converted into connective-tissue cells. He soon ascertained that catgut was faulty for two reasons, viz.: (1) Because, as it was the connective tissue of the small intestine of the sheep, it must be separated from the other coats by maceration, which was necessarily a process of putrefaction; (2) because of the disposition of the connective-tissue fibres themselves, these fibres crossing each other obliquely. Catgut when dried was comparatively strong, but when wet it was soft and liable to break, and it was in this condition when buried in the tissues. By culture tests he had ascertained that the tendon suture uniformly remained sterile, and it was easily prepared by immersion for half an hour in warm sublimate solution just before use. It was for the purpose of closing the inguinal ring and restoring the obliquity of the canal, so as to prevent the occurrence of hernia, that he had, as long ago as 1870, employed buried animal sutures. There was as much difference between different samples of tendon as in leather. A great variety of tendon suture was exhibited. In marsupials, Dr. Marcy said, was to be found the best tendon material. He hoped to live to see the buried animal suture universally adopted, and constituting an important part of the technique of modern aseptic surgery.

Prize Essay: Experimental Research into the Effects of Temporary Closure of the Carotid Arteries, with the Report of a Case.— Dr. George W. Crile, of Cleveland, sent this communication, which was awarded the Senn medal for original work in surgery.

Radical Cure for Hernia and Hypertrophied Prostate in Old Men.— Dr. George W. Johnson, of Dunning, Ill., reported in this paper twenty-eight cases, with a *résumé* of the literature. Surgical treatment was resorted to, he said, only after years of suffering and pauperism, when all other sources of relief had repeatedly failed. A digital examination per rectum should be made in every case when there was a suspicion of prostatic disease. When acute, there was frequent and painful urination, with pain and sometimes a few drops of blood at the close of the act. There were also usually distress in the perineum, and rectal and vesical tenesmus. In the chronic forms, the symptoms simply differed in degree. There was usually a history of nocturnal pollutions, impairment of the sexual function, pyuria, and vague neuralgic pains in the pelvis. In cases of prostatic hypertrophy there was a history of difficulty in emptying the bladder, tardiness in the onset of the flow of urine, and lack of force, together with a sense of fulness in the bladder, perineum, and rectum, especially during and after stool. Sometimes there were retention and enuresis. Several different groups of cases were described, as they had been observed in the inmates of the Cook County Infirmary. In one group there was bilateral hernia, with large orchidocele on one side. Here orchidectomy was done upon that side, and herniotomy and gonangiectomy upon the other side. The surgical treatment consisted in making an incision, under chloroform anæsthesia, according to the Bassini method. The cord, testicle, and hernial sac were removed from the scrotum in one mass. The cord was separated and ligated high up, and the testicle was removed. The sac was then dissected out high up and ligated, and the stump was dropped back into the peritoneal cavity. The upper and inner portion of Poupart's ligament and the under and outer surfaces of the conjoined tendon and the margin of the internal oblique were freshened with a sharp curette, and formalin catgut sutures were introduced in such a way as to draw the conjoined tendon and internal oblique above Poupart's ligament, entirely closing the external ring and obliterating the canal. The external wound was then closed with silkworm gut, and wet bichloride dressing

applied. A herniotomy after Bassini was done on the left side, with resection of the vas deferens. There was no relief from the prostatic trouble for three weeks: then gradual improvement was noted, and this continued until recovery took place some months after operation. The patients whose cases formed the subject of this article were kept in bed for three or four weeks, and then, if no good effect was observed from the palliative measures employed during this time, they were given stimulants, strychnine, and nutritious diet. The operation was done under chloroform anæsthesia in all but one case. Mental symptoms were observed in only three cases, and in these the presence of albumin in the urine seemed to offer a reasonable explanation. There had been no recurrence in any of the cases of this series. All of them had been followed up, and in every one there had been complete relief from all former urinary disturbances, and the herniotomy had made them very much less helpless. Most of the patients were kept in bed from one month to six weeks. The speaker said he had no hesitancy in saying that, with proper study and diagnosis, and with good preparation and rapid operating, this class of patients could be successfully treated. Although a heroic treatment, it was warranted, as it rendered these old men comfortable and less helpless than any other method. There had not been a single accident. The relief from the distressing symptoms had not been so immediate as in some others reported, but in every case there had been some benefit, and it had always been evident in less than three weeks after operation. In every case there had been a diminution in the size of the prostate, and in none had the libido sexualis returned.

Contribution to the Study of the Symptoms of Chronic Gonorrhœa.—Dr. Ferd. C. Valentine, of New York, presented this communication. He said that in many cases the chief symptom was "the morning drop," which varied considerably in both color and consistence. To obtain the drop for microscopical examination, the patient should be examined before passing the first morning urine. The absence of such discharge did not, however, prove that the patient was cured, and the same was true of the absence of all "floaters" in the urine. Painful urination was not a prominent feature of chronic gonorrhœa.

Adrenal Tumors in the Kidney.—Dr. Barnard Holmes, of Chicago, read this paper. He said that the adrenal body itself was one of the earliest embryonal tissues to be found in place. As a result of an exhaustive study of the subject he had arrived at the following conclusions: (1) Remnants of the adrenal bodies were found in various parts of the genito-urinary tract in about ninety per cent. of all autopsies. (2) The adrenal body was a ductless gland essential to life. The removal of this body resulted in death, and its partial destruction led to a condition the symptoms of which resembled those of Addison's disease. When the adrenal body was greatly increased in function, it caused contraction of the capillaries, blanching of the skin, slowing of the pulse, and arterio-sclerosis of all the blood-vessels in the body, and resulted frequently in young people in sudden death from apoplexy. Nearly all who had suffered from this disease had had severe headaches, and indeed most of the symptoms of cirrhosis of the kidney, but without diminution of the urinary secretion. (3) About one-third of all tumors of the kidney appearing in adult life were of adrenal origin, but only a small proportion of these showed a tendency to metastasis. When metastatic foci did occur they were to be found either in the lung or in the bones, and they did not show a tendency to appear in both at once. Some of these metastatic tumors gave rise to the constitutional symptoms of increased secretion of the adrenal. (4) A few of the adrenal tumors produced symptoms of poisoning with the adrenal extract, and this too whether the tumors showed a tendency to metastasis or not. The poisoning did not seem to be proportionate to the size of the tumor. (5) The removal of the tumor before metastasis took place resulted in the subsidence of the symptoms of poisoning. The tumor might be removed without loss of kidney substance, as it did not infiltrate the kidney except in the advanced stages.

Pneumaturia.—Dr. Howard A. Kelly, of Baltimore, made a few remarks on this subject. He said that as far back as 1823 mention was made of the passage of gas from the bladder, and it was then supposed that the gas was secreted by the mucous membrane of the bladder, or was the result of fermentation. The cases might be divided into three groups, viz.: (1) Those in which the air was mechanically introduced from without: (2) those in which the gas arose from some fermenting organism; (3) those in which the air reached the bladder through some air-holding viscus, usually the bowel. In sixteen cases nine were found also to have glycosuria. In cases in which the urine was free from sugar, organisms were usually discovered which evidently belonged to the colon group. The gases produced were carbonic acid, nitrogen, hydrogen, oxygen, and marsh. Cripps had reported sixty-three cases belonging to the class in which the air came from air-holding viscera.

Dr. Ransohoff, of Cincinnati, said that he had had a case of malignant disease of the rectum in an advanced stage at the time of coming under observation. Adhesions had formed between the rectum and the bladder. Before a fistula formed between these two viscera the man had suffered from obstruction, but the establishment of the fistula had caused a disappearance of the symptoms of obstruction. In inguinal colostomy we should have an absolute means of putting an end to the pneumaturia. In his case of pneumaturia there was no suffering from the passage of air into the bladder, but burning pain was experienced from the fæcal discharge passing into the bladder.

Dr. Graham, of Chicago, reported two cases of gonorrhœal stricture and acute abscess of the prostate, associated with the passage of air into the bladder. One of these patients had been under observation for a number of years, and at intervals there had been a passage of a few drops of urine into the rectum and an escape of air from the bladder, lasting for a few days at a time.

Dr. A. F. Jonas, of Omaha, reported a case in which both gas and fæcal matter were passed from the bladder. The patient was a man, about fifty-five years of age, who had passed from his urethra at intervals for several years small particles like strawberry seeds. He was losing strength and presented an extended area of abdominal tenderness. An abdominal section was made, and very extensive intestinal adhesions were found, together with a general miliary tuberculosis. Because of the tuberculosis it was considered advisable not to break up the adhesions. The patient recovered from the operation, but died about six months later from peritoneal tuberculosis.

Ether Pneumonia.—Dr. James M. Anders, of Philadelphia, contributed a paper on this topic. He said that pneumonia after ether narcosis was a comparatively frequent complication, and might at times be endemic in certain institutions. W. H. Prescott had collected 40,000 cases, in only three of which did pneumonia ensue. In his own series of 12,842 there were 30 cases of typical secondary pneumonia, or 0.23 per cent. The grand total of reported cases was 57,842, with 46 pneumonias, or 0.07 per cent. His own experience led him to believe that more accurate statistics than those available at present would show ether pneumonia to be much more frequent. There

was very good reason for believing that this form of pneumonia had been often overlooked. It had been suggested by Mr. Clement Lucas that a possible source of infection in these cases was the ether mask or inhaler, but this was not probable, as in the past five years a sterilized towel had been used for this purpose in two of the Philadelphia hospitals, from which a goodly part of the statistics had been collected. During ether narcosis it was not improbable that micro-organisms in the upper air passages were drawn downward and so gave rise to bronchitis or pneumonia. This would seem to be supported by the fact that persons suffering from disease of the upper air passages were subjected to special dangers when etherized. A latent or active tuberculous focus in the lungs might, under these circumstances, give rise to serious trouble. In this connection it was worthy of note that in a large proportion of his cases there was a distinct history of frequent colds and coughs. A proper toilet of the upper air passages would seem to be a useful prophylactic measure, as well as the frequent turning of the patient's head to one side during etherization. In prolonged operations it was also well to avoid undue cooling of the body surface, and to reduce to a minimum the quantity of ether administered. It was a significant fact that a very large proportion of his cases of ether pneumonia occurred during the cold season.

Dr. Ochsner said that during the past three years he had had kept accurate records of twenty-six hundred etherizations in hospital practice, and had found that the mere fact of keeping these records had caused the anæsthetizers to exercise more than usual care, and with very gratifying results. Of the twenty-six hundred cases in only two had there been suffering from pneumonia. One of these was a case of septic appendicitis, and much frothy mucus was secreted during the etherization. The point had been well taken that care should be exercised not to cool the body surface by operating in too cool a room, or by applying moist towels over the body surface. At the time when irrigation was almost constantly used he had observed more of these cases. He was of the opinion that aspiration of mucus was a common cause of pneumonia, and consequently there was less danger from this source with the patient in the Trendelenburg position. His practice was to administer chloroform at first, then chloroform and ether, and finally pure ether, using the Esmarch mask.

Dr. Mayo said that at one time a Clover inhaler had been used by him, in which there was a sponge inside of the mask. One septic case had resulted fatally shortly after operation, and in a comparatively short period after this there were several cases of pneumonia following etherization. The sponges had been cleansed in the usual way. Examination of these sponges showed that they were teeming with various forms of micro-organisms, particularly streptococci. This had taught him the necessity of having an absolutely clean mask for each patient. His experience had shown him that operations on the stomach were particularly liable to be followed by ether pneumonia. Prior to these operations lavage of the stomach was performed, yet at the time of operation the stomach was invariably found to contain a certain amount of food and fluid. When the stomach was brought out this material ran back into the œsophagus, whence it was probably aspirated into the lung.

Dr. M. B. Tinker, of Philadelphia, said that while a hospital interne he had observed a very severe ether pneumonia following a trifling operation for the removal of a keloid from the back of the neck of a negro. The operation had been done in the warm season of the year, and had lasted only about fifteen minutes. So far as known there was no predisposing cause and the ether had been carefully administered.

Dr. Graham said that some of these cases of so-called ether pneumonia followed operations on fatty tissue, and resulted from fat embolism and not from the ether. He believed that external causes had as much, if not more, to do with the production of these pneumonias than had the ether or aspiration of mucus.

Echinococcus of Lung.—Dr. Carl Beck, of New York, sent a brief report of a case of echinococcus operated upon by him in November, 1897. The patient was presented before a local medical society in the following May as cured. The case was reported because of its rarity.

Treatment of Congenital Dislocations of the Hip.—Dr. Harry M. Sherman, of San Francisco presented this paper. He said that he had employed the operative method in these cases only during the past two years. He had done the reposition by operation nine times. In the first case he could not definitely locate the acetabulum. This part of the operation was rendered simple if it was remembered that the femoral head was always in the capsule, and that the latter always had its original attachments to the pelvis and femur. Through an incision into the capsule the finger was inserted, and then it easily found its way to the acetabulum. He had noted in some cases that on the removal of the splint there had been good motion in the joint, but within a short time this had diminished, and ultimately there had been practically an ankylosis. He could explain this only by supposing that it was due to contraction of cicatricial tissue within the capsule. In one case of double congenital dislocation the luxation had returned on both sides. Manipulative reposition was done on ten hips in eight children. The capsule was directly over the hollow of the acetabulum, and closed it except for a very small slit, which often would not admit of the passage of the head until it had been enlarged. The object of the manipulations was to tear this slit, so as to make it larger, but this could not always be done. If the manipulations succeeded only in placing the femoral head in the acetabulum, with the capsule pushed before it, there would be a recurrence of the dislocation.

Dr. J. E. Moore, of Minneapolis, said that this deformity was one which existed in every community, was very commonly overlooked, and was almost always neglected. Experience had taught all surgeons that the mechanical treatment of these cases was unsatisfactory; hence we must look to the bloodless operation of Lorenze, or the bloody operation developed by Hoffa. One must not think that the bloodless method could be tried, and if it failed the bloody operation could then be done; he had learned this by sad experience. In the case referred to, the bloodless operation having been unsuccessful, he had immediately resorted to the cutting-operation, with the result that there had been marked swelling and the formation of a thrombus in the femoral vein. Dr. Bradford now modified the operation by cutting downward and outward across the femur just below the lesser trochanter, and retracting the soft parts, thus exposing the capsule most satisfactorily. The capsule was then incised and the head of the bone was turned out. Then the finger was passed into the capsule until it reached the acetabulum. With the finger as a guide, the head of the bone was then readily slipped into place.

Dr. Sherman said that the bloodless method really produced a sprain and contusion, and sometimes a synovitis. If the tearing of the soft parts could be definitely located, so as to bring the capsule away from the acetabulum, then this operation would have a more brilliant future. Ankylosis at the hip with the limb in good position was preferable to the persistence of the dislocation, because of the increased stability of the

limb. The unreduced dislocation became progressively worse.

Officers.—Dr. W. J. Mayo, of Minnesota, was appointed chairman, and Dr. M. L. Harris, of Illinois, secretary of the section.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

JOSEPH PRICE, M.D., OF PHILADELPHIA, CHAIRMAN.

First Day—Tuesday, June 7th.

Address of the Chairman.—DR. JOSEPH PRICE, of Philadelphia, delivered the address. After alluding to the importance of recent advancements in the branches belonging to his section, he said that few even of the more eminent operators were agreed as to pathology or surgical methods, and that progress had been in the face of the most bitter professional antagonism. He mentioned the successful operations of the pioneers, Bainham, McDowell, John Light Atlee, and John Clay, and said that to the extent to which these pioneers carried their work the profession had followed their methods, perfecting somewhat the lessons they taught and enlarging the field of their application. The profession and the world marvelled at the great bounds to unexampled successes. Ignorance and prejudice were yet to be faced at every turn. Those whose courage was great and whose motives were worthy were abused for throwing light on the darkness in which the great body of the profession groped. He quoted Dr. Atlee as saying that "gentlemen who were bold enough to witness the operation of ovariotomy were even directly accused by their professional acquaintances of being *participes criminis* in committing murder, notwithstanding these murdered patients recovered." He called attention to the danger in specialization of being only specialists. He regretted that the younger school of gynæcologists had neglected plastic surgery, the majority having been seized by that strange, unexplainable infatuation for the surgery of the peritoneal cavity. The vital questions relating to plastic work, he stated, were dropped out of society discussions. He considered that in the results obtained in vesico-vaginal fistula, about "two attempts at closure resulted in benefit to the patient, reducing the size of the fistula." Distressing conditions were not corrected, because gynæcologists were not giving the subject the careful study its importance demanded. He considered careful training in plastic work of more importance than in abdominal surgery. The speaker then alluded to the successful treatment of uterine displacements by Hodge, Sims, Gaillard Thomas, Albert Smith, and others, with simple methods, and considered the very common office attempts at local treatment and the correction of displacement an error. Such patients should be put to bed, the uterus brought forward, all lacerations repaired, and a well-fitting pessary placed. He commended the rest treatment for the correction of displacements as the shortest, surest, and most satisfactory. He also called attention to the risks associated with the use of the pessary, and described curious varieties he had removed, some of which would have made acceptable mule collars or balance wheels for a corn sheller, while some resembled the wings of a flying-machine. He quoted a statistical record of accidents as a warning in the application of the pessary. Thus "twenty-three cases of perforation of the rectum alone by the pessary; twenty cases of perforation of the bladder alone; ten cases of perforation of the bladder and rectum; one case of ureteric fistula alone; one case of ureteric and vesico-vaginal fistula and one case of perforation of Douglas' pouch (neither fatal); three cases of perforation of the vaginal wall, the extruded portion of the pessary lying in the pelvic connective tissues; and six cases of entry of a vaginal pessary into the uterus." He anticipated that during the association meeting there would be many new methods advanced for the treatment of uterine displacement, and for the benefit of such claimants he quoted Mr. Tait: "Nothing is so useless or so stupid as this squabbling about priority, for in a few years the names of all concerned will be forgotten and only the progress will be familiar to our successors."

Dr. Price then called special attention to the nervous disorders arising from the connections between the vagina, uterus, and ovaries through their nervous supplies with the splanchnic nerves, and with the spinal cord in the sacral and lumbar regions through the pelvic and hypogastric plexuses, and cited the mature opinions of MacNaughton Jones and other English specialists. The author believed that many nervous disorders could be averted or cured by early and careful attention to uterine and ovarian troubles, and examination of pelvic viscera. He considered surgery a science without limit to its extension, with no tolerance for obstructionists, no false reverence for the venerable, but which replaced the old with the better new. He accredited to the medical journals the scientific spirit, the earnestness of research diffused through the profession.

In conclusion, the author briefly mentioned the gratifying reduction in the mortality of childbed, due largely to cleanliness of environment and everything in touch with the patient. He considered that in the majority of maternity cases it was dirt or meddlesome and unskilful instrumental interference that killed, and that to have skilful obstetricians the teaching in the schools should be more thorough, theoretically and practically.

DR. HOWARD A. KELLY, of Baltimore, moved that a vote of thanks be tendered the chairman for his paper, which, he said, must have struck a sympathetic cord in the heart of every gynæcologist.

Treatment of Simple and Complicated Cases of Retrodisplacements of the Uterus, by Shortening the Round Ligaments through the Anterior Vaginal Fornix.—DR. J. RIDDLE GOFFE, in presenting this paper, stated that the number of operations which had been devised for the relief of retrodisplacements of the uterus was an indication of the importance ascribed to this condition by the medical profession. All of these operations, however, were not based upon true principles of dynamics, and especially the dynamics of the female pelvis. Great advance had been made in the understanding of the forces which were at work to retain the uterus in its normal position and to displace it by counteracting force. The author said that before we could understand this subject thoroughly, we must accept the fact that the uterus, like all other organs in the human body, was suspended and held in place by ligaments. The normal position of the uterus was one of unstable equilibrium, and its chief support was the swing or cradle of tissue reaching from the sacrum to the symphysis pubis, and known posterior to the cervix as the utero-sacral ligaments and anterior to the cervix as the vesico-uterine ligaments. As long as this tissue was intact and functionating properly, the uterus could not be displaced except by some extraordinary force. When a woman was upon her feet the uterus rested upon its anterior face, and all that was necessary to retain it in this position was that the cervix should be held up in the hollow of the sacrum. Under these conditions both gravity and intra-abdominal pressure assisted in carrying the fundus into a position of normal anteversion. The utero-sacral ligament, therefore, was the all-important structure in retaining the uterus in its normal position. The two most potent factors in producing retrodisplacements of the uterus were, first, subinvolution of the uterine lig-

aments following parturition, more especially of the utero-sacral ligaments; and, secondly, diseased and prolapsed appendages which, resting upon the utero-sacral ligaments, so interfered with their nutrition as to cause them to lose their contractile power. The most rational procedure for the relief of displacement consisted in shortening or restoring tone to the utero-sacral ligaments. An effort had been made in this direction by both German and American operators, but thus far without success. It was within the bounds of expectation that some such procedure would be devised that would be both practicable and efficient. The next most rational procedure consisted in utilizing the round ligaments for retaining an anteverted position of the uterus. The round ligaments might be shortened either by Alexander's operation or by a laparotomy, lapping them upon themselves inside of the pelvis; or they might be approached through the vagina. The latter method was the one to which he called attention. The operation, he said, consisted in making a transverse incision in front of the cervix, and a second longitudinal incision at right angles to this, extending throughout the whole length of the vagina (through which incision sufficient room was obtained for breaking up adhesions both of the uterus and the appendages); bringing the uterus down into the vagina, and, after treating the appendages by whatever method seemed to be indicated, shortening the round ligaments of both sides by lapping them upon themselves and stitching them together with twisted silk. The operation had been applied in thirty-one patients, three of whom had become pregnant; two had passed through their pregnancies with unusual comfort and had been delivered of living children. Of the remaining cases three were partial failures, due to giving way of a ligament on one side. This was accounted for, however, by the fact that the appendages of the relaxed side had been removed and the round ligament shortened by including it in the ligature instead of lapping it upon itself and stitching it in that position. These three patients were made comfortable, however, and relieved of all their symptoms by insertion of retroversion pessaries. All the other cases had proved completely successful, not only anatomically but in the relief of all symptoms. The first operation was done in March, 1896, and the last in May, 1898. The first and the fifth patients had had children. It was therefore to be expected that as time advanced similar reports would come in from a fair proportion of the remaining cases.

Dr. Goldspohn, of Ohio, in discussing the paper, said that he had done the operation but a limited number of times. He considered it entirely feasible and to be esteemed above other non-surgical operations, which should be relegated to the past ventro-fixation, vesico-vaginal fixation, and ventro-suspension. He believed diseased conditions of the adnexa were due in a large majority of cases to displacement, and that if displacement led to disease in the ovary something should be done with the displacement after resection, and that could not be done through a vaginal approach.

Dr. H. P. Newman, of Chicago, was much gratified with the stand taken by Dr. Goffe, and referred to the visionary aspect with which the operation was regarded ten or twelve years ago. He believed that the objections met with to-day were faults in the technique.

Dr. Howard A. Kelly, of Baltimore, said he was much interested in the discussion, as he had operated a great many times for this condition. He did not think the uterus and tissues could be put in exactly the same condition as they were before; but that the question was, what was the best surgical operation from a surgical standpoint? If something about the mechanics of the abdomen was borne in mind, it could be readily seen what was the best form of operation, from a mechanical standpoint. He said that if the uterus lay in the anterior position the very pressure which was a disadvantage would then tend to increase the advantage of the antedisplacement, and that he needed but a thread at this point to hold the uterus in position, because the abdominal pressure worked with him. This he considered the best mechanical advantage to be obtained. He had operated in this way in some four hundred cases, opening the abdomen by minute incisions transversely so that the scar would be invisible. An incision of an inch or an inch and a half was made vertically, and the fundus brought up and attached to two silk sutures. About two per cent. of his cases had gone back. Some twenty of his patients had become pregnant, and none out of the four hundred had died.

Dr. Craig, of Denver, stated that his experience with the Alexander operation had been something short of one hundred cases. He had been looking for some of the accidents detailed in the journals, but had not found them. He considered any fault in the operation entirely in technique. Any surgeon with a little preparation he thought could do an Alexander operation with almost perfect success, but it required an expert to do a vaginal operation. He considered the tactile sense of much importance in attempting to restore the uterus. He did not believe that the vaginal operations would ever be without mortality. In his series he had had one recurrence.

Dr. S. C. Gordon, of Portland, Me., thought the broad ligaments had more to do with supporting the uterus than anything else. In relation to the support of the uterus which had a certain amount of descensus, he thought something which would hold must be at the top. The only exception he had to Dr. Kelly's operation was that he used catgut instead of silk, so having nothing to act as an irritant. He was not in favor of vaginal operations, and certainly would not do a vaginal operation for the condition under discussion. He objected to the long process described by Dr. Goffe.

Dr. H. O. Marcy, of Boston, said he had had a very considerable experience with the operation through the vagina and had utterly abandoned it. In the great majority of cases he believed there was something besides the retroversion of the uterus, and approved of carefully opening the abdomen, so that the factors with which the surgeon had to deal could be seen. He made a double instead of a single fixation. He thought it important to know the condition of the endometrium, the cervix, and the peritoneal structures.

Dr. Ferguson, of Chicago, made a preliminary report of an operation in which he made an incision with the patient in the Trendelenburg position, exposing the rectus muscle on both sides, making an incision through the rectus muscle about three-fourths of an inch from the median line, and retracting the muscle to one side. The peritoneum was opened and a small incision about an inch away from the pubis was made, cutting through the posterior shaft of the rectus and the peritoneum. The uterus was brought into view, a clamp placed upon the round ligament about an inch away from the cornu, and the womb sutured. The first two sutures passed through the broad ligament and then through the posterior fibrous surface; the next one passed through the round ligament, and the fundus was closed posteriorly with catgut. The rectus muscle was allowed to fall back, the recti sheaths were sewn over, and the abdomen was closed. He claimed for this procedure the advantages of the non-opened median line, the opening being behind the recti muscles; of firm suture for the uterus, not in the form of a string, which predisposed to hernia; of allowing one to deal with a prolapse or a cystic ovary;

of avoiding the danger of injuring the bladder or incurring hernia; and that it could be done in a very short time. He felt that it covered all classes of cases, and could see no surgical objection to it.

Dr. Ward, of Kansas City, thought the paper very interesting, but could not see how it was possible so to dissect with perfect impunity to the bladder and uterus. He considered that in almost all cases something was to be done with the appendages and that it was necessary to go into the abdomen and bring forward the adherent appendages, and he did not consider that this could be easily done through the vagina.

Dr. William H. Humiston, of Cleveland, did not approve of the Alexander operation, since with the displaced organ he found a diseased condition of the adnexa, and stated that the large majority of his cases of retrodisplacement of the uterus were cured by curetting the uterus, placing it forward, and supporting it for a few weeks with a pessary.

Dr. Henry, of Omaha, said the operation seemed to him to be difficult and serious. He preferred to open the abdominal cavity and fasten the uterus, as Dr. Kelly had suggested, by a slender peritoneal attachment. He thought that the remarks of Dr. Kelly should be emphasized. He believed that bad results followed ventro-fixation, and that in many instances the displacement could be cured by the use of a simple pessary, but when the operation was necessary he advocated opening the abdomen.

Dr. Engelman, of Boston, preferred shortening the round ligament with a restoration of other coexisting conditions.

Dr. Etheridge, of Chicago, said that after drifting and floundering about on operations for retroversion, he had finally settled down to doing nothing but abdominal fixation. He thought there was very little difficulty in doing the operation through an inch or an inch and a half. He advocated suturing through the entire abdominal wall, and one internal abdominal suture was all he generally used. He always used silkworm gut, allowing the sutures to remain in for three weeks, but removed the abdominal stitch at the end of eight or ten days.

Dr. Ruth, of Iowa, thought the pessary had its place in suitable cases. He thought that if the condition of the adnexa could always be known he would feel inclined to take up the operation more extensively, and did not consider that these parts could be so well dealt with through the vagina as through the abdomen. He was slow to believe that all cases of uterine retroversion were pathological and demanded treatment, but thought that when such seemed to be the case it was better to make a small abdominal incision and be absolutely certain as to the existence of the pathological condition of the uterine adnexa.

Dr. Price said that he was very old-fashioned in his treatment of displacements. He believed that if the patients were put to bed and allowed to occupy a comfortable Sims position for some days, and the slightest tear in the cervix or anything approaching an unhealthy condition was repaired, they would in all probability recover. This had been his custom, although he had the reputation of cutting everything; he wanted to use this opportunity to correct this error. In fairness to Dr. Goffe, he wished to say that his paper was a scientific one and that the fixation of the uterus in the anterior vault was in all probability the operation which would give the least inconvenience. He believed it not difficult to make the incision, and used the finger in all of the manipulations.

Dr. Goffe, in closing the discussion, said he would be glad if time permitted him to answer in detail the points suggested which had not been agreed upon. He noted that the point was pretty well concurred in that simple retroversion of the uterus was not so serious a condition as to require an elaborate surgical procedure for its relief. Only in selected cases did he advise patients to resort to an operation. He believed that when pessaries were applied promptly after confinement while involution was going on, the ligaments would recover themselves sufficiently to retain the uterus in place, but that chronic cases were never so cured. He believed that, as he looked over the literature, the men who had kept watch of their cases had only about five per cent. of patients submitted to the treatment of a pessary cured. Another point on which they were pretty well agreed was that the indication in these cases was to be found in diseased appendages. To reach these appendages the pelvic cavity was to be opened, and the question was whether to use the abdominal or vaginal route. He believed the question would be decided within the next three years in favor of the vaginal route. He stated that his own conduct was never to do a laparotomy if it could be avoided. He desired to induce some of the profession to adopt the operation, and, although it required more time, he believed that the patient received the benefit.

Further Experience in the Management of Uterine Displacement.—Dr. Augustus P. Clarke, of Cambridge, read a paper with this title. In speaking of the treatment of anteflexion he said that he had relied much upon a resort to dilatation of the uterine canal. In those cases in which there had been considerable hyperplasia or induration of the cervix, incision of the tissues within the canal had often resulted in marked benefit. If sterility or dysmenorrhœa still persisted, dilatation, curettage, and intra-uterine applications should be repeated at proper intervals. The author, in speaking of retrodisplacement, remarked that the organ should first be restored and should be maintained in its proper position. In order to effect this, firm adhesions might sometimes have to be broken up, a lacerated perineum might have to be repaired, relaxation of the vulvo-vaginal tissues might have to be reduced by recourse to a plastic operation, and every factor that tended to weaken the normal intra-abdominal pressure would have to be eliminated. The author further added that the Alexander operation was the most useful in those cases of backward displacement in which the vulvo-vaginal walls were sufficiently firm for maintaining the intra-abdominal pressure. If the severity of the symptoms could be relieved by the adoption of extraperitoneal treatment, ventro-fixation or ventro-suspension might be the next measure of proceeding. For overcoming retrodisplacement in married women the author advised that the operation should, if possible, be deferred until the approach of the menopause. If conditions admitted of a choice between the Alexander operation and ventro-fixation, the former was the less dangerous to the patient's life and the less likely to interfere with the normal evolution of pregnancy.

Second Day—Wednesday, June 8th.

Descensus Ovarium.—Dr. A. Goldspohn, of Chicago, in a paper with this title, considered that a most fruitful cause of disease of the female internal organs was their displacement, which induced a varicose condition and seriously disturbed their trophic conditions. He said that, while this fact was generally accepted with reference to the uterus, it was not appreciated with reference to the appendages. He believed that the indications for operative cure in cases of displacement extended as well to the adnexa as to the uterus itself, and he was convinced that many failures to restore good health were due to an imperfect or partial filling of these conditions. He divided the causes into three classes: (1) those which increased their weight; (2) those which induced relaxation of the ligamentary

supports (sometimes heedlessly done by operation through the vagina); (3) retroversio-flexion, which he considered the most prolific cause. He believed the ideal structures with which to deal for surgical repair were the round ligaments of the uterus, accessible by way of the vagina, by ordinary laparotomy, and by way of the inguinal canals. The latter two routes alone he considered gave sufficient access to the lateral walls of the pelvis to secure replacement. Cases of utero-ovarian displacement in which by repeated bimanual palpation he could not exclude septic elements, he treated by the abdominal route. Other such displacements, whether simple or complicated, in which sepsis had died out, he treated by the Alexander operation with sufficient dilatation of the internal inguinal ring to introduce an index finger, by which he could intelligently loosen all fixations. With the finger thus introduced, while the uterus was being steadied, when necessary two additional fingers were introduced into the vagina. The author had elaborated these important adjuncts to the Alexander operation during the past five years, and out of approximately one hundred and forty cases had had no deaths, herniæ, or other evil sequelæ.

Dr. Joseph Eastman, in discussing the paper, said that it showed study of the subject along anatomical lines in a conservative way, and with the absolute view of cutting only for cure and not for the sake of new experiments.

Dr. Howard A. Kelly said he had never felt perfectly clear as to the pathological significance of these ovaries, which could be felt with unusual distinctness in Douglas' cul-de-sac, and had never felt warranted in opening the abdomen to stitch up such an ovary, because when they were opened for other causes disease had not been found; but he would watch with a great deal of interest the effects of operations upon these descended, prolapsed, more or less tender ovaries.

Dr. William H. Humiston, of Cleveland, said he did not operate until the patient had been through a course of treatment. His experience was to find the ovary prolapsed with the uterus, and the history usually indicated the result he would secure by ordinary treatment. If the condition had existed for a long time, he found that the majority of cases failed to be permanently benefited by putting the uterus in proper position, and he favored the conservative method before resorting to surgical procedures. Conditions of a year's duration, he stated, were recovered from by placing the uterus in proper position, and supporting it with rest in bed, hot douches, and glycerin pads. If this method failed in results he opened the abdomen, and if pathological conditions were found removal was the only thing which would give permanent relief; in these operations his success had been most pronounced. He was glad that Dr. Goldspohn had modified the Alexander operation; as put out by Alexander and practised by some leading men it had not been an operation for which he could find an indication.

Dr. E. Gustav Zinke, of Cincinnati, regretted not hearing the first of the paper, but it was his belief that if the operation was done simply and solely for symptoms dependent upon a merely prolapsed ovary, it would not hold a place among the operations in gynæcology. He did not wish to criticise the doctor's efforts. He could not believe that an otherwise healthy ovary or ovaries prolapsed, even though they were behind or in front of the uterus, would give rise to any symptoms which would justify surgical interference. In his practice of a number of years exclusively in this department he had not had a case of prolapsed ovary or ovaries, without adhesions, that had given rise to symptoms warranting operative procedure.

Dr. Chestnut, of Philadelphia, said his experience included but a limited number of cases, but that his opinion coincided with those of Drs. Humiston and Zinke. He had not felt called upon to operate except in evidences of intrinsic disease. His usual treatment was the placing of the patient in the knee-breast position, the retention of the ovaries in their position by tampons medicated with glycerin or ichthyol, and the hot douches: in case of adhesions he removed the ovary.

Dr. D. S. Fairchild, of Iowa, said his experience in this kind of operative work had been very little, and he could hardly imagine there would be any considerable number of cases of ovarian trouble not involving disease or organic change in the structure that would warrant abdominal procedures, but he considered his experience in this direction too limited to offer an opinion.

Dr. Porter, of Fort Wayne, thought the profession should not lose sight of the fact that there was a class of patients suffering from prolapse of the ovary who could not afford to spend several hours a week in the doctor's office for the purpose of having the uterus and ovary replaced, and probably in the end have to submit to operative procedures. He believed there was a class of cases in which the shortest and happiest treatment was some method of fixation or removal. He had had no experience with Dr. Goldspohn's method, but had had some of the very happiest results from abdominal fixation of the ovaries in cases in which apparently there was absolutely nothing, save that the ovary was out of position.

Dr. Bonnefield, of Cincinnati, said he had found cases of displaced ovary attended with retroversion of the uterus to be amenable to office treatment after the retroversion was relieved, but that when the ligaments were so stretched that replacing the uterus did not also replace the ovary, his experience had been that local treatment was very hard to carry out and that it was almost impossible to make it effective. Malposition he believed to interfere with the nutrition of the ovary, and sooner or later disease developed which would require the removal of the organ. His sentiments had also been voiced by the gentleman from Indiana—that some patients could not afford to spend the time for office treatment—and for such cases he thought some surgical measures were certainly indicated and was glad that Dr. Goldspohn had suggested something which seemed to be effective.

Dr. Clarke expressed himself as much interested in the operation, but before attempting the procedure preferred to watch more closely the results. He believed that in most part the retroposition of the ovary was owing to parturient processes. He was glad to hear that Dr. Goldspohn distended the canal and removed or corrected any adhesions of the adnexa. He placed much value on intra-abdominal pressure in maintaining the uterus in position. He considered the ligaments merely guys, that did not hold the uterus in place.

Dr. Joseph Price said he had not resorted to surgical procedures except in pathological conditions, with retention of blood, pus, or water. For simple displacement of the ovary he did not approve of the office treatment, but believed it necessary to put the patient to bed and to use both local and general treatment.

Dr. Goldspohn, in closing the discussion of his paper, said that ninety-five per cent. of these cases of descensus were associated with retroversion of the uterus, so that in nineteen out of every twenty the operation would be for retroversion as well as for descended ovary, and that he did not advocate operating simply for descended ovary. He believed, however, that in the course of a year the descended ovary would become inflamed.

Discussion on the Relation of Pelvic Diseases to Nervous and Mental Affections.—The discussion was

held jointly by the sections on neurology and obstetrics.

Is Pelvic Disease a Cause of Nervous and Mental Affections?—Dr. Frederick Peterson, of New York, opened the discussion with this paper. The author said it was in the sixteenth century that Montaigne, a friend of physicians, wrote that it was safer to follow the example of the ancient Egyptians and employ specialists for every particular organ of the body rather than to trust one's self to the general practitioner. As there were distinct trades to clothe us, so should we be treated in our cures. If that was good advice in Montaigne's day, how much more valuable must it be to-day when the bounds of scientific medicine were so extended. No single mind, he said, could grasp and apply the vast store of human knowledge accumulated in the domain of the healing art during the last century. His preference was for the well-rounded general practitioner rather than for the ordinary specialist. The tendency was for each to consider his subject the centre, around which the whole human organism revolved; he should rather regard man as a biological unit, in which every organ had its place. He did not deny that pelvic disease in women attended by exhausting pain might give rise to neurasthenic or hysterical states, but he believed the influence of the exhausting pain was not greater than that of similar exhausting pains elsewhere in the body. He said he did not deny that disorders of the female organs, such as excessive hemorrhages or suppurations, which affected the nutrition of the nervous system, produced neuroses and even insanity. These were the main concessions, however, which he would be willing to make. In insanity he believed the two great etiological factors to be the hereditary instability, and some physical or moral circumstance directly affecting the nervous system. There was no evidence to show that epilepsy or chorea could be induced by disease of the female organs. He would by all means allow the gynæcologist to treat any serious disease of the pelvic organs present, but would say, let him not sacrifice those who trusted to his skill and good judgment. It was better to err on the side of science rather than to give the patient the so-called benefit of the doubt, which should rather be called the affliction of the doubt.

Are Nervous and Mental Diseases Cured by Pelvic Operations?—Dr. F. X. Dercum's paper, with this title, was read by Dr. Patrick. In this paper Dr. Dercum reviewed briefly the nature of the functional nervous diseases most frequently met with in practice. He considered the most important of the neuroses met with by the gynæcologist, and the general practitioner as well, neurasthenia and hysteria. He said that the symptoms of neurasthenia were always expressive of chronic fatigue, and he therefore termed the disease the fatigue neurosis. The other great neurosis which medical men met with so frequently was hysteria, or, as Dr. Dercum prefers to term it, the psycho-neurosis. The writer knew of no affection concerning which there was still so great a lack of knowledge in this country and in England, notwithstanding the fact that the French and later the Germans had unmistakably defined and described the symptomatology of the disease. The considerations given of neurasthenia and hysteria warranted the following conclusions as regarded neurasthenia: (1) That neurasthenia might exist independently of any local disease, pelvic or other. (2) That there was no necessary relation between neurasthenia and pelvic disease when the two affections happened to coexist in the same case. (3) That when pelvic disease occurred in a case of neurasthenia, the pelvic symptoms might be more readily recognized by the patient and therefore become more prominent, because in neurasthenia there was an increased irritability, an increased reaction to local impressions—nervous weakness and nervous irritability going hand-in-hand. Regarding hysteria, his conclusions were: (1) That hysteria might exist independently of any local disease, pelvic or otherwise. (2) That there was no relation between pelvic disease and hysteria even when the two affections coexisted in the same case. (3) That while in hysteria there was increased reaction to external impressions, this reaction was purely psychic. These considerations of neurasthenia and hysteria led the author to answer the question allotted to him by an unequivocal "No." He believed that all idea of curing neurasthenia or hysteria by operations upon the pelvic organs must be absolutely abandoned. Healthy organs should never be removed in the vain and grotesque attempt to cure the neurosis. He believed that in neurasthenia, operations for the cure of actual pelvic lesions were indicated and should, other things being equal, be performed. If organic disease complicated hysteria, operation should if possible be deferred until the patient had been cured of the hysteria. If the hysteria was very profound, operation should never be undertaken unless the surgical indications were urgent, and of such a character as to make operation necessary to save life. He did not believe insanities to be due to local organic disease, but to disease of the neurons, structural and functional, the result of various poisons circulating in the blood.

Nervous and Mental Diseases Following Pelvic Operations.—Dr. Harold N. Moyer, of Chicago, read this paper. The author said he would treat the subject in a manner to show that there was no difference in the nervous and mental effects following operations upon the pelvic organs from those following operations in other parts of the body. The writer said an examination of the statistics would show a surprising number of cases operated upon for pelvic disease with insanity, neurasthenia, and other nervous troubles following the operation and probably resulting from it; also that some writers had come to the conclusion that these operations were peculiarly liable to be followed by such phenomena, but that a closer analysis of the statistics would show that the operations were largely done upon persons whose general health was impaired. He considered infection a by no means infrequent condition. In a series of cases involving the prostate, in which the author thought there might be some comparable relation between the pelvic organs in the male and those in the female, he found that the nervous and mental effects following operations were much greater in those upon the male than in those upon the female, and he therefore concluded that this operation was not attended with more nervous disturbance, such as insanity or neurasthenia, than were operations in general. The character of the mental disturbances which might follow operations was substantially the same, whether upon pelvic organs or upon other parts of the body. The bulk of the effects fell within that variety of neurasthenia described by alienists as primary confusional insanity. Those operations which included the ovary or Fallopian tube and which were followed by an artificial menopause or an early menopause, were also studied, and he particularly addressed himself to the question whether there was any difference between the mental effects of the artificial menopause and those of the ordinary menopause. His conclusion was that they were practically identical. Regarding the removal of the ovary, the author believed that it, or a part of it at least, should be left in if possible.

Indications and Contraindications for Surgical Interference.—Dr. Humiston, of Ohio, read this paper, in the absence of Dr. Franklin H. Martin, the author, who considered the indications for operation in these cases numerous. He did not believe that there was a man of any standing practising this branch

who was operating on normal structures to relieve neuroses. He believed that the indications for operation must be a marked deviation from the normal. The perineum he believed to have a direct influence upon the nervous system in the condition of a rectocele, a cystocele, or a lacerated cervix; he mentioned a thickened condition of the uterus even when in a normal position, except a slight prolapse, as giving rise to a great many marked nervous symptoms. Endometritis with its concomitants he also regarded as giving rise to a variety of symptoms. In many cases in which he had found the organs misplaced but freely movable, there were few symptoms referable to the uterine organs; but with a misplaced, adherent, inflamed uterus, marked symptoms might be expected, and he believed this condition to be a strong indication for operative measures. He regarded the history very important in arriving at the determination of the origin of the nervous symptoms, and cited the case of a young lady who began menstruation at the age of fourteen. There was no disturbance until she was sixteen; while she was riding horseback the saddle turned, and she was thrown and dragged some distance. She recovered after a few weeks, but at her next menstruation the pain was very severe; this increased month by month, and she became a physical as well as a nervous wreck. She had been confined in a sanatorium and at last in an institution for the mildly insane. The case was brought to him by a neurologist and from the history he received a clew for the local examination. The pelvic organs were retrodisplaced and adherent; there were fixed masses in both vaginal vaults, and evidences of recurring inflammatory attacks. He removed the appendages and put the uterus in proper position and supported it there. There was marked improvement in the first few weeks. The operation was done two years ago; the patient had remained in perfect health and was seen in his office but a few days before, the picture of happiness with a full return of strength. In teaching gynæcology, Dr. Humiston said, he would teach students not to examine the pelvis until a most complete and thorough examination had been made of the whole body. He would desire his pupils to be first general practitioners, and specialists last.

Dr. M. B. Ward opened the general discussion. He said that he believed the influence of disease of the pelvic organs was so marked in nervous disturbances that there was a great field for investigation and work. He related the case of a young lady who had been a sufferer from epilepsy and was cured by the removal of diseased appendages; also two cases of severe headache, in which after the removal of the diseased appendages the patients had been perfectly well. He referred to an instance of one hundred and nine patients in an asylum for the insane, each one of them had had several operations done and seventy-five had been sent home well. Another case, that of a woman with homicidal insanity, who was confined in an insane asylum, had been brought to his notice. He found marked pelvic disease, and after operation there had been no symptoms of insanity.

Dr. J. T. Eskridge, of Denver, said he had been much impressed with the change which had taken place during the last fourteen years in the antagonism between the neurologists and gynæcologists, and believed that the mutual relations of certain specialists were so close that they must work together if they would work for the good of their patients. For himself, he felt very closely associated with the general practitioner, with the gynæcologist, the laryngologist, pathologist, and with that practitioner who was a specialist in all acute and chronic diseases in both men and women. He felt that every man must know something of everything and everything of something. He believed that the neurologist should investigate most thoroughly, but only after certain conditions were excluded. He believed it possible that a person might be simply in a neurasthenic condition, which, extending over a number of years, might develop some pelvic difficulty, and the gynæcologist, getting hold of this patient, might think she had suffered all the time from intrapelvic trouble, but which condition had subsequently developed from the impaired state of the health.

Dr. Joseph Price said that during the last year or two neurologists had paid as much attention theoretically and not quite so much practically to the discussion of the pelvic viscera as to the theory of neurasthenia, or they would not have appeared in print quite so often as they had during that time. He said he believed the majority of the cases treated for nervous disturbance, so called, were largely due to actual disease, which conclusion he based upon an every-day clinical experience, and he also believed that every specialist would fortify the statement. He believed insane asylums had been largely in the hands of the politicians and neurologists. He cited several cases showing entire relief from mental disorder after operation.

Dr. Hughes stated that the gynæcologists and neurologists were obliged to work together, and both were trying to determine how, when, and where to interfere gynæcologically, and how, when, and where to proceed neurologically in a given case involving a woman. The way was becoming clearer and they were walking together in it. They were not attempting to stay rational gynæcological procedures; they were fighting against a certain class of practitioners who were just as objectionable to the gynæcologist as they were to the neurologist.

Dr. S. C. Gordon said that in 1888 he had had the honor of being chairman of the section, and in his paper at that time he had described operations which were proof to him that removal of the ovaries had procured relief from the nervous symptoms in hysterical women. He said he had learned that conservative operations had been as beneficial as the total extirpations, but that in every case, when he felt obliged to remove the adnexa, he removed the uterus as well.

Dr. Gibbons did not feel inclined to say much. Dr. Price had said that the insane asylums were in the hands of the politicians and the neurologists. He would be very glad to think he was a good politician or a good neurologist, but the average hospital superintendent, though not claiming to be either, did have a claim to be considered a good physician. He believed that the physician of an insane asylum ought to be a good all-round specialist, and that most of the insane-asylum physicians were such. He also believed that the patients should be treated from the broadest standpoint. He disputed the correctness of the stated percentage of insane patients cured by operation for pelvic disease.

Dr. Riggs, of St. Paul, said he had no question about the influence of pelvic conditions in the production of neurasthenic states. He thought, however, there was one source of serious trouble that had not been estimated—the expectancy on the part of the patient to be hysterical or neurasthenic.

Officers.—The nominating committee reported the nomination of Dr. A. H. Cordier, of Kansas City, chairman, and Dr. William D. Haggard, Jr., of Nashville, secretary.

Third Day—Thursday, June 9th.

Plea for the More Correct Application of the Emmet Methods in Plastic Surgery.—Dr. W. D. Haggard, Jr., of Nashville, Tenn., the author of this paper, stated that the brilliant achievements in abdomi-

nal surgery had so far outshone the humbler plastic operations that the perfection of the latter had been very much impaired; that plastic surgery of the vaginal walls and cervix uteri of the present was a polyglot of many methods widely different in principle and hopelessly diverging in practice. In addition to these obvious reasons for the deplorable lack of excellence in much of this class of work, and in addition to the general apathy in this department of surgery, there were more material and serious impediments to perfected results—a somewhat exaggerated idea of the importance of the perineal body, so called; the lingering belief in its similitude to the keystone of the arch in its office of supporting the uterus; failure to appreciate the rôle of the pelvic fascia in maintaining the integrity of the pelvic floor in its functional relations, and more especially failure to grasp the results of its injury and the mechanics of the production of rectocele and the exact methods for its correction; finally, the employment of other suture material than silver wire. Successful execution of plastic surgery, in the writer's opinion, required a special aptitude and nicety of judgment, delicacy of manipulation, and inherent ability in modelling and coaptating parts. The pioneer work of Sims was referred to. The instruments and principles which made his early success possible had remained, but Thomas Addis Emmet had devised and perfected the operations on the cervix and posterior vaginal wall, which, with the operation for vesico-vaginal fistula devised by Sims, constituted the immutable trilogy of plastic surgery. The necessity for removing all indurated tissue in injuries of the cervix was compared with the necessity for removing sequestra. The details of the Emmet operation on the cervix as well as amputation were described. The misconception of the operation for laceration of the perineum, the speaker said, was due to two causes: (1) Misconception of the exact nature and pathology of the injury; (2) difficulty in describing the operation by diagrams. He estimated the essential lesion in injuries of the pelvic floor to be a tear of the pelvic fascia running along the lateral sulci of the vagina to which it was attached, the tear occurring where it was reflected upon the front of the perineal muscles, of which it formed the sheath and which it bound together. The destruction of the integrity of this fascia he declared to be the sole pathology and the cause of the rectocele, bearing down, displacements, and prolapsus. The operation for its relief would not be to sew the labia together, or simply a variable denudation on the vaginal wall, but to catch up the retracted fascia so as to take in the slack throughout the pelvis and thus to lift up the posterior vaginal wall to the anterior vaginal wall. The technique of Emmet's operation was then minutely described.

Indications for Plastic Surgery upon the Cervix Uteri; Tracheloplasty, with a New Method of Operating.—Dr. Henry P. Newman, of Chicago, read the paper. His technique differed from any so far advanced in the method of making the incisions and in the placing of the sutures. The lids of the cervix were transfixed above by a right-angled knife designed by the author for the purpose. A single smooth cut downward in both anterior and posterior lips left a V-shaped section of diseased tissue to be taken out by a cut or two of the curved scissors. The sutures were applied high up and wrapped the flaps closely but without straining. There were no danger of secondary hemorrhage, and no granulation or cicatrization in the canal; the after-treatment was simple and limited. The tampons, uterine and vaginal, were removed on the second or third day and were not replaced. The sutures were tied in groups after a method which favored nice adjustment and ease in removal. In speaking of the indications for the operation, the author called attention to the importance of the cervix as an etiological factor in very many local and general pathological conditions. It might be a storehouse of infectious germs; it was the portion of the uterus which suffered most from maldevelopment at puberty, causing dysmenorrhœa, sterility, and a train of related ills; and it was the part most frequently injured in childbirth. Until preventive medicine succeeded in eradicating the more common causes of cervical disease, this organ would continue to offer wide opportunities for plastic surgery of the most careful and progressive kind. The indications for such operating were at present, besides malignant disease, some minor displacements, the various diseased conditions following laceration, chronic metritis and cervicitis, hypertrophy and elongation, malformations and stenosis, in the reality of which the author's experience taught him to believe. Dr. Newman had used this method for above five years, he said, and his results in a large number of cases had been uniformly satisfactory, justifying him in bringing it before the profession. He proposed that the careless nomenclature be changed and that "trachelorrhaphy"—sewing of the cervix—and amputation of the cervix, both limited and misleading terms, give way to "tracheloplasty," which correctly expressed what every operator meant when he was talking about plastic work upon the cervix.

The papers of Drs. Haggard and Newman were jointly discussed.

Dr. Clarke, of Cambridge, made mention of the gratitude of the profession to Emmet for his operation in lacerations of the cervix. His method differed somewhat. He did not believe amputation was necessary unless growth was present.

Dr. Goldspohn, of Chicago, recognized that Emmet's operation for laceration of the perineum was the best of those which dealt with the exsection of a flap, but, it being essentially intrapelvic work, he thought a more desirable method was to remove the adjacent posterior portion of the vagina. The finger could then trace the inner border of the levator ani muscle and its fascia and the sutures could be distinctly inserted. He would remove no tissue, but temporarily elevate the whole posterior wall of the vagina.

Dr. J. Riddle Goffe had seldom heard a more glowing tribute to any man's work than that given to Emmet's operation in the paper by Dr. Haggard. His explanation of the mechanics of the female perineum seemed to him perfect. The operation to the majority of men he thought appeared complicated. In his hands the operation had not accomplished the permanent results desired. Dr. Goffe said that he had modified the operation slightly in the line of simplification, and explained his method.

Dr. A. H. Cordier, of Kansas City, believed it absolutely necessary to see the perineal operation to understand the technique of Emmet's method. He did not believe there had ever been an operation to take the place of Emmet's.

Dr. Haggard agreed with Dr. Goldspohn with reference to the correct apposition of the pelvic fascia, the only question being as to the way of doing it. He believed the Emmet method better determined the exact whereabouts of the pelvic fascia. The admirable method of Dr. Goffe was the only one he knew of which had anything in common with that of Emmet, the ordinary forms of the operation being a bunching up of the tissue, which did not give the woman much benefit. In regard to Dr. Newman's paper Dr. Haggard agreed that amputation was preferable to trachelorrhaphy, because in the entirely new method of obstetric practice there were not so many lacerations as formerly. It was rare to see Dr. Emmet do a classical trachelorrhaphy, amputation being much in the predominance.

Dr. Newman objected *in toto* to Dr. Clarke's meth-

od, because it left a glass tube in the cervical canal. This necessitated the introduction of a sound, to which he objected very much in plastic surgery. In doing a trachelorrhaphy he removed all the cervical endometrium and had a surface which must heal by granulation. The advantage in the amputation was that the suturing was done at the very edge of the flap.

Do We Drain too Frequently in Pelvic Surgery?—Dr. W. H. Humiston, of Cleveland, Ohio, read a paper with this title, in which he reported that his mortality rate had decreased *pari passu* with the declination of the rate of drained cases. Thus, in 1894, 71 per cent. drained—14 per cent. mortality; in 1895, 36 per cent. drained—7 per cent. mortality; in 1896, 33 per cent. drained—6 per cent. mortality; and in 1897, 4 1/3 per cent. drained—4 2/3 per cent. mortality. All of the cases in 1897 which were reported as drained were really those in which gauze was used for the control of oozing, and not for drainage. Several of the cases were cited in detail to show their serious nature and the happy results obtained. He expressed his conviction, founded on a close study of his later cases, that the major part of the decline in the mortality rate was due directly to the immediate closure of the abdominal wound and to his dependence upon the natural channels of absorption and drainage.

Treatment of Ambulatory Gynæcological Cases.—Dr. Denslow Lewis, of Chicago, in a paper with this title, referred especially to his experience at the Chicago Polyclinic during the past four years. The patients whom he had treated were chiefly working women, unable to spare the time for attendance in a hospital, and who were obliged to work for a living while under treatment. Under these conditions it was gratifying to observe that in many cases treatment was practicable and sometimes surprisingly successful. Reference was made to the treatment of venereal warts, chancroids, chancres, and condylomata. Cases of so-called irritation of the neck of the bladder were frequent. Their condition was improved by the exhibition of twenty grains of benzoate of sodium three or four times a day and the copious drinking of water. In cases of leucorrhœa the gonococcus was looked for, and when found an application of nitrate of silver was made to the vagina and the portio vaginalis. In cases of infection that had extended beyond the endometrium, and in many cases when pus was suspected or demonstrated, improvement and symptomatic cure were noted under the persistence of what was called the routine treatment. This consisted in a 1–4,000 bichloride-of-mercury douche, taken twice a day, the assumption of the knee-chest position morning and evening, the application of a ten-per-cent. solution of ichthyol in glycerin, and the production of free and regular catharsis by the systematic use of cascara sagrada. It was found that in cases in which operation had been originally recommended, improvement would occur in a very large percentage of cases under this treatment while the patient continued her daily work.

Hæmatosalpinx and Congenital Uterine Atresia.—Dr. Alexander Hugh Ferguson, of Chicago, reported a rare case of this condition, relieved by operation, and showed photographed drawings representing the cyst wall and contents, the distended tube, the ovary, and Fallopian tube.

A Uterine Irrigator.—Dr. Charles B. Nichols exhibited a uterine irrigator, particularly adapted to secure a perfect return flow in curettage, and which Dr. Price pronounced the best instrument of its kind he had seen.

Use of the Curette in Acute Infection of the Uterus with Adherent Placenta.—Dr. D. S. Fairchild, of Clinton, Ia., read this paper. He contended that great care should be observed in the use of the curette in acute infection of the uterus. In cases in which portions of the placenta were adherent they should be removed with the sharp curette, but before infection had occurred, under antiseptic precautions. If infection had developed he considered it safer to remove all detached portions with a dull curette without inflicting trauma, irrigate, and drain. If infection of the uterus had occurred without offensive lochia but with serious constitutional symptoms, neither curettage nor irrigation should be employed. He described the dangers of the free use of the curette as twofold: (1) Inflicting trauma, which might facilitate absorption of infection material; (2) the penetration of the softened uterine tissue. If the os had closed, retaining in the uterus suspicious or decomposing material, very careful dilatation should be employed under an anæsthetic, detached masses removed with a dull curette, and gentle irrigations employed; the whole procedure being so conducted as to inflict the least possible trauma.

Use of Uterine Curettage and Drainage in Tubal Diseases.—Dr. W. W. Grant, of Denver, in this communication considered inflammation in the Fallopian tubes to be one of the commonest and most serious in its consequences of the diseases of the pelvic organs and generally secondary to disease elsewhere. He regarded a purely surgical procedure as necessary for the permanent cure of pyosalpinx, although patients did occasionally recover without the knife. He presented a few cases typically accentuating certain facts and probabilities in reference to disease of the tubes, and their cause and treatment. The best treatment of subacute and chronic and interstitial salpingitis he believed to be curettage and drainage of the uterus, with the use of such other local and constitutional means as were indicated. Antiseptic gauze in his opinion was the best possible material at command for drainage.

Dr. Goldspohn, of Ohio, indorsed *in toto* the ideas of Dr. Fairchild; he thought sufficient distinction was not made between the bacterial uterus and the ordinary gynæcological uterus. In curettage he considered the use of the sharp curette most abominable.

Dr. Wetherill advocated the use of the finger, but if this was not long enough then a dull curette. When the infection had extended to the lymphatics he believed curettage useless.

Dr. M. B. Ward spoke of the difficulty sometimes encountered in the irrigation when the cervix was not sufficiently dilated; also of the finger nails as another prolific source of infection. He wished that his epitaph might read: "Here lies the greatest crank on finger nails, except Dr. Joseph Price."

Dr. Humiston said, in reference to curettage in abortion or delivery at term, when symptoms indicated that the uterus was not in perfect condition, if retained material was found it should be removed, if possible with the finger; if not with the finger, with the dull curette. In case of infection extended to the lymphatics and into the broad ligaments, more harm than good was done by curettage.

Dr. Lawrence, of Colorado, believed that in puerperal conditions no curettage should be done, and that more women had been killed by the improper and unskilful use of the curette than by any other gynæcological procedure.

Dr. Nichols considered curettage one of the most important operations in gynæcology, and one which should be done as thoroughly aseptically as an abdominal operation. He believed the dull curette should be discarded.

Dr. Dunn thought curettage of the uterus more dangerous than abdominal section, and believed the consensus of opinion of gentlemen with large hospital experience to be that more women had been crippled

for life by the use of the curette in the hands of incompetent general practitioners or gynæcologists in embryo than in any other one procedure in surgery.

Dr. Gordon, of Maine, considered curettage a serious operation, and stated that his instructions to young men were that every precaution should be taken and the patient prepared with as much care as for an abdominal section. An important point in the operation was the absolute necessity of dilating beyond doubt; an opening of one and one-fourth inches he did not consider proper dilatation. He also considered it important to have inserted for twenty-four hours a tape for drainage.

Surgical Treatment of Uterine Myoma.—Dr. Henry O. Marcy, in order to economize time, read only a portion of his paper, and showed a series of photo-micrographs of small uterine myomata, taken with the purpose of endeavoring to learn their origin and their bearing upon myomectomy.

Gonorrhœa as a Factor in Puerperal Fever.—Dr. Albert H. Burr, of Chicago, read a paper with this title, in which he stated that the new science of bacteriology and the accumulating evidence of the pathogenic nature and far-reaching effects of certain micro-organisms had invested the subject of the prophylactic, aseptic, and antiseptic protection of the parturient with increasing interest and importance. Notwithstanding the advancement along these lines, the question still confronted us as to why there was not greater freedom from septic complications. He suggested that there might frequently be sources of danger in the mother herself antedating childbed. He reviewed some of the most important characteristics in the life history of the gonococcus and examined its opportunities for endangering the puerperal state. He believed that the proportion of both sexes never completely cured of gonorrhœa was much larger than is commonly supposed. The diagnostic points were mentioned in detail. He considered treatment in childbed fever under the divisions of general, specific, prophylactic. In conclusion, he regarded gonorrhœa as a widely disseminated disease, especially persistent and dangerous in females. (1) It was directly or indirectly a factor in puerperal sepsis and accountable for a larger percentage of complications and fatalities than commonly supposed. (2) Prophylactic measures, general and specific, he deemed most important in averting the septic dangers of childhood.

A Consideration of Some of the Remote Symptoms of Pelvic Diseases.—Dr. H. D. Niles, of Utah, very ably addressed the section in a paper having this title. With the present conception of the pathology and surgical treatment of pelvic diseases, he considered it both possible and necessary to obtain a clearer understanding of their remote symptoms and complications. The remote effects of pelvic diseases he thought probably due to: (1) Septic infection; pressure upon nerves, vessels, ureters, bowels, or bladder; (2) bladder, bowel, or omental adhesions; (4) nervous reflexes. The resulting symptoms he cited as: (1) All thos due to deterioration of the blood, either by septic absorption or defect in the eliminative organs. (2) Those due to pressure upon the nerves or blood-vessels of the pelvis. (3) Those due to functional disturbances or organic disease of the stomach and intestines from omental or bowel adhesions. He described a case illustrating the points emphasized. The point most difficult to make apparent and agree upon he said was the estimate of the serious remote consequences of peritoneal adhesions, partially devitalized tissue remaining in the peritoneal cavity, pressure symptoms, etc.

Pneumaturia, or Gas in the Urine.—Dr. Howard A. Kelly, of Baltimore, addressed the meeting on this subject. He stated that for the past two centuries observations had been made by various authorities as to the passage of gas with the urine, but only lately had any detailed accounts of this phenomenon appeared. In 1825 De Boismont considered that pneumaturia was due to the spontaneous formation of gas in the bladder, arising from a species of flatulence or secretion of gas by the mucous membrane. Later, Chomel suggested that the gas might be due to fermentation. Up to 1860, however, almost all the cases observed were due to a fistulous communication between the bladder and the intestinal tract. The author divided cases of pneumaturia into three groups: (1) Those in which air was mechanically introduced into the bladder from without; (2) those in which gas developed in the urinary tract through some fermenting organism; (3) those in which there was a communication between the bladder and some air-holding viscus. The first class of cases the writer stated were seen most frequently after instrumentation, as after catheterization or cystoscopic examination of the bladder by his method. The air introduced in this way was usually painful and was expelled spontaneously by the patient sitting upon a vessel. In the examination of the male by his method through a straight open cystoscope the effect produced was quite curious, and the air was afterward expelled from the bladder thoroughly mingled with the urine in minute bubbles, producing a hissing sound. It had also been noticed that air might even enter the ureters with the patient in the knee-breast position, and might sometimes serve the valuable purpose of locating the ureteral orifice in cases of disease in which it was concealed. The air entering in this way was of course at a temperature lower than that of the body, and upon being warmed in the ureteral tract expanded and bubbled out, showing the situation of the orifice. The second group of cases depended on the invasion of the urinary tract by some organism which by its action upon the urine produced gas. The gas in most cases was produced in the bladder; in only a few instances has it been noticed in the outer urinary tract. A wide field for investigation in this group remained, since so little was known of the etiology. Most of the cases described had occurred in the aged, when there had been for some time an obstruction to the flow of urine or when calculi had existed. In two there was paralysis following myelitis. Out of sixteen cases nine had glycosuria and in most instances a formation of gas followed catheterization. The micro-organisms described belonged to the group of the bacterium coli commune. The gases produced were carbon dioxide, oxygen, nitrogen, and marsh gas. The author stated that three cases were recorded in which the gas was produced in the kidney instead of in the bladder itself. Le Dentu referred to a case of a child eight years old. Pisne cited a case in which there were both pyonephritis and a perinephritic abscess. In the author's own case, that of a person aged thirty-six, there was a dense left renal tumor with excessive surrounding infiltration of the cellular tissue. Upon examination of the bladder through a No. 10 cystoscope its mucous membrane was found to be normal, but numerous bubbles of gas were seen mingled with pus which had escaped from the left ureteral orifice. When the kidney was cut into, a large quantity of fetid, thick, viscid pus escaped with bubbles of air. The patient recovered without extirpation of the kidney. The organism found was not identified. The last group of cases, it was stated, had been worked up by Cripps and Chavanez. The author had had two instances in his own practice, both arising from a communication of the sigmoid flexure with the bladder. The treatment varied according as the fistula was located high or low. The writer considered the most satisfactory cases to treat those in which the sigmoid

flexure opened into the bladder. These could be cured by abdominal section, severing and paring the attachments, and closing the fistulæ by suture.

SECTION ON PRACTICE OF MEDICINE.

First Day—Tuesday, June 7th.

Address of the Chairman.—Dr. Samuel A. Fisk, of Denver, Col., delivered this address. He said that the climate of Colorado was unsurpassed, so far as pulmonary disease was concerned; favorable results could be seen on every hand, and recoveries were to be numbered by the tens of thousands—which, after all, was the best proof of the efficacy of the Colorado climate in this class of diseases. The man practising medicine exclusively was frequently hampered by the professional brother, on the one hand, who demanded a demonstration to his senses; and, on the other, of the laboratory man, who demanded that the clinical results should tally with those of mechanical appliances. As had been ably pointed out by Prof. F. C. Shattuck, "internal medicine" should use these different results rather than be used by them. Even now, having been thoroughly scared, it was again resuming courage, and great things were to be hoped for in the future. It might be that it was somewhat to be blamed for these conditions, and that many a fault had been allowed to be covered up by a theory rather than by a fact. "The peculiar type of disease" was often used as a cloak for one's shortcomings, or, when this failed, one was wont to take refuge behind the theory of "self-limitations," which led the first Dr. Warren, many years ago, when asked what was good for acute rheumatism, to reply, "Six weeks." Fortunately, text-books did not contain the whole of medicine and disease did not necessarily direct its course according to the tactics of a treatise on medicine. We recognized nowadays that, if our joints were swollen and painful with acute articular rheumatism, we did not have to wait the whole six weeks, and we knew that the old idea of "twenty-one days," as applied to typhoid fever, did not hold, and that we had the peculiar types of disease known as typhus levissimus, afebrile typhoid, and abortive typhoid. The fact that we did have these peculiar types, whether the result of practice or in spite of practice, led us to the hope that disease of any sort which had once been aborted could be aborted a second time, and that after a while the "peculiar" type might become the prevailing type. It seemed to the speaker that in this direction, that of abortive medicine as well as of preventive medicine, the section had a considerable scope for the future. The speaker then alluded to the recent centennial anniversary of Jenner's famous discovery, that persons accidentally inoculated with cow-pox were subsequently insusceptible to small-pox. It was needless to do more than make mention of this fact, and to recall the blessings which had accrued to the world from its introduction—how one of the greatest blights to mankind, one that frequently decimated a population, had been virtually blotted out, and the average limit of man's days increased in consequence. It might not be amiss to mention the fact that these were the results of the purest clinical observation, and not those of laboratory toil. He did not wish to seem to depreciate the results of experimentation and of exactness, so called, but chafed under what at times threatened to restrict progress. One was often reminded of *Hamlet's* little frenzy: "Why, look you now, how unworthy a thing you make of me. You would play upon me; you would seem to know my stops; . . . S'blood, do you think that I am easier to be played on than a fife?"

Discussion on Perforation Peritonitis.—Dr. J. C. Wilson, of Philadelphia, opened the discussion. He said that in the list of visceral diseases not yielding to medical treatment, and sooner or later to be transferred to the care of the surgeon, were the following: empyema, pericardial effusions, troublesome cases of cholelithiasis with persistent symptoms and empyema of the gall bladder, cysts of the pancreas, echinococcus cysts. Extirpation of the kidney might be performed when that organ was the seat of malignant or other growths; nephrorrhaphy for the relief of symptoms due to displacements. Hydronephrosis and nephrolithiasis might require operation; certain cases of stubborn nephralgia might require incision into the capsule. The field of the surgery of the gastro-intestinal tract had been greatly extended, as in the establishment of gastric fistulæ in stenosis of the œsophagus, pylorectomy, partial or complete extirpation of the stomach, gastro-enterostomy, removal of carcinomatous growths of the lower bowel, appendicitis, ulceration of the stomach and intestines, especially peptic ulcer and the perforative ulcer of enteric fever. What the speaker had to say had no bearing upon the purely surgical lesions followed by extravasation of the intestinal contents and infection of the peritoneum, for it was well known that in suitable cases immediate operation was the only hopeful procedure. Aside from the traumatic and gynæcological cases, the list of diseases in which acute general peritonitis might arise was most extensive: (1) In the alimentary canal: (*a*) peptic ulcer, gastric ulcer, and duodenal ulcer; (*b*) enteric fever; (*c*) appendicitis. (2) Other hollow viscera, the contents of which might be infected: (*a*) the gall bladder; (*b*) the contents of the kidney; (*c*) the urinary bladder. (3) Rupture of abscesses: (*a*) purulent pleurisy; (*b*) subphrenic abscess; (*c*) hepatic abscess; (*d*) abscess of the pancreas; (*e*) appendicular abscess; (*f*) other pus collections in regions in relation to the peritoneum. (4) Necrotic processes involving abdominal viscera: (*a*) internal strangulation; (*b*) intussusception; (*c*) volvulus; (*d*) embolism and thrombosis of the mesenteric vessels; (*e*) gangrene of the pancreas or the spleen; (*f*) displaced kidney or spleen with twisted pedicle; (*g*) acute hemorrhagic pancreatitis; (*h*) fat necrosis. In some of these conditions the previous underlying disease could be readily determined if the patient had been under observation prior to the accident which caused the peritonitis; but in other cases the patient, while out of health, was able to be about and attend to his duties up to the time of his accident. In the first cases a clear pathological relationship to processes of the antecedent condition might be arrived at and a reasonably accurate diagnosis of the immediate cause of the inflammation of the peritoneum reached. The distinction between the cases in which an immediate diagnosis could be made and those in which it could not be made was a matter of theory rather than of practice. It was the acute fulminant peritonitis that required immediate consideration. Here was a question of diagnosis. In the early stages, when operative interference was advisable and not without hope, the symptomatology might be grouped as follows: (1) Pain, general, becoming local; or local, becoming general, according to cause. (2) Tenderness, general, becoming local; or local, becoming general. (3) Rigidity of the abdominal muscles. (4) Vomiting green, and exceptionally absent. (5) Rise of pulse and temperature, exceptionally also absent. (6) Shock, varying in depth. (7) Diminished peristalsis. In fully developed peritonitis, in which the wisdom of interference was questionable, the symptoms were: (1) Pain, lessened or absent. (2) Tenderness, general. (3) Distention excessive, replacing rigidity. (4) Vomiting excessive, dark, and fæcal. (5) Obstipation; peristaltic movements not heard. (6) Rapid and fee-

ble pulse. (7) High or low temperature. (8) Lividity of abdominal skin; cold extremities. (9) Peritoneal facies. (10) Mind clear. In hopeless cases these symptoms were increased by collapse; the patient was moribund. (Richardson and Cobb: Park's "Surgery by American Authors," vol. ii., p. 386.) The importance of the condition of the abdomen could not be overestimated. The early rigidity of the abdomen was a symptom of the utmost importance, and its value was not sufficiently recognized by the practitioner. In a recent series of six cases of perforating ulcer of the stomach reported by different observers, in which the operation was performed within a few hours after the development of the symptoms indicating perforation, five patients recovered. In Keen's "Surgical Complications and Sequels of Typhoid Fever," there was a table of eighty-three cases of operation for intestinal perforation in enteric fever. As a general result, they give sixteen recoveries, or 19.36 per cent. of cures and 80.64 per cent. of deaths. When this was contrasted with Murchison's unchallenged figures of ninety or ninety-five deaths without operation, we could well take courage for the future. As regarded the time of operation, in the cases operated upon within twelve hours the percentage of recoveries was 26.7 per cent.; between twelve and twenty-four hours, 30 per cent.; after twenty-four hours the mortality was total, except in one operation after twenty-six hours, and in two cases in which the patients recovered in between two and three days. In conclusion, the speaker formulated for discussion the following propositions: As regards operation in acute general peritonitis due to perforation and analogous conditions: (*a*) A definite causal or local diagnosis of the lesions can be made in comparatively few instances. (*b*) The diagnosis of acute general fulminant peritonitis is of itself sufficient to justify interference in proper cases. (*c*) The earlier the operation the greater the prospect of success. After twenty-four hours, especially if great distention of the abdomen has shown itself, operation is not likely to be followed by recovery. (*d*) A small proportion of the cases are manifestly hopeless from the onset. (*e*) When the patient is not obviously past hope the fear of death upon the table should not deter the surgeon from operating.

Dr. W. W. Keen, of Philadelphia, said that the catalogue of diseases which caused perforative peritonitis was great enough to challenge attention. First, in regard to the symptoms the previous speaker had given he was not entirely in accord, although with the rest that he had said he agreed. He thought the pulse and temperature in perforative peritonitis were of unequal value. While, as a general rule, he thought the temperature to be the best index of a septic condition, still it was not always to be relied upon. The temperature, in his experience, was of not much moment. In regard to the statistics given by Dr. Wilson, he would like to speak further. This was a matter of extreme importance. If the case was seen twenty-four hours after perforation, one could assign the patient to the grave; we were bound to confess that perforation in typhoid fever meant that ninety-five per cent. would die. Drs. Weir and Tinckler reported that cases operated upon within sixteen hours gave a mortality of over thirty per cent. In cases of appendicitis in which perforation had taken place, especially if there were no adhesions or localized abscess, but there was general peritonitis, he thought that all present would agree that the only practical hope was offered by operation, and the earlier it was done the better. As regarded the incision in these cases, he did not care if it was two or six inches long, so far as it influenced the mortality. In these cases of perforation he recognized the fact that general and complete cleanliness of the abdomen was all-important. He did not believe it wise to clean nine-tenths of the abdominal cavity and leave one-tenth to be a focus of infection. He believed, too, in general agglutinative peritonitis, in making incision not only on one side but also on the other, and in thoroughly cleansing the abdomen. He was pleased that the section had taken up this topic for discussion, for it was one that touched every physician and surgeon and one in which all should unite and go arm in arm in the march for life and humanity.

Dr. J. H. Musser, of Philadelphia, said he would speak only from his personal experience on the topic under discussion. He looked upon pain continuing from twelve to twenty-four hours as very significant, and this, to him, was a symptom to be greatly dreaded. No symptom other than the occurrence of pain, which was usually localized in the course of the disease, gave him so much dread. If opportunity was given to examine these cases after death, one usually found that the perforation had been preceded by localized inflammation, and that there was a considerable amount of lymph covering the intestines in that region, matting them together. The phenomenon preceding perforation was the pain, the degree of which depended upon the intelligence of the patient at the time. In typhoid fever the patients were not susceptible to pain or else their state of mind did not admit of their complaining unless their attention was called to the pain. Pain and localized tenderness, the antecedent history, and slight rigidity followed by symptoms of shock should call attention to the possibility of an accident. Symptoms of shock in the course of typhoid fever, hemorrhage being excluded, were the ones to be relied on in the making of a diagnosis. He was in accord with the surgeons who wished to make exploratory incisions for diagnosis. The speaker referred to the case of a young girl, seen in the first week of typhoid fever, in whom the diagnosis seemed undoubted, although the reaction did not verify the disease. The temperature, mental and intestinal and other symptoms all pointed to the fact that she had typhoid fever. At the end of the first week she complained of some pain in the abdomen, but there were no rigidity and no tympanites. The next day the pain was more severe and was referred to the back. In order to exclude pelvic disease, an examination was made, which disclosed a large mass in the pelvis. The patient dying, there were found a pelvic tumor and also evidences of typhoid fever. The complication was not quite sufficient to lead astray, but it might have given rise to a mistake; this also showed the importance of early diagnosis. An early exploratory incision would have removed any question that might have arisen in regard to diagnosis.

Dr. C. G. Stockton, of Buffalo, N. Y., thought it was best first to discover whether the viscus was a hollow one containing air, like the stomach or intestines, or whether it was the gall bladder, urinary bladder, etc. The symptoms differed materially in different cases. There was not much difficulty in diagnosing a perforation following a peptic ulcer. He cited the case of a patient who was picked up on the street, complaining of intense pain and who was in collapse. The pain was in the region of the bladder, and it was thought she had rupture of the bladder. For some reason operation was not performed. The patient survived nearly a week and then died. The autopsy showed a perforation of the stomach. There was a round ulcer from which discharged the gastric contents into the abdominal cavity, and, in this instance, the patient survived several days. In the speaker's mind the symptoms that stood out as the best guides to perforation of the stomach, intestines, gall bladder, or urinary bladder, were those of suddenness of the symptoms or of the onset. It was true that perfora-

tion might be preceded by a slow inflammatory process producing tympanites before the symptoms of shock appeared. He referred to one case of peritonitis in which the pain was referred to the region of the kidney. The patient succumbed, and on post-mortem examination a number of renal calculi were found, one of which was just passing through the ureter. His views were in accord with those already expressed, he wished, however, to state that it often happened that there was an absence of symptoms that one most expected.

Dr. L. F. Bishop, of New York, believed that opium obscured the diagnosis and gave false confidence. He called attention to the fact that ice bags would relieve the pain in these cases.

Differential Diagnosis between Dengue and Yellow Fever, with Some Account of the Epidemic of 1897 in Texas.—Dr. H. A. West, of Galveston, Tex., read a paper with this title. He said that the following hypotheses had been assumed in relation to the recent epidemic: (1) The disease was dengue only. There was no yellow fever in Galveston, Houston, or the State of Texas in 1897. (2) There were anomalous cases of dengue, presenting all the symptoms of yellow fever, but proven not to be that disease by the indisposition to spread from numerous foci and the low mortality rate. (3) During the progress of an intense epidemic of dengue throughout the State, in Galveston, Houston, and possibly other places, yellow fever made its appearance, and in consequence of its mild form and resemblance to the prevalent disease was generally unrecognized. (4) An imputed hypothesis that the epidemic of 1897 in Texas was yellow fever only. (5) A few cases terminated fatally, and others, attended by marked jaundice and albuminuria, were denominated acute infectious jaundice (Weil's disease). It appeared from the above that the symptoms which had heretofore been relied upon to differentiate between yellow fever and dengue were the occurrence in the former of albuminuria, the characteristic facies (inclusive of jaundice), the divergent pulse and temperature, excessive irritability of the stomach, and increased disposition to hemorrhages. The absence of such symptoms in the main, the presence of an eruption in the large proportion of cases, and the lack of mortality were characteristic of dengue. Admitting that there was a greater similarity in the symptomatology of the two diseases than had been heretofore acknowledged, the question arose, "How could they be differentiated? In the speaker's opinion this was to be done chiefly by the symptom complex of an acute nephritis in yellow fever and its absence in dengue. In the latter, simple parenchymatous changes might occur in the kidneys and be manifested by an evanescent and mild albuminuria, while in the former in a series of cases many would afford incontestable evidence of the occurrence of a severe nephritis—viz., scanty urine of high color and specific gravity, intense and persistent albuminuria, hæmaturia, casts, decided tendency to suppression, and the accompanying uræmia.

Second Day—Wednesday, June 8th.

Diabetes Mellitus at the Massachusetts General Hospital, from 1824 to 1898. A Study of the Medical Records.—This was the joint production of Drs. Reginald H. Fitz and Elliott P. Joslin, of Boston, read by the latter. He said that from 1824 to 1898 the total number of cases treated was 172. Within the last thirteen years there were as many cases as in the previous sixty-one years. Of the whole number of patients 127, or 74 per cent., were males; 45, or 26 per cent., were females. The average age of 40 female patients was 39.1, being higher than in 121 males, in whom it was 31.4 years. Tables showing the proportion of diabetic cases to other medical cases in the hospital, as well as the classification of the diabetic cases as regarded age, nationality, occupation, heredity, and trauma, were presented. There was only one negro in the 172 cases. In the early days the impression prevailed in the hospital, as in the literature of the time, that more urine was passed than liquids were ingested. Sugar was determined by taste till 1851, sometimes by the patient, at others by the doctor. In 1835 occurred the statement: "A curious smell in the breath which he has had since entrance." After that time frequent allusions were made to the odor of the breath and urine—long before the tests for the acetone were discovered. In one case the disease had lasted twelve years, in another two weeks. The average duration was one and one-half years. Tables were also given which showed that the duration in nearly seven-eighths of all the fatal cases was less than two years. Of 172 patients, 47, or 27 per cent., died. The mortality among 172 males was 30.7 per cent.; of 45 female patients, 8 died, giving a mortality of 17.7 per cent. The lowest mortality was in the period from 1824 to 1840, but the total mortality from 1824 to 1885 was the same as from 1885 to 1898. In 18 of the 47 fatal cases the patients died comatose. It was noteworthy that of the patients dying with complicating diseases, only 6 had pulmonary tuberculosis and only 6 chronic nephritis; disease of the pancreas was present in only one instance. The diet of the first period was "animal food and bread in small quantities." Since then there had been no essential change. Opium was the only drug continuously used. In the period between 1840 and 1855 experiments were made with yeast, and between 1870 and 1885 with glycerin, but with poor results. Eight of the comatose patients were treated with subcutaneous or intravenous injections of salt solution or bicarbonate of sodium. All died. In some there was a temporary improvement.

Dr. West, of Galveston, Tex., thought that the small proportion of cases occurring in the negro might be due to the small number of negroes in that section, although in his experience he had never seen a case occurring in that race. He had found diabetes and gout frequently associated. Diabetes pursued a rapid course in the young. Albuminuria was said to be found in about sixty per cent. of the cases, and yet the autopsies failed to show kidney lesions; this to him was quite remarkable.

Dr. Tyson, of Philadelphia, said that about three years ago he gave a clinical lecture in which he made the statement that he had never met with a case of diabetes in a negro. There happened to be present a negro physician who had a large number of negroes in his practice. In a few days three negroes came to him with unmistakable diabetes. The speaker thought the disease was more common in this race than was supposed.

Dr. Bond, of Indiana, said he thought this trouble was more common in the Hebrew race than in the Christian, because the former had a peculiar life, giving parties, and often congregating together and having evening meals. They had the disease more than any other people.

Influence of Sunlight on Tuberculous Sputum in Denver, and of Immunity against Tuberculosis in High Altitudes.—This paper, by Drs. William C. Mitchell and H. C. Crouch, of Denver, was read by the former. The statement was made that in high altitudes both the absolute and the relative moistures were low, and this, together with much lessened atmospheric pressure and almost constant winds of greater or less force, greatly facilitated evaporation. Thus were created conditions extremely favor-

able for the abstraction of moisture by the atmophere from whatever substances it came in contact with. The moist surface of the lungs must suffer considerably more loss from moisture in this altitude than at lower ones, and it was this eternal battle for moisture compensation, especially as it occurred in the lungs, that the writers believed to be one, and by no means the least, of the factors which either aided in granting such a large measure of immunity against tuberculosis here, or in arresting or retarding such processes in their incipiency. It was known that the tubercle bacilli grew but sparsely if at all on media deficient in moisture, and, while it hardly seemed possible that there could be moisture enough extracted to leave the alveolar linings in a state too dry to offer a suitable nidus for the invading bacillus, yet it was not improbable that this constant and rapid pulmonary evaporation created conditions extremely unfavorable to its development. When the animal organism was subjected to increased atmospheric pressure, the blood was caused to recede from the capillaries of the skin and mucous membrane, thus producing an anæmia of these parts. In extremely high altitudes the diminished air pressure caused a great dilatation of the capillary vessels of both skin and mucous membrane, giving rise to a mechanical hyperæmia. These vessels were often ruptured, and there might be hemorrhages from the mucous membrane of the mouth, the nose, or even the lungs; the tympanum was bulged outward, the respiratory and cardiac movements were quickened, and muscular motions were facilitated. In short, we had the conditions described by adventurous mountain climbers and known as mal de montagne. There were two things which militated against the spread of tuberculosis in high altitudes: (1) The powerful influence of the solar rays acting through a thin atmosphere rapidly destroyed the virulence of the exposed tuberculous matter. (2) The vital functions were so operated on by the various meteorological phenomena that they were specially fortified against the invasion of the tubercle bacillus. The authors believed that their experiments clearly demonstrated that the immunity did not proceed from the first named of these theories, and that they had every logical right to attribute it to the second proposition.

Course and Management of Complicating Myocarditis.—Dr. Louis Faugères Bishop, of New York, read a paper with this title. He said that in the course of the practice of medicine, as diseases and conditions were unconsciously classified, ideas gradually developed themselves that it was not always easy to formulate into the language of exact scientific observation. One of these impressions had been that in the debility following severe diseases there was some more definite underlying condition than was generally formulated. The explanation alone of an exhausted and deteriorated nervous system was not sufficient. His attention was drawn to the heart muscle, and clinical observation, confirmed by the pathological observations of others, had led to the belief that complicating myocarditis was an important factor in the course and progress of many conditions. The signs of disease of the heart muscle should therefore be studied with care. In acute diseases and wasting diseases, whatever their nature, there came times when it seemed evident that the heart had participated in the debility and degeneration that were visible in the other tissues of the body. So were found in the milder cases a condition of simple weakness of contraction, and in the more severe cases signs more suggestive of myocarditis, namely, irregularity in force and rhythm. When after an acute disease or in the course of a chronic affection these signs were noted, it became important to interpret their meaning and study their indications. The conception of the condition under consideration was that it was an inflammatory state of the myocardium following acute diseases, occurring in the course of chronic wasting diseases, or beginning as an extension of inflammation from an endocarditis or a pericarditis. It was not proposed to consider conditions secondary to diseases of the coronary arteries or excessive hypertrophy. The object did demand an extended reference to pathology. A form might occasionally originate in an acute interstitial myocarditis, but more frequently it was a parenchymatous degeneration. Dr. Osler had remarked that it was probably the effect of a toxic agent, and that there was no definite relation between it and high temperature. Every one was familiar with the appearance of the heart muscle in a patient dead of an acute prolonged illness. It differed in appearance from the heart of a person who had been killed by accident while in good health. In the former the muscle was pale and grayish looking, while in the latter it was firm and red and of a healthy color. Probably in many diseases there was this low grade of inflammation, that was not more than a slight degeneration. These cases were too often diagnosed as "general debility," or as instances of disturbed cardiac innervation. It was important that the real condition should be recognized, because the treatment might otherwise be prejudicial. Stimulants directed to the heart itself were certainly philosophically contraindicated. We might whip a lazy horse or we might improve the behavior of a nervous horse by discipline, but a sick horse should always be rested and fed. So in the case of the heart that was feeble and behaving badly on account of myocarditis following a severe illness, muscle stimulants should be avoided. Especially was the care of the heart important in those cases of acute infectious diseases in which a valve lesion had unfortunately been developed by complicating endocarditis. In severe endocarditis myocarditis also probably existed, so that there was a double call upon the forces, as the heart must not only regain its normal power, but must also learn to do greater work to make up for the lesion in the valve. Particularly was it important for such patients to follow a long and strict regimen, avoiding indiscretions of diet, sudden exertion, and dissipation of all kinds. The treatment of degeneration of the heart fibre when far advanced was a difficult problem. Indeed, often when on account of the evidence of well-marked symptoms we could say definitely that such a process was going on, it was too late to accomplish a great deal. The hopeful cases and those which it was especially desired to call attention to at this time, were those of complicating myocarditis met with as an accompaniment of acute diseases. One of the dangers to the person suffering from myocarditis was the possible result of sudden overexertion, causing an acute dilatation of the heart, from which recovery was not easy. The proper regulation of the muscular activity of the patient was therefore of the utmost importance. Exercise undertaken to improve the general bodily nutrition, and that of the heart muscle in particular, should be light, slow, and systematic. Next to exercise came diet. The food should be concentrated, so that nourishment was administered in small volume, leading to an easy performance of the functions of the stomach without the tendency to distention, such as might mechanically embarrass the functions of the heart and lung. With the principle of a small volume of food, much latitude as to variety might be permitted. The use of alcohol without its abuse was very difficult in cardiac cases. Probably a small quantity with meals was not harmful, but any excess was always followed by injury. The use of tea and coffee was a good deal a matter of experience with particular patients, but the extreme frequency of cardiac symptoms produced in persons

with normal hearts by tea, and the fact that both tea and coffee were recognized as cardiac stimulants, should make the physician take the stand with patients that these, being cardiac drugs, should be controlled by him. The use of tobacco would better be discontinued. The picture presented by the convalescent from an acute disease, who had escaped with a healthy heart, was very different from that of the one who had suffered from degeneration of the heart muscle. The former regained health and strength rapidly; the pulse became strong, the color returned, and the patient was soon in good health again. The patient with complicating myocarditis lingered along in a state of semi-invalidism. The disease from which he originally suffered had entirely disappeared. There was apparently no reason why he should not recover strength and health, but the heart for a long time remained weak unless its state was recognized and particular measures were employed to restore its integrity. This chronic complicating myocarditis explained symptoms so often witnessed after diphtheria, grippe, scarlet fever, and other diseases characterized by a violent infection.

Differentiation of the Cardiac Incompetency of Heart Disease and that of Chronic Nephritis.—Dr. Frank Billings, of Chicago, read this paper. Certain phenomena common to both of the above conditions he enumerated. Special phenomena, however, were sometimes present which, although they may be common to both, were more often the result of a primary heart or a primary kidney lesion alone, and these signs or conditions were of some aid in a differential diagnosis. He said that if the urine, even though scant, showed a relatively low specific gravity, with diminished total solids, lessened urea, much albumin, and casts of all varieties; if the arterial fibrosis was marked and the pulse full and sustained, or without arterial thickening if the pulse was sustained; if the dropsical effusion contained urea in a considerable amount; if there was a tendency to inflammation of serous surfaces, pericarditis and pleuritis especially; if there was a tendency to persistent morning nausea and vomiting of stringy mucus; if there was a tendency to periodic diarrhœa; if there was much headache, especially severe frontal and occipital pain; if there was a tendency at one time to unrest and mental excitement or at another to somnolence or to coma; if cerebral hemorrhage occurred; if the dyspnœa of exertion became of the Cheyne-Stokes type; if severe epigastric pain occurred; if the eye showed the changes common to albuminuria, and if the patient presented a pale, waxy, puffy face, a heavy expression, and a general anæmia—the diagnosis was in favor of nephritis. If there was a history of antecedent disease in which endocarditis may have occurred; if the heart showed physical signs of valvular disease with characteristic murmurs; if there was an irregular heart action, persistent in character; if the pulse was weak and not sustained, with or without arterial fibrosis; if the dyspnœa of exertion was attended with cyanosis; if there was a normal amount of red cells and hæmoglobin or only a moderate degree of anæmia; if the dropsical effusion began in the lower extremity, appearing during the day, and if the dropsical effusion was rich in albumin, and if the dropsical effusion contained little or no urea; if there were much enlargement of the liver and tenderness of the left lobe; if the urine was scant, of high specific gravity, with much deposit, with little or no albumin, a high percentage of urea, although the total urea in twenty-four hours was deficient, and there were a few casts only slightly hyaline or finely granular; if there were little or no headache, no eye changes; and if venous thrombosis or embolism occurred, the diagnosis was in favor of intrinsic heart disease. The recognition of an incompetent heart was usually not difficult. The dyspnœa of exertion, the sense of poststernal weight and constriction of the chest, the cough of exertion and upon assumption of the recumbent position, the enlarged liver with often tenderness and pain or a feeling of weight in the epigastrium, the indigestion of portal congestion, the usually scant urine, the œdema of the feet, or all of the above-mentioned symptoms, were much exaggerated, until constant dyspnœa with orthopnœa, general anasarca, excessive physical weakness, marked pallor, and cyanosis gave unmistakable evidence of cardiac weakness. The local signs of valvular disease might be absent or present. Signs of cardiac enlargement with dilatation of the chambers of the heart were present and could usually be recognized. These symptoms were usually present in varying degrees of severity in an incompetent heart. When due to intrinsic heart disease, a valvular lesion or some other cause of dilatation of the heart and weakness of the heart muscle was present. In chronic nephritis, cardiovascular changes occurred, and especially in the form classed as diffuse interstitial nephritis. In the later stages especially of chronic nephritis the heart might become so dilated as to be incompetent and cause the symptoms and signs enumerated to appear. The urinary findings, the symptoms of uræmia, and other characteristic signs might plainly indicate the primary nephritis. In many cases, however, the differentiation could not be easily made, and in a few examples the diagnosis might remain in doubt until the light side of the dead-house cleared up the darkness. It was with these doubtful cases that this paper had to deal.

Dr. West, of Galveston referred to the therapeutic test in determining which condition was the primary disease.

Dr. Bond, of Indiana, said there was one important factor in both diseases, which was an arterio-sclerosis; he doubted if it was possible to have either disease without this condition being present.

Diabetic Gangrene.—Dr. N. S. Davis, Jr., of Chicago, read this paper. He detailed the history of three cases. The first and third cases typified well the milder forms of spontaneous gangrene in diabetes. The successive invasion of different toes in the last of his cases was noteworthy. The diminution and even disappearance of glycosuria in two of the cases, while mummification existed and spontaneous amputation of the phalanges was progressing, were interesting. A similar marked diminution or disappearance of glycosuria the speaker had observed in several cases when tuberculous disease of the lungs was active. Both cases were upon diabetic treatment, which consisted mainly in a regulation of the diet, the use of arsenical preparations, and at times of opiates. The second case was one of mal perforant, which was an occasional complication of diabetes. The association was no more an accidental one than the association of diabetes and gangrene proper. Diabetic gangrene occurred much more often in the legs and feet than elsewhere. Those cases of gangrene occurring in the course of diabetes which were associated with or superimposed upon inflammation, were undoubtedly chiefly due to the low vitality of tissues in diabetes and the consequent ease with which putrefaction took place in them. The frequency of gangrene in the lungs in diabetics who also had tuberculous or other disease of the lungs could be accounted for in this way. The cause of spontaneous gangrene which was not preceded by visible wounds or infection was of more interest. Neuritis and atheroma had both been assigned as causes of the spontaneous gangrene of diabetics. Both lesions frequently accompanied diabetes. Godlee admitted two varieties of spontaneous diabetic gangrene—one due to neuritis, in which he advised operation close to the point of necrosis; and

one due to atheroma, in which he advised amputation at the knee or above. According to Heidenhain's view, spontaneous gangrene in diabetics was pathologically identical with senile gangrene. The speaker also called attention to the very frequent occurrence, even in early life of adults, of arterio-sclerosis in diabetics. Hunt claimed that areas of gangrene in diabetics were mapped out by a less-defined line of demarcation than in cases of senile gangrene. Surgeons had been disinclined to operate upon diabetics because of their susceptibility to infection. Recent experience had shown that amputation could be performed upon them with good success, if only sufficient care was taken to prevent infection. Heidenhain (*Deutsche medicinische Wochenschrift*, 1891, xvii.) recommended that if gangrene was confined to the toes, the physician should wait until a line of demarcation developed, and if there was no evidence of general infection, that the dead tissues be allowed to separate spontaneously. If, however, the sole or the dorsum of the foot was involved, the leg should be amputated at the knee or above it. The speaker believed that amputation of the toe after a line of demarcation had become well established was preferable to the tedium and pain of spontaneous amputation. The greatest care should be taken gently to remove the sloughing tissues, and by the free use of antiseptics to limit putrefaction.

Use of Iron and Opium in Bright's Disease.—Dr. James Tyson, of Philadelphia, read a paper with this title. In 1880, in speaking of the treatment of chronic interstitial nephritis, he stated that iron was an important and indispensable drug, and might be given in the form of the acetate or in Basham's mixture. Since writing the above he had been led to believe that a good deal of mischief had been done in Bright's disease by iron, and he was not sure but it would have been better for the patient if the gallons of Basham's mixture used had been poured into the street gutter rather than into the stomachs of the patients. Not every case of Bright's disease was anæmic, and as iron had no specific curative effect it was clearly not indicated in non-anæmic cases; nay, more, it was often harmful. It locked up the secretions and checked elimination already restricted by a diminished function of the kidney. It might be laid down as a rule, to which there was almost no exception, that iron was not indicated and should not be prescribed in cases of acute Bright's disease. Iron, too, was contraindicated in chronic interstitial nephritis. In this form iron was more promptly and dangerously harmful than in any other form of Bright's disease. The form of Bright's disease in which iron was best borne was chronic parenchymatous nephritis, especially as this was more likely to be associated with anæmia. Here doses were usually given in too large amounts. The speaker held that if iron appeared in the fæces this unabsorbed portion was useless, and it was this useless portion that acted as an astringent and caused constipation. In regard to the belief that Basham's mixture was a diuretic, he did not think this was true, except it was so on account of the amount of water that it contained. As to the use of opium in this disease, he said he had seen a fatal uræmia produced by a couple of spoonfuls of paregoric. Opium was certainly contraindicated in chronic interstitial nephritis; in this form of the disease he had seen many patients launched upon their last sleep, and the danger was especially great in those not suspected of having the disease. He emphasized the importance, therefore, of always examining the patient's urine before administering opium. The greater the destruction of the kidney the greater the danger from the use of opium. The treatment of puerperal convulsions by the hypodermic injection of morphine was justifiable, on the ground that most of these cases were of the acute form; but even here caution must be used. We should be certain that cases of disease requiring the use of morphine were not complicated with chronic Bright's disease.

Dr. West, of Galveston, Tex., thought that iron was of use in acute Bright's disease. In uræmic convulsion he thought many lives could be saved by the heroic administration of morphine.

Dr. Stockton, of Buffalo, thought that hypodermics of morphine had saved many lives when all other remedies had failed. In regard to the use of iron, he did not agree with the reader of the paper. He did not think that small doses of this drug were so beneficial as large doses, for not so much was absorbed.

Dr. Brown, of Cincinnati, Ohio, thought that both iron and opium were dangerous in any form of Bright's disease.

Rare Cases of Arrhythmia.—Dr. J. M. Anders, of Philadelphia, read this paper, concluding it by restating in sequence some of the most interesting points embodied in the report of the cases given. (1) The presence of reduplication of both first and second sounds (double reduplication) in the first two cases—one of tobacco poisoning, the other of exophthalmic goitre. (2) The occurrence of a typical pulsus biferiens in one case, dependent upon the toxic effects of tobacco, in the absence of combined aortic regurgitation and stenosis. (3) The presence of a cyclical increase in the rapidity of the movement of the heart, followed regularly by a brief pause; and the striking mechanical effect of the respiratory function upon this peculiar variety of arrhythmia. (4) The temporary production of apical systolic murmurs during the inspiratory element of the respiration. (5) All the cases developed in subjects in whom previously existing valvular lesions of the heart, so far as determinable, were absent.

A Consideration of Four Cases of Epilepsy, with Reference to the Cause.—Dr. Charles S. Bond, of Richmond, Ind., detailed the history of these cases and said: "It will be observed that these cases present great variety as to age. They include three boys and one girl, but they all have something in common, some form of irritation originating in the alimentary canal, causing, according to the best of belief, a cortical disturbance which in turn produces unconsciousness directly and reflex tonic and clonic spasms of peripheral muscular fibres. This causal relationship has been traced in a number of cases under observation; and these cases are worthy of careful study as adding to our knowledge of peripheral irritants in epilepsy—a fact which a few bright minds in the profession are wont very rapidly to appreciate. Whether we believe in the causative influence of uric acid or leucomain products from this group, or whether confidence is given to the total toxic effect of maldigestion, the fact still remains that a very strong relation exists between these products and those cortical disturbances seen in the various forms of so-called idiopathic epilepsy. Other sources of extrinsic irritation are numerous and have received due credit in most instances long since, while this more obscure field, and therefore all the more interesting one, still presents much for careful study in the differentiating of such irritants. If the rationale of this phase of the disease is, therefore, that irritants from the digestive tract, through the blood, come in contact with the cortex, thereby causing a constant or intermittent efferent current, in like manner controlling the muscles, it would seem the highest service to such patients must come in the prevention of these products from entering the blood current. Under this view it is difficult to understand how the bromide salts can do more than palliate and thereby perpetuate an evil which

is quite removed from the drugged cortex. Indeed, I shall venture the opinion that in many of these cases, in the end, the bromides do much harm—more than good; in the first place by suppressing to a certain extent the evidence of an evil which at that period is the most amenable to treatment; in the second place, by injury which these drugs often inflict upon the already diseased digestive tract; and lastly, on account of the unusual effect which sometimes occurs in the cortex itself."

Dr. Stockton, of Buffalo, said he had seen just such cases as Dr. Bond had described. His own opinion was that cases of epilepsy could be relieved by attention to the gastro-intestinal tract. Some cases of epilepsy were aided by aiding digestion. Again there was a class of cases in which no improvement followed attention to this portion of the canal.

Dr. Lockard, of Colorado, said that on the 12th of May last he had been called to see a child of twelve years who was in a convulsion. Upon questioning the parents he elicited the fact that on the paternal side the grandfather had been subject to epilepsy since childhood (he was now sixty-four years of age); also that when he moved to Colorado the attacks became fewer. He also learned that one or two members of the family on the paternal side were victims of epilepsy. He therefore felt reasonably sure of the hereditary condition. Thinking of the possibility of poisoning, he administered a hypodermic of apomorphine and produced emesis. After the contents of the stomach were evacuated the child got better and has been well since.

Dr. Tyson, of Philadelphia, thought that the explanation of these cases might often be, as Dr. Bond had stated, that they were due to reflex irritation and absorption of toxic substances. He referred to the case of a young girl who had convulsions, who got well upon the expulsion of a tapeworm. Another case was that of a man who was the victim of convulsions for two or three years; the relief of a chronic constipation afforded him relief from his attacks.

Dr. Jones, of Buffalo, spoke of the probability of the reflex disturbances causing irritation, which produced these seizures. He related the instance of a boy, aged nine years, who had nocturnal convulsions. He tried to eliminate some factors which might have a causative influence on these attacks and he soon discovered a catarrhal gastritis with hypochlorhydria and gastric dilatation. After regulating the patient's diet and his manner of eating, etc., for fourteen or sixteen weeks, the boy had no evidences of any more seizures.

Dr. Anders, of Philadelphia, understood Dr. Bond to speak against the use of bromides in epilepsy. He thought it was the duty of the physician to use the bromides in epilepsy, this being the best-known way to ameliorate the attacks and lessen their frequency.

Dr. Robins, of Illinois, reported a case of epilepsy occurring in a child of six years. Upon careful examination he found the child's head covered with boils or abscesses; he concluded that the child was pyæmic. These abscesses upon the child's head had existed since birth and the blood was so poisoned. The treatment directed to that condition cured the child.

Constipation sometimes seen in wasting infants may often be successfully treated by frequent and long-continued kneading of the abdomen with the oiled hand; by small enemata of warm water, or soap and water, or containing a drachm or two of castor oil; or with a few drops of castor oil occasionally repeated by the mouth. Other drugs, such as senna, aloes, or cascara, may be tried. As soon as a proper diet is well taken this medication may almost always be discontinued.

Reviews and Notices.

Daydreams of a Doctor. By C. Barlow, M.D. Buffalo: The Peter Paul Book Company. 1898.

There have been a few philosophers who could moralize on their own emotions to the limit of many editions and without nauseating their readers; but C. Barlow, M.D., is not one of them. Perhaps a reverence for Thoreau's impromptu treatise on watermelon seeds or Dr. Holmes' delightfully impersonal personalities inspired the author to surround himself with his dictionaries and microscope, and all his available professional paraphernalia, and then call in his admiring audience to watch him "invite his soul," after a hard day's work. He points out to his imaginary friends, who have no conception of anything, the infinite detail, the terrible anxiety, the heroism, the magnanimity and self-sacrifice of the hard-working physician's life.

In his preface he calls attention to the justice with which he treats women in his book, and, with a delicate desire to include them gracefully in his dedication, he inscribes the work "to his wife, to physicians and their wives and their husbands." In his chapter upon woman he briefly reviews the superior women of history, beginning with Eve immediately after the rib episode, and skipping lightly from Semiramis, Hygeia, and Esther down to Joan of Arc and Isabella, and ending up with "that magnificent lady, Louisa M. Alcott."

There is a fine moral tone in the book. The "lady doctor," who has a chapter to herself, expatiates upon the foul tobacco habit and upon the sin of drunkenness. The imaginary guest who accompanies her upon her round of calls is deeply impressed and asks leading questions, calling forth a series of pretty illustrative anecdotes that merit reproduction by the Tract Society. The combination of scientific and religious and philanthropic sentiments portrayed in these pages makes the book a rare one of its kind. It should be in every Sunday-school library and old ladies' home. We ought also to mention that it has a beautiful green cover.

Atlas and Essentials of Pathological Anatomy. Vol. I. By Dr. O. Bollinger. Wood's Medical Hand Atlases. With 60 Plates and 18 Illustrations in the Text. New York: William Wood and Company. 1898.

While it is given to but few to have the opportunity to make many post-mortem examinations, indications seem to be pointing to a more enlightened sentiment on the part of the relatives and friends of the dead in this matter, so that all physicians are having more and more occasion to perform such autopsies and thus can reap the benefits of this important branch of their science. To have a trustworthy guide in such examinations, other than that given by verbal descriptions, has been hitherto denied the general practitioner, and the present volume, with its finely colored plates, cannot but prove of much service to the student of gross pathology. The work treats of the more common diseases of the circulatory, respiratory, and digestive apparatus, including the liver, bile ducts, and pancreas. The succinct and accurate text helps to make clearer the interpretation of the changes produced by disease. The book is a timely and much-needed work on gross pathology, and will be an invaluable aid to the student, the post-mortem worker, and the practising doctor.

Text-Book of Physiology. Edited by E. A. Schäfer, LL.D., F.R.S., Jodrell Professor of Physiology, University College, London. Vol. I. New York: The Macmillan Company. 1898.

We have nothing but the highest of praise for this first volume of a new text-book of physiology. Although its various chapter subjects—chemical constituents of the body; the food; the tissues and organs; the blood, hæmoglobin; general considerations of diffusion, osmosis, and filtration; lymph production and absorption; chemistry of the digestive processes; the salivary glands; mechanism of the secretion of the gastric, pancreatic, and intestinal juices; mechanism of the bile secretion; chemistry of the urine; mechanism and secretion of the urine and milk; secretion and absorption by the skin; chemistry of respiration; animal heat; metabolism; and the ductless glands—have been treated by different authors—Halliburton, Gamgee, Schäfer, Reid, Starling,

Langley, Paton, Pembrey, and others—the contributions have been so ably edited that there are a distinct coherence and a lack of over-lapping rarely seen in a book of such composite character. There is also a good balance between the subjects treated, so that the integrity of the work is maintained throughout.

Through and through the book is carefully written, scientific, and up with the latest literature. It is full of good information, and not padded out to an enormous size nor interlarded with numerous non-explanatory cuts, though in this latter matter more illustrations would not come amiss in this volume. There are some features of the work which are, we believe, especially commendable. The discussions of mooted points are full and yet not too diffuse, and they give to the careful student more incentive to thought than dogmatic statements taken from a single monograph or a recent article. Full citations of literature are given, a feature especially valuable to the advanced worker.

A Compendium of Insanity. By John B. Chapin, M.D., LL.D. Philadelphia: W. B. Saunders. 1898.

This small work, with a preface stating that the book was intended for the student and trained nurse, would be warmly commended; but, when it is presented "with the hope that it might be of service to the physician and lawyer," we believe it to have missed its vocation, for it is distinctly popular in tone, and, though very readable, can hardly be conceived to be a trustworthy guide for the seeker of exact and co-ordinated information on a subject fraught with a multitude of difficulties. The work is well printed, and is an excellent non-technical presentation of the subject from a layman's point of view.

How to Become a Trained Nurse. A Manual of Information in Detail. With a Complete List of the Various Training-Schools for Nurses in the United States and Canada. Edited by Jane Hodson. New York: W. Abbatt. 1898.

Every young woman who thinks of taking up nursing as a profession should send for this book as her introduction to the details of the life she will lead. It is a clear, concise handbook of practical directions, not about nursing, but about the routine duties and the system of hospital life. It contains a detailed description of every training-school in the country, the number of nurses on the staff, the number of beds, the hours of work, the amount of remuneration, the regulations concerning probationers, and the name of the proper person to address for information. More than half the book is taken up with this index. The literary part is a series of short contributions by well-known nurses on various topics of interest. These are interspersed with many good illustrations of uniforms, etc., giving to the reader a very good idea of the nurse's life and duties. It is a neat, attractive, and well-printed book, that cannot fail to be interesting and profitable to the lay reader and to the profession.

Diagnostik und Therapie der Darmkrankheiten. Von Dr. J. Boas. 1. Allgemeine Diagnostik und Therapie der Darmkrankheiten. Mit 22 Abbildungen. Leipzig: Verlag von G. Thieme. 1898.

Boas, whose work on diseases of the stomach is so well known to every practitioner, has just issued his book on diseases of the intestines. The present work is masterfully written and is of great help to every one who tries to steer clear of the entanglements which the intestinal tract presents. We quote a few sentences which show how very practical the present volume is. On page 147 Boas says: "If a patient with good teeth, living on a diet containing a moderate quantity of meat, constantly shows in his fæces coarse undigested particles of muscular fibres and at the same time an abundant amount of mucus, the diagnosis of catarrh of the small intestine is almost certain." . . . "The theory of indigestible and easily digestible substances grows more and more uncertain; each patient has brought with him into the world his individual digestibility." . . . "The usefulness of opium in inflammatory processes of the intestines is best shown in appendicitis. The stage in which the process exists is of the greatest importance. The administration of an opiate in appendicitis is indicated only in the stage of excitation, in which fever, pains, metorism form the principal symptoms and the general condition is satisfactory. If after a repeated dose of an opiate (as, for instance, tr. opii, twenty drops every three hours) the above symptoms disappear, the opiate has done its duty. Though its further application is not harmful, it is by no means necessary. If the excitation stage has disappeared for the last three or four days, the opiate should not be used any further. Its administration may evoke a paresis of the intestine which can be overcome only with great difficulty." The present work forms a most valuable addition to the literature of gastro-enterology, and will be read and studied with great benefit by the medical profession at large.

Die Störungen des Kreislaufs und ihre Behandlung mit Bädern und Gymnastik (Nauheimer Methode). Von Dr. S. Ch. Gräupner, Arzt in Bad-Nauheim. Berlin: Verlag von S. Karger. 1898.

The much-discussed Nauheim treatment of cardiac diseases is given full expression in this work of one hundred and fifty pages. Before discussing the treatment by means of exercise and hydrotherapy, the author deals with the innervation of the heart, the normal and hypertrophic cardiac muscle, and the consequences of valvular and myocardial lesions. The various methods of exercise and bath treatment are set forth with scientific exactness, and the indications for each case are clearly defined.

Transactions of the Ohio State Medical Society, 1897. Edited by R. Harvey Reed, M.D., Columbus, Ohio. Norwalk, Ohio: The Laning Printing Company.

This book contains many able and interesting articles, together with their discussion by various members of the society. It certainly shows great care and exactness in its compilation, and the editor has beyond a doubt succeeded in his object—namely, that of making this volume superior to any of its predecessors.

The American Academy of Railway Surgeons. Report of the Third Annual Meeting, held at Chicago, Ill., September 23, 24, and 25, 1896. Edited by R. Harvey Reed, M.D., Columbus, Ohio. Chicago: American Medical Association Press. 1897.

In this report, Dr. Reed has once more shown a thorough acquaintance with the workings of medical societies. In a report of this kind one would naturally expect to find much of a medico-legal interest and he does not have to look very far to find it, for the first articles deal directly with this subject. The book also contains much of a practical nature, particularly such topics as are not found in text-books. The discussions by the members are exceedingly interesting.

A Laboratory Text-Book of Pathology for the Use of Students and Practitioners of Medicine. By Horace J. Whitacre, B.S., M.D. Philadelphia: P. Blakiston, Son & Co. 1897.

While this compend of pathology will prove of service to the student during his laboratory hours or before an examination, it can hardly be considered a book of reference for the practitioner. The subjects are discussed very abruptly and superficially, although the arrangement of the subject matter is very commendable. The photo-micrographs are for the most part good, but those dealing with the blood in general and with malaria in particular would hardly convey a clear idea to one not already familiar with the conditions. In the discussion of renal diseases the author follows the classification of Delafield very closely, and hence presents the subject very clearly; in fact, throughout the entire work the teachings of Delafield are apparent.

An Index to the Transactions of the Clinical Society of London. Vols. I.–XXX. London: Longmans, Green & Co. 1898.

To those familiar with the transactions of this society, and for a ready reference to the authors and the discussion of their subjects, this index (covering a period of thirty years, from 1868–1897) is invaluable. The book is divided into two parts, the first giving an alphabetical arrangement of the authors' names and their articles, the second dealing with the subjects themselves. The work covers two hundred and six pages.

Sanitary Engineering. By William Paul Gerhard, C.E. New York: Published by the Author. 1898.

While in the strictest sense of the word, this little book of some one hundred and thirty pages is intended for the use of civil engineers, there is much in it which might prove of in-

terest and worth to the physician. The subject is discussed very concisely and the writing shows evidence of a thorough experience. The appendix on "the work of the sanitary engineer in time of epidemics, in time of war, and in sudden calamities in civic life" should prove of especial interest in these turbulent times.

A Clinical Text-Book of Surgical Diagnosis and Treatment for Practitioners and Students of Surgery and Medicine. By J. W. MacDonald, M.D., Graduate in Medicine of the University of Edinburgh, Licentiate of the Royal College of Surgeons, Edinburgh; Professor of the Practice of Surgery and of Clinical Surgery in Hamline University, Minneapolis, etc. With 328 Illustrations. Philadelphia: W. B. Saunders. 1898.

The author's aim has been to put into the student's and practitioner's hands "a single volume containing the most practical part of practical surgery." This he has in a measure accomplished. A good feature is the endeavor to lay down rules as to methods of examination in injuries. The belief is entertained, and probably with justice, that too much attention has been paid by writers and students to operation and too little to surgical diagnosis. The endeavor to supply a want in this direction is praiseworthy. There are three hundred and twenty-eight illustrations, but with the exception of a few *x*-ray pictures there are not many that can be praised; indeed, many appear crude, and it seems almost a shame to waste colored inks on such a plate as Fig. 131; Fig. 130, however, is decidedly instructive.

Illustrated Skin Diseases. An Atlas and Text-Book. By William S. Gottheil, M.D.

Parts XI., XII., and XIII., deal with the various atrophic changes of the integument and its appendages, and include scleroderma, albinismus, vitiligo, canities, and the important subject of alopecia in its different forms. A full description with formulæ is given for the harmless coloration of the hair, our only remedy for whiteness. The section on alopecia contains one colored and four plain illustrations, showing its commencement forms; its treatment is detailed at some length, more especially that method so successfully used by Lassar and bearing his name. Part XIII. ends with a brief outline of the cosmetics of the skin; a subject usually left in the hands of lay empirics, but concerning which the practitioner is not infrequently consulted. The hygiene of the healthy skin, the various kinds of soaps to be employed, and the cosmetic powders, lotions, and creams that can be recommended, are described. The part terminates with brief directions for the care of the hair, for the stimulation of its growth where deficient, and for its temporary removal by depilatories when that becomes necessary. The very complete index is an unusual feature, and will doubtless greatly enhance its value as a work of reference for the practitioner.

Aids to Aseptic Technique. By A. D. Whiting, M.D., Assistant Surgeon to the German Hospital. Philadelphia: J. B. Lippincott Company. 1898.

This little work of one hundred and fifty-seven pages gives an excellent insight into the proper manner of preparing surgical dressings and materials for operation. There are six chapters arranged for practical instruction and they are so written as to accomplish their purpose with the least loss of time.

Annuaire des Eaux Minérales. Paris: Maloine. 1898.

This is a convenient guide to the health resorts and mineral springs of France, which has now reached its fortieth year of usefulness.

A Text-Book on Surgery, General, Operative, and Mechanical. By John A. Wyeth, M.D., Professor of Surgery, New York Polyclinic, late Surgeon to Mount Sinai Hospital, Consulting Surgeon to St. Elizabeth Hospital, etc. Third Edition, Revised and Enlarged. New York: D. Appleton and Company. 1898.

This work has already proven its popularity, and the present issue shows considerable improvement over that of 1886. The advances in surgical pathology and in operative technique have received due consideration, and much care has evidently been bestowed upon the revision to bring it up to the critical requirements of the day. Students and those in the actual work of surgical practice will find the work a trustworthy guide.

Introduction to Chemical Methods of Clinical Diagnosis. By Dr. H. Tappeiner, Professor of Pharmacology and Principal of the Pharmacological Institute of the University of Munich. Translated from the Sixth German Edition, with an Appendix on Microbiological Methods of Diagnosis, by Edmond J. McWeeney, M.A., M.D., L.R.C.P.I.: Professor of Pathology and Bacteriology, C. U. Medical School; Pathologist to the Mater Misericordiæ Hospital, Dublin; Examiner, Royal University of Ireland. New York: Longmans, Green, & Co. 1898.

Dr. McWeeney was well inspired when he made up his mind to translate this most practical little guide to the modern chemical methods of diagnosis, and he rendered still greater service to the busy physician in giving him in the appendix such an excellent description of the microbiological procedures which are now so necessary in many cases in order to arrive at a correct diagnosis. He says that he has striven to compress a large amount of practical information in small compass, and we can but congratulate him upon his successful accomplishment of so difficult a task. "Infinite riches in little room" might well have been chosen as the motto of this welcome little work.

Premature Burial: Fact or Fiction? By David Walsh, M.D. Ed., Physician to the Western Skin Hospital, London; Hon. Sec., London Roentgen Society. New York: William Wood and Company. 1898.

The subject of premature burial has attracted some public and professional attention of late through the sensational presentation of more or less incredible tales of persons who had been buried alive and had recovered consciousness either just in the nick of time or too late. Dr. Walsh has taken up some of the least silly of these narratives and has shown how little credence they are worthy of, for scarcely one is based on evidence that would stand the first breath of scientific criticism. The subject is hardly worth discussing at all, yet so many persons have been made unhappy by this foolish agitation that it is well to have the rational side presented in a rational manner by a rational man. We would advise any one who is distressed lest he or some one dear to him meet such a dreadful fate to get Dr. Walsh's book and set his mind at rest by a careful perusal of it.

Sir James Young Simpson and Chloroform, 1811–1870. By H. Laing Gordon. New York: Longmans, Green & Co. 1897.

This is another of the "Masters of Medicine" so attractively put forth by the New York publishers. A delicately tinted frontispiece portrays the pleasant features of the subject of the sketch of two hundred and twenty-two pages, exclusive of appendix and index. The work and struggles of so interesting a character, and one who has done so much for humanity, cannot be anything but interesting, and the author has done extremely well in bringing out the features which make them doubly so. The binding is handsome and the presswork attractive.

The Elements of Clinical Diagnosis. By Prof. Dr. G. Klemperer. With 61 Illustrations. Authorized Translation by Nathan A. Brill, M.D., and Samuel M. Brickner, M.D. New York: The Macmillan Company. 1898.

This little book, which contains the rules governing the clinical diagnosis of medical cases, has had seven editions in as many years in Germany. The present work is a translation of the last edition and will undoubtedly be very useful to the American students and practitioners. With regard to the Roentgen rays in medical diagnosis we quote the following:

"The lungs are visible as filling the thoracic cavity as a weak shadow, and their size can thus be easily judged. The diagnosis of emphysema can thus be made without further difficulty. Pleuritic effusions, adhesions, and large infiltrations are readily recognized by the deeper shadows they produce. It is not yet certain if small infiltrations, whose presence we have as yet no objective methods of demonstrating, can be made recognizable by means of the skiagraph. Tumors of the lungs or of the pleuræ can be diagnosticated

with certainty much earlier than previously. This is beyond doubt an important step in the progress of diagnosis.

"The observations so far upon the abdominal organs have not been very satisfactory. Large tumors have been easily seen, but an early diagnosis of them has not yet been accomplished. It is frequently impossible to differentiate the outlines of various organs. The œsophagus and stomach can be more readily distinguished by the preliminary passing of a stomach tube surrounded by a spiral of metal or filled with small shot. Even this measure has not furthered diagnosis."

Cataphoresis, or Electric Medicamental Diffusion as Applied in Medicine, Surgery, and Dentistry. By William James Morton, M.D. New York: American Technical Book Company. 1898.

The present book contains invaluable information, not alone in regard to the mere practice of the art of electric diffusion, but also as to the fundamental principles which govern this art. There is a great interest at present centred in the application of the principle of cataphoresis to dental practice, but according to Morton it takes no special prescience to foresee a time, and that not far distant, when this interest will spread into medicine and surgery, particularly as to its relations to the production of an effective local anæsthesia in minor surgical operations.

The author has succeeded in giving in a clear style all the known literature, including his own extensive work, upon electric medicamental diffusion. The perforated electrodes devised by the author make possible an extension of electric cocaine anæsthesia into surgery hitherto impossible.

We quote the following from the chapter on antisepsis or sterilization of the teeth:

"There is, in addition to all this, the possibility of carrying medicaments into the peridental membrane for the treatment of acute infectious inflammatory conditions of that tissue. It seems to me that in the application of the cataphoric principle there is the promise of not only painless dentistry, but of absolute thoroughness in the therapeutic treatment of pulpless teeth and the many disorders to which they are liable. We may then accept it as a fact, and one of prime and novel importance, that electricity by reason of its property of cataphoric action is a sterilizer of the tooth and of its surrounding tissue, and that in the case of a tooth thus sterilized alveolar abcess is not likely to occur."

William Harvey. By D'Arcy Power, F.S.A., F.R.C.S. Eng. Vol. II. of "Masters of Medicine." Pp. 263. Edited by the late Ernest Hart, D.C.L. London: T. Fisher Unwin. 1897.

This handsomely bound volume is intended quite as much for the layman as for members of the profession to which this great worker and discoverer belonged. The manner in which he became interested in the blood's circulation, and the circumstances which led up to his refutation of the erroneous views concerning it which had prevailed up to his time, will always be numbered among the interesting things in the history of medical progress. The original works of Harvey have been freely used by the author, and forcible quotations are introduced here and there to give the reader an insight into the scientist's true nature and methods of work and reasoning. The peculiar charm of his life, filled as it was with eccentricity of action making the term "original" apply almost as much in its French as in its English sense, is forcibly brought out in the author's happiest style.

Die Zuckerkrankheit und ihre Behandlung. Von Prof. Dr. Carl von Noorden. Zweite vermehrte und umgearbeitete Auflage. Berlin: Verlag von August Hirschwald. 1898.

Those familiar with the writings of Dr. von Noorden will hail with delight the second enlarged edition of his book on diabetes. To say that he presents the subject in an interesting, systematic, and novel manner, leaving no phase of the disease untouched, would be expressing it mildly. The work covers two hundred and fifty pages, and is divided into seven chapters. Beginning with a definition and history of the disease, the author devotes two chapters to the physiology of digestion and the theories of diabetes mellitus. These are discussed so clearly as to be easy of comprehension, and one enters upon the following chapters with the full conviction that each succeeding one will prove more interesting and instructive. The third chapter treats of the etiology, presenting the influence of country, race, age, and sex, heredity, contagion, psychical conditions, other diseases, and occupation upon the production of the disease. The fourth division contains a discussion of the most prominent symptom of the disease, namely, glycosuria. The various degrees of this symptom, that is, the mild, medium, and severe forms, are entered into and the methods of determining which one we have at hand are set forth with clearness and precision. This chapter also contains the remaining characteristics of diabetic urine, as well as enters into the chemistry of the other secretions, blood, gastric and intestinal juices, saliva, spermatozoa, etc. The next chapter treats of the complications. Here, every organ that was, is, or perhaps ever will be affected during the course of this disease receives attention. There is no specialist in medicine who will not find something of interest in this chapter. By this time one's interest has been thoroughly aroused; and, the two closing chapters on the general clinical picture, with its course and prognosis, and the treatment of the disease, form a fitting climax to this most interesting work. The chapter on treatment covers one hundred pages and leaves no room for questioning, so thoroughly is it discussed. Toward the end four excellent diet tables of the various food stuffs for the different conditions are given. The author has certainly mastered the subject, and his acquaintance with the literature is by no means a small one, as can easily be seen from the very numerous references at the end of the work. This book of Dr. von Noorden forms so valuable a contribution to the literature of the subject that it is to be hoped, in the near future, an Anglicized version will appear for the benefit of those not familiar with the German language.

Ueber den therapeutischen Wert des Alkohols bei acuten Krankheiten. Eine kritische Studie. Von Dr. B. Kantorowicz, Hanover. Berlin: Verlag von Oscar Coblentz. 1898.

In this brochure of thirty-seven pages the author discusses his subject in an argumentative and interesting manner. The article abounds in reference to works on the subject and the conclusions are clearly drawn. Altogether it forms agreeable reading-matter.

The Aphasias and their Medico-Legal Relations. By F. W. Langdon, M.D. Cincinnati.

This little book of forty pages is the embodiment of a paper read before the Ohio State Medical Society. So far as we can determine from reading the booklet the title is a misnomer, as the medico-legal relationships of aphasia are not considered except in two short paragraphs on page 31. The remainder of the text devoted to this part of the subject is made up of quotations, mainly from Bateman, who, it may be contended without fear of contradiction, had a very insignificant conception of the meaning which attaches to aphasia to-day. It cannot be said that the status of aphasia and its medico-legal relationships is particularly advanced by Dr. Langdon's brochure, although the article is a very readable one.

Brief Essays on Orthopædic Surgery. By Newton M. Shaffer, M.D., Surgeon-in-Chief to the New York Orthopædic Dispensary and Hospital; Clinical Professor of Orthopædic Surgery, University of New York (Medical Department); Consulting Orthopædic Surgeon to St. Luke's and the Presbyterian Hospitals, New York; Consulting Surgeon, New York Infirmary for Women and Children. New York: D. Appleton and Company. 1898.

In this collection of essays the author contends for the recognition of orthopædic surgery as a mechanical art, in opposition to those of his colleagues who would extend it to cover all methods of treatment of deformities whether by operation, by exercises, or by the application of mechanical apparatus. While we cannot agree with the author in this strict limitation of orthopædics, we are nevertheless forced to admit that the case is well argued from the viewpoint of the mechanician, who, if he would be nothing else, should drop the honorable title of surgeon.

The Care and Feeding of Children. By L. Emmett Holt, M.D. Second Edition. New York: D. Appleton & Co.

This little book is arranged like a catechism. It is intended to convey to the beginner the rudiments of feeding and nursing of a baby; it is well adapted for this purpose.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GENERAL COUNCIL SESSION—A DENTAL MEMBER—THE PRESIDENT AND MR. HORSLEY—PROPOSED INQUIRY INTO THE LEGAL BUSINESS REFUSED—CLINICAL SOCIETY—CASES OF INTUSSUSCEPTION—OPERATION OR INJECTION—PERFORATION OF VERMIFORM APPENDIX DURING TYPHOID.

London, May 27, 1898.

The General Medical Council met on Tuesday. It seems a pity the business could not have been done at the late special session and so reduced the enormous cost of the meetings. Mr. C. S. Tomes, F.R.S., F.R.C.S., L.D.S., took his seat as the new crown member. The appointment of this distinguished man gives great satisfaction to the dentists.

I hoped that the new president would omit the useless opening address, but he followed the old precedent and told the council things they all knew from the newspapers and medical journals. It must be tedious to listen to a *réchauffé* of subjects which have been threshed out in the press, and the time and money of the council are too precious to waste in this way. On the present occasion there was one bit of spice in the address. The president was of course expected to give some explanation of the course he had taken in interrupting Mr. Horsley's investigations into the archives of the council, which he had carried on from November last up to April. I have previously informed you that the president then directed the registrar to supply no further documents to Mr. Horsley without the authority of the council or the executive committee. In his address Sir W. Turner sheltered himself behind the opinion of the standing counsel, which he had taken on the question as to whom the documents belonged to. No authority but his own seems to have been obtained for taking counsel's opinion on a matter which common sense and the usage of most bodies should have sufficed to settle. The president pointed out that the present meeting would afford an early opportunity to Mr. Horsley to apply for permission, but he does not seem to have perceived that it would have also been time enough for him to submit his own view to the same meeting, if he was so fully convinced that a member of the council should be denied the opportunity of studying its history. Since Mr. Horsley protested against the assumption of the new president, I have talked with both London and provincial men of note, and they all regard the president's action as unwise and unconstitutional. Some looked forward to the address with keen interest, as likely to produce some explanation, and all were astonished that Sir William, with his experience and sound sense, should so hastily have committed himself to a policy of obstruction directed against the most active and most eminent direct representative of the profession.

Mr. Horsley raised the question on the first day, and showed that the opinion given by Mr. Muir Mackenzie was totally at variance with that of Mr. Farrer given in 1882. He said he would like to see the case submitted—so much depending on that in all legal opinions. This was produced, and Mr. Horsley at once said it was not parallel with his position.

Then the obstructives came out in full force. The old fogies were shocked that the president's action should be called in question by the junior member, and proceeded to testify their sympathy with and support of the president. Then a red herring was drawn across the scent—it was altogether too dreadful for Mr. Horsley to have communicated the facts to the medical press, and it was pretended that doing so was a personal attack. Even Dr. Glover, who is a direct representative, urged that there was no "obligation to publish the charge against the president" before the present meeting. He should have seen there was no obligation on the president to interrupt Mr. Horsley's work until the same time. To talk of a simple statement of facts as a "charge against the president" or a "personal attack" upon him, is not calculated to blind the profession to the fact that their energetic champion has been deliberately obstructed in very useful work on their behalf.

Mr. Horsley subsequently moved for a committee to inquire into the legal business of the council and its cost. Then the obstructives again gave tongue. Another red herring was brought out. It was pretended that the motion was a vote of censure on the legal advisers. Mr. Horsley retorted that when he wished to censure he would do it in plain English. His innocent motion was no such censure.

There was much talk as to whether Mr. Horsley should be a member of such a committee, but the *vis inertiæ* was not to be overcome, and the lawyers were held up as infallible and almost as terrible fetishes as the president himself.

Some voices gave support to Mr. Horsley. On this point Dr. Glover and Mr. Brown, his co-direct representatives, supported him, but the council refused inquiry by eighteen to nine. In this no one outside is likely to approve the decision.

The subject of abdominal surgery was again prominent at the last meeting of the Clinical Society, intussusception furnishing several cases. Dr. David Lees and Mr. Quarry Silcock related the case of a boy, aged four and one-half, treated by rectal injection and discharged from the hospital apparently cured, who had to be readmitted two days later for the same symptoms. These were relieved by injection and subsided, but recurrence took place several times. Eventually operation was performed and intussusception found at the lower end of the ileum and the cæcum. It was irreducible and excision was done. The ileum was divided two or three inches above the ileo-cæcal valve, the colon some inches below the cæcum. The cut ends were then united by Lembert and quill sutures, and the lad made an uninterrupted recovery. The specimen showed that the posterior wall of the cæcum, carrying with it the appendix, had been invaginated into the ascending colon, and the ileo-cæcal valve, being dragged upon, had carried with it about an inch of the ileum. Clearly complete reduction by injecting air or water was impossible.

Dr. W. S. Colman and Mr. T. H. Kellock then related a case of chronic intussusception of the cæcum in a boy of eight, the symptoms being extremely misleading; the authors called them latent. Severe attacks of pain and vomiting, returning almost daily, with no change in the motions and nothing to be felt in the rectum, and at length a definite sausage-shaped tumor, one end of which was very hard, led to operation. A large intussusception was found in the transverse colon and splenic flexure. It was reduced with some difficulty. There was a perforating ulcer close to the root of the appendix. The ulcer was excised, and the edges were united by Lembert's sutures. Two days later the wound had to be reopened for pyrexia and pain over the cæcum, when some pus was evacuated, but the child died and a post-mortem was refused.

Dr. Lees then described a case of six weeks' duration which he had successfully treated by irrigation and ice bags locally, the child's feet and legs being at the same time kept warm with hot-water bottles, and fomentations being sometimes employed over the bladder to aid micturition. The ice was continued for eight days, and after another enema the lump had quite

disappeared. Evidently there had been no adhesions to prevent reduction, although the symptoms had lasted six weeks before treatment. Large enemata reduced the size of the lump, but Dr. Lees thought that the cold applications reduced the congestion of the intestine and allowed the last enema to complete reduction. He thought in similar subacute cases the treatment deserved a trial, but in acute cases he would not recommend it, on account of the tendency to collapse.

Mr. Barker remarked that the most important question suggested by this interesting series of cases was whether to resort to injections or to operate at once. That some patients recovered under the use of injections he admitted, but there were others in whom they could not succeed. Of the fifteen cases he brought before the society this session, three were ileo-colic and could not have been reduced by injections. Five of his patients died, three being gangrenous when operated on. His results encouraged him to earlier operations, as injections involved delay and were not without risk.

The president (Mr. Langton) was also in favor of operation, which he thought less dangerous than delay.

Dr. Guthrie said that diagnosis was the chief thing, and he held that injections were dangerous in acute cases, for the actual condition of the intestine could not be known nor could we be sure that irrigation had completely reduced the invagination.

Dr. Poynter insisted on the necessity of careful and frequent examinations to fix the diagnosis.

Mr. Kellock said the experience of the Children's Hospital showed that laparotomy is extremely dangerous in them, whatever the cause for undertaking it, and he could not admit that the risk is so slight as is often represented.

Dr. Lees concurred in the view that the operation is a very serious one. He had known a number of recoveries from irrigation, and when that failed surgery also sometimes failed. He mentioned that three cases at the same hospital received in one day were handed over to the same surgeon, and all three were fatal.

A case of perforation of the vermiform appendix in the course of ambulatory typhoid was related by Dr. Rolleston. On laparotomy fibrinous peritonitis was found, due to perforation of the appendix close to the cæcum. The appendix was removed, the peritoneum washed out, and a drainage tube left. The case proved fatal and at the post-mortem typhoid ulceration was found. Attention was directed to the frequency of lesions of the appendix in typhoid, and statistics on the subject were cited.

Dr. Goodall was surprised at the frequency of the complication, as he had not met with it at the fever hospitals.

Mr. Barker remarked that without operation the cases were uniformly fatal, but after operation twenty-three per cent. went on to recovery.

OUR PARIS LETTER.

(From our Special Correspondent.)

TUBERCULOSIS—NOT INCURABLE AND HEREDITY ALONE NOT SUFFICIENT TO CAUSE IT—ZONA AND FACIAL NEURALGIA CAUSED BY IODIDE OF POTASSIUM—PROFESSOR DIEULAFOY'S NEW WORK.

PARIS, May 28, 1898.

WHEN we think that every year in France 150,000 people die of tuberculosis, it is not surprising that its prevention and cure are subjects of constant, burning interest. In Paris, with a weekly mean mortality of eight hundred to one thousand, tuberculosis claims alone from two hundred to two hundred and fifty. Professor Grancher, in his interesting and valuable report, read recently before the Academy of Medicine, deals with the subject of family tuberculosis, attributing the heavy mortality rate largely to the fact that the disease is not taken in time. Tuberculosis is not considered as an incurable disease. It becomes so because it is left to itself—because at the beginning, when it might be cured, the doctor and the family think only of deceiving the patient, if not themselves, forgetting that by that very act they interdict to the patient the treatment most indicated and really the only means of saving him or her. Having disposed of this fallacious doctrine of silence and deception, Professor Grancher touches briefly and pointedly on heredity. It is contagion and not heredity that is most at fault in the propagation and spread of tuberculosis. What family, either in the direct or collateral line, is not tuberculous? If, he adds, heredity is sufficient to create the disease, everybody in Paris would be tuberculous. Heredity may prepare the ground, but it is contagion that spreads the disease. The bacilliferous sputa are the direct means. These two great points—that tuberculosis is not incurable and that heredity is not sufficient to create the disease—are the most potent arguments against that silence and deception regarding the diagnoses that have sent so many tens of thousands to the grave. And how are we to impose upon our patients the long and severe treatment that their cases demand, if we do not open their eyes to the true nature of their malady? If a tuberculous patient is to get well, such a one must will to get well; and, being apprised that tuberculosis is not incurable, the will will be forthcoming and the requisite treatment can be inaugurated and carried out. As for the rest, do we not find after post-mortem the remains of old tuberculous deposits in the lungs healed long since, the lungs remaining otherwise perfectly healthy, the patients having died of a disease in which the lungs were not in any way involved? And if tuberculosis can and does heal of itself, how much more readily ought it to heal under proper treatment and hygienic surroundings? With reference to the latter, he is inclined to consider them the more important of the two. It is, as already noted, the sputa that are the real means of spreading the disease. First of all, the declaration of the disease ought to be made by the doctor with authorization of the family. The disinfection of the apartment should be done every now and then, and always after a death from tuberculosis. But it is against spitting that our chief effort must be directed. A pocket spittoon should be provided for each and every patient, especially in hospital practice; spitting on the floor prohibited; and every room occupied by a tuberculous patient disinfected as soon as left. Above all, no sweeping should ever be allowed, but the broom should be replaced by cleansing with a wet sponge or mop.

At a recent meeting of the Société Médicale des Hôpitaux, Dr. Jacquet presented an interesting case of ophthalmic zona and facial neuralgia caused by iodide of potassium. The patient had received daily two grams, or about thirty-five grains, of iodide of potassium for four days, at the end of which time a slight ophthalmic zona on the right side with a neuralgia of the right facial nerve appeared, the neuralgia extending to all the branches of the right facial nerve. There was no paralysis of that nerve nor of the trigeminus. Four years before, the same dose of iodide of potassium had caused in the same patient a paralysis of the left facial nerve.

Professor Dieulafoy has just issued a very attractive and valuable volume entitled "Clinique Médicale de l'Hôtel Dieu de Paris, 1896-97." This is a compilation of the first eighteen lessons delivered by himself at the Hôtel Dieu in the chair of clinical medi-

cine, occupied by the late Prof. Germain Sée. The volume begins with Professor Dieulafoy's inaugural address and ends with a chapter on peritonitis by pneumococci. A considerable portion of the work is devoted to appendicitis. Brightic œdema of the lung, syphilitic lesions of the aorta, tabetic angina pectoris, and a case of mortal chorea occupy the first eight lessons. Then follows a chapter on Jacksonian epilepsy, followed in turn by two chapters on Basedow's disease. The twelfth, thirteenth, and fourteenth chapters deal respectively with perforation of simple ulcer of the duodenum, transformation of stomachal ulcer into cancer, intestinal lithiasis, and sandy entero-colitis.

The work is profusely illustrated and contains a sepia plate of Professor Trousseau on his deathbed, and on the title page is an engraving of the Hôtel Dieu and the cathedral of Notre Dame.

It is written in Professor Dieulafoy's clear, lucid, and limpid style, and is the first of a series that will be one of the most important and elaborate of our day and generation. It is published by Masson et Cie., "libraires de l'Académie de Médecine."

Professor Raymond is just issuing his third volume of "Clinique des Maladies du Système Nerveux." This is also a compilation of lessons—those given by Professor Raymond at the famous "Salpêtrière" in Charcot's clinic.

A SUIT FOR MALPRACTICE.

To the Editor of the Medical Record.

Sir: Under any circumstances a suit for malpractice excites widespread interest among medical men. But a case came to trial recently in Part VII. of the supreme court of this city, before Justice McAdam, of much more than ordinary importance to the profession. This trial had features which should make it celebrated in medical jurisprudence, not alone on account of the purely technical aspects of the case, but also because of the relation of medical men to it and its well-nigh sensational culmination in favor of the defendant. The facts in this case are so instructive and valuable to medical men, in whatever line of practice, and touch their highest interests so vitally and palpably, that to allow the lessons which they teach to go by unnoticed, would be an irreparable loss to the profession.

On the morning of February 26, 1896, a woman in middle life slipped and fell on the ice, severely injuring her left wrist. Her family physician, a man of high standing as a surgeon, was called and responded immediately. That the joint had been severely injured was apparent, but after very careful examination, with a view of ascertaining the possible existence of Colles' fracture, the conclusion was reached that there had been a severe sprain but no fracture.

Treatment consisted in the application of soothing lotions, with an injunction of absolute rest for the joint. After the acute symptoms had subsided sufficiently, a felt splint was applied. The surgeon continued his visits daily for a month, making frequent examinations of the joint and beginning passive motion as soon as the painful character of the injury permitted. For some time longer the case was under frequent observation, and the surgeon was able to confirm his diagnosis to his entire satisfaction. About the middle of April the woman removed to New York and placed herself under the care of a physician there, who promptly decided that the case was one of Colles' fracture, whereupon the husband wrote to the surgeon who had treated his wife, acquainting him with the discovery, and stating that his treatment had been wrong, that his position was a grave one, and asking what he proposed to do about it. The surgeon's reply was prompt and decisive, "Nothing." In due time a suit for $25,000 damages was entered. To a suggestion of compromise the defendant refused to listen, declaring that, while he might have made a mistake, this was a fatality which attends the work of every surgeon, however skilled or eminent; that the charge of neglect could not justly be brought against him; that he had exercised the best skill and judgment of which he was capable in the care of the case, had been assiduous and painstaking in its treatment, had indeed neglected nothing within his power to do to forward a good result. Further, that if he were to compromise, its influence would be to encourage such suits, and he owed it to the profession to fight the battle to a finish. It might serve to encourage and save some other unfortunate in a similar crisis of dire extremity.

Such was the issue which came to trial in the supreme court on April 13, 1898. The attitude of the court was that of impartial justice. The jury was all that could be desired in general intelligence and interest in the proceedings. The theory of the plaintiff was that a Colles' fracture had been treated as a sprain. Upon this hypothesis—and this alone—was suit brought for $25,000 damages. The medical testimony is all that need concern us for the purposes of this statement. It was plain at the outset that the physician who made the discovery of a Colles' fracture was not to be the chief dependence of the plaintiff. His statements were oracular, too oracular indeed to weigh heavily in the minds of the jury, and the cross-examination placed the plaintiff's case in serious jeopardy. It is no disparagement of this witness to say that the inspiration which animated and encouraged the prosecution did not have its source in him. The secret was out in the next move, when the plaintiff's attorney unconcernedly offered a letter in evidence. The writer is a surgeon of this city, who enjoys the distinction of being a professor in surgery in an advanced medical college, visiting surgeon to its hospital, and has recently been appointed to assist the executive surgeon at one of the large hospitals up town. This letter plainly was the corner stone of the prosecution's case. On it they built their plans, and in it centred their hope of securing from the defendant the trifle of $25,000, besides inflicting upon him the impairment of prestige and the mental agony which a suit for malpractice involves. The writer had given the weight of his name and influence to cast a brother practitioner into the slum pit of a malpractice suit in heavy damages, qut was not present in person to face the ordeal of cross-examination. All this, not because of any want of assiduity or painstaking interest in the case on the part of the defendant, but wholly on the theory that he had mistaken a Colles' fracture for a sprain.

The next medical witness was also from the Harlem district. He had been employed on the case only the day before the trial. Why the prosecution had delayed to secure the aid of this witness till this late day, and what means were employed, must be largely a matter of conjecture. Did their professor leave them in the lurch at the last minute and finally write a letter as a salve to allay their irritation at his non-fulfilment of contract? Did he name the person to whom the letter was to be shown? This letter, which bore the name of a professor of surgery with many appointments and associations, would be potent to influence a credulous man, ambitious of preferment and fame, in the belief that the office he was asked to perform was quite within the domain of ethical propriety.

It is certainly of interest to note that the author of the letter which was offered as evidence by the prosecuting attorney and the medical witness last referred to are members of the New York Academy of Medicine and of the Medical Society of the County of New York.

The defendant, himself an accomplished surgeon, was supported by four other surgeons, one of them surgeon-in-chief to a large up-town hospital, by whom some of the most brilliant work in American surgery has been done, and whose name would easily occur to any one who should attempt a list of the few great surgeons of the world. The others were all surgeons of wide experience in both hospital and private practice, who have achieved large success in their work, and whose opinion would carry weight in any company of medical men.

After careful examination of the plaintiff's wrist and close comparison of it with the other, these men all declared that there was no Colles' fracture and never had been. While the joint was somewhat thickened, it showed none of the characteristic deformities of a Colles' fracture. The styloid processes sustained precisely the same relation to each other in both wrists. The thickening was entirely consistent with a severe sprain, and this they believed the injury to have been.

The jury had ample opportunity to observe the injured joint and compare it with the other, and they were intelligent enough fully to comprehend the explanations made of the characteristic deformities of a Colles' fracture by the medical witnesses. They promptly rendered a verdict for the defendant. Indeed, the intrinsic merits of the case were too striking and obvious to admit of a different result.

Such in brief is the history of the case. Inquiry is stimulated as to the genesis of such suits. Doubtless occasionally they are undertaken from ingenuous motives and sense of great injury, but even then under the most obvious misconception of the physician's benevolent attitude toward human ills. The great majority, however, spring from purpose of blackmail, pure and simple, in which division of spoils is the incentive to financial and legal backing. They must also have medical support, and, humiliating as is the fact in the face of our oft-vaunted nobility and benevolence of purpose, they get it. What is the motive? Why should a physician lend his name and influence to such ignoble ends? Doubtless, the reasons are various. In one instance it may be jealousy or revenge—a desire to humiliate a hated rival. In another, cupidity—a longing to share in spoils, or to earn a generous fee. In still another, vanity—a distorted notion of personal importance or ambition to bask for a brief hour in the light that beats on the eminence of public notice. Did either or all the medical witnesses for the plaintiff in this case yield their aid for such base reasons to rob a brother practitioner of his hard-earned savings and well-merited reputation? May the fates grant not. But what was the motive? Who knows? Only one other is possible, viz., that they had reluctantly, from a conscientious sense of duty, thrown themselves in the breach to right a grievous wrong. Let us consider this incentive from their viewpoint. No claim was made of negligence or malicious intent, only that a mistake had been made in treating as a sprain what was really a Colles' fracture. In order to habilitate and justify this reason, we must assume that no surgeon of experience and reputation can make a mistake without liability of pursuit as a criminal by accusing justice.

Now let us ask these men a few questions and let the medical profession of the world be their jury. They could ask none higher or better. Did you ever make a mistake? Has your judgment in every instance been infallible? Has your skill never been at fault? Have the revelations of a post-mortem never surprised you? Have you never been pained with the thought that if you had pursued a different course some cherished one might still live to comfort those who loved him? If not, then truly, as was said of Hamilton, "you stand on an eminence and glory covers you." A countless multitude of common practitioners will hasten to lay the oblation of reverent, devout worship at your feet.

Brief comment may be pertinent and possibly helpful in fixing the lesson which this case inculcates. Of all the learned professions ours is the only one whose members are exposed to the humiliation and loss of malpractice proceedings, albeit in none other probably are sympathy and benevolence so frequently the only incentive to heroic, unrequited personal sacrifice to minimize the measure of human suffering. In none other is the lofty ideal of disinterested charity toward human ill more conspicuously held forth, and it is a curious commentary on these reflections that the only standing which such proceedings have or can have in a court of justice is derived wholly from the aid and support which medical men for one consideration or another, in violation of a solemn oath registered at their graduation, in violation of every moral consideration, are willing to extend. More curious still, when moral considerations fail to restrain, that self-interest does not deter, for no physician in active practice is beyond the menace of this danger, always constant, always imminent. Alas, it is doubtless too true, notwithstanding all our vaunting, that men in our ranks, as in all other fields of human activity, are ready to venture to the very verge of the precipice, trusting their agility or the complacence of moral mentors to save them from the gulf in the enjoyment of ill-gotten advantage, financial or other.

To sum up in a word, the medical witnesses for the plaintiff in this case, one of them acting as monitor for the prosecution attorney during the trial, had lent themselves in a supreme effort, for some unassigned reason, to the spoliation of a brother practitioner in the sum of $25,000, his good name, and bodily freedom; for, not being able to pay judgment in an adverse verdict, he must go to prison, and all on a hypothesis that was clearly proven to have no foundation in fact. Truly the medical profession has not yet emerged into the glories of the millennium. When our mental and moral consciousness grasps firmly the fact that the medical profession is not a money-making institution in the usually accepted sense of this term; that while it gives competency to many it brings wealth to none; that the great majority of its members are poor; that the highest and noblest attribute of our professional labor is its philanthropic purpose and aim; and that its highest emoluments are to be found in the pleasures which flow from a consciousness of deeds well done for humanity's sake; when these considerations have permeated all the strata of medical life to the very bottom, we shall hear less of malpractice suits, except as they are invoked to bring the criminal to justice.

HIPPOCRATES.

THE TUBERCULIN TEST.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. H. P. Loomis, in an article in your issue of May 21, 1898, describes the method of applying the tuberculin test in man and advocates its usefulness as a criterion of cure for patients who have apparently recovered under the usual climatic and open-air treatment. His reference to myself as making use of "practically the same method" may give the impression that I use the test as a criterion of cure and consider it reliable for this purpose, and it is in order to correct this impression that I ask for a few lines of your space.

I have had recourse to the tuberculin test as a means of diagnosis on rare occasions only, in cases of suspected pulmonary tuberculosis, when a careful study of the rational and physical signs failed to enable a

positive conclusion to be reached. Satisfactory as the test has proved in my hands in throwing light on these obscure cases, I have not made use of it as a criterion of cure nor do I believe its application for this purpose can prove reliable, as it is well known that patients in whom arrested lesions are present, even though they have remained quiescent for a long time, perhaps years, may nevertheless give a reaction when injected with tuberculin. E. L. TRUDEAU, M.D.

SARANAC LAKE, May 25, 1898.

ELECTROLYSIS IN DERMATOLOGY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reading Dr. Jackson's very interesting article on electrolysis in the MEDICAL RECORD of two weeks ago, I was pleased to see that he advocated the removal of certain tumors, xanthoma, etc., by means of a knife-like instrument. Having employed this method for a number of years, I can state that it is much superior to the older way of using a round needle and leaving the withered excrescence to fall off in the course of time.

In an article entitled "Some of the Uses of Electrolysis in Dermatology," which I published in the MEDICAL RECORD of January 25, 1896, I described a method of removing growths by the use of a flat-bladed, sharp-edged needle, or to all intents a small knife-shaped instrument. Up to this time the method had, so far as I am aware, not been suggested or put into practice. I demonstrated my instrument before the Lenox Society, and subsequently to the New York Dermatological Society, at whose meetings I have also mentioned the method on several occasions and shown patients operated upon. Dr. Jackson states that he has as yet had no opportunity to test his little knife in xanthoma. I may say that in a number of these cases I have succeeded at a single sitting in removing quite large xanthoma growths, to the great satisfaction of the patients.

At a meeting of the German Medical Society about a year ago, Dr. Klotz presented the method as one of value and stated that it had originated with me. I am glad others are also finding it as useful as I have.

CHARLES W. ALLEN, M.D.

A LIVER WITH SIXTEEN LOBES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reference to Dr. Smith's criticism of my article in your issue of May 7th, that the liver then demonstrated was syphilitic, is it possible, but the evidence is negative. Fissures and hence lobulations do occur in syphilis, but they are due to cicatricial bands—an interstitial hepatitis. The surface of the organ in specific hepatitis is not smooth, but rather granular, like the cirrhotic or "gin-drinker's liver." The fissures, to one who has seen specimens of both, are different. In one word, fibrous bands, the yellowish discoloration of the organ, sometimes seen in syphilis, gummata, and the granular condition of the syphilitic liver, were conspicuous by their absence. It is true the organ was smaller than normal, but this anomaly was not due to contraction as the result of syphilitic hepatitis. In accessory lobes fine intralobar adhesions or bands are seen, similar to those I have noted in anomalous lobulations of the spleen. Dr. Smith's theory of "atavism" is good.

WILLIAM MOSER, M.D.

BROOKLYN.

Splenectomy for hydatid cyst of the spleen (Hartmann). Contraindication is found in leucocythæmia (Jonnesco).

Medical Items.

The Evils of Overeating. — Large eaters are generally deficient in activity and endurance. I used to know one who tried hard to be a Christian, but failed because of too much dinner. That man was a curiosity. He worked in a small wood-turning shop and ate five times a day. When he consulted me about his "poor stomach," I told him flatly that he was a pig. He replied: "You are mistaken. I am faint half the time, and have to eat extra meals to keep up my strength." I went at him with fact and physiology. At length he was convinced and promised me that he would follow my prescription, which was this: Take but two meals a day. In fifteen days his faintness had disappeared and he rapidly recovered. To-day he is a healthy, active man and a warm advocate of two meals a day, and moderate ones. Temperate people with good digestion never feel their stomach- forget they have a stomach; while these big eaters are always hungry, faint, or bloated, troubled with eructations, acidity, diarrhœa, or some other unhappy condition of the digestive apparatus. Persons having a good stomach to begin with can by practice learn to digest an enormous quantity of food. If they give their whole force and vitality to this business of grinding grist, they can in even the course of a short life grind through immense quantities. But the wiser, the more human way, is to find just how much food is needed to run the machine, exactly what will keep the system at the best working-point, and never pass those bounds. —*Journal of Hygiene.*

War Loans.—We take pleasure in commending the following circular to the attention of such of our readers as desire to make a safe investment:

1898.
Department Circular No. 102.
Division of Loans and Currency.

TREASURY DEPARTMENT,
OFFICE OF THE SECRETARY,
WASHINGTON, D. C., June 13, 1898.

To the Press of the United States:

It is intended to give the bonds of the war loan authorized by the act to provide ways and means to meet war expenditures, the widest distribution possible, in order that all the people may have an opportunity for participating in the loan.

I have the honor, therefore, to ask the co-operation of the press in disseminating information which will give a better understanding of the nature, characteristics, and incidents of a government loan, and to that end I will thank you to lend your aid by publishing in your columns the statement inclosed, which is intended to give, in as brief a manner as possible, a description of the registered and coupon bonds of the United States, and how to subscribe for them.

Respectfully yours,
L. J. GAGE, *Secretary.*

UNITED STATES BONDS.—United States bonds are recognized as the most secure and stable form of obligation that investors can hold. They are attractive, not only because of the absolute security offered, but because there is at all times a public market for them on which holders can quickly sell; and they also offer the most desirable form of collateral if the holder wishes to secure a temporary loan. The fact that United States bonds are not subject to taxes of any character—federal, State, or municipal—is a valuable feature of that form of investment. United States bonds are issued in both coupon and registered form.

Coupon Bonds. A coupon bond is payable to the

bearer. It may be bought and sold without formality as freely as any kind of property and without indorsements of any kind. Owing to the freedom of transfer, coupon bonds are usually preferred by persons who expect to hold them but a short time. Their disadvantage for the person who wishes to make a permanent investment lies in the danger that they might be lost or stolen, in which case the loss to the owner would be as complete as would be the loss of a bank note. The coupon bonds take their name from the method by which interest is collected by the holder.

Printed on the same sheet with the bond is a series of coupons or small certificates of interest due, which are so designed that one is cut off at each interest period. Each coupon bears the number of the bond and shows the date of the coupon's maturity. The holder of a coupon bond, at each interest period, detaches the coupon due that day and collects it. The coupons are payable at any subtreasury, and may be collected through any bank, and will usually be accepted by any merchant having a bank account, with whom the holder of the bond has dealings. The holder of a coupon bond may at any time have it converted into a registered bond free of charge.

Registered Bonds.—A registered bond is payable to the order of the owner, and can be transferred only by being properly indorsed and assigned by the owner. Such assignment is made by the owner filling in the blank form on the back of the bond, and must be witnessed by some officer authorized by the regulations of the treasury department to witness assignments. The owner of the registered bond who wishes to part with it writes his name on the back of the bond in the presence of the officer; then the witnessing officer writes his name in its proper place and affixes an impression of his official seal.

The officers who are authorized to witness assignments are a United States judge, United States district attorney, clerk of a United States court, collector of customs, collector or assessor of internal revenue, United States treasurer or assistant treasurer, or the president or cashier of a national bank, or, if in a foreign country, a United States minister or consul. In cases where there is no officer within a reasonable distance, or when, through sickness or for some other good reason, the owner of registered bonds cannot go before one of these officers, the treasury department will designate some person near the owner to act as witness.

When the owner of a registered bond disposes of it and has properly assigned it, he delivers it to the new owner, who should at once forward it to the register of the treasury for transfer on the books of the department. The register cancels the bond so forwarded and issues a new bond in the name of the new owner, and sends it to him by registered mail. The department makes no charge for transferring bonds.

If the owner of a registered bond loses it, or if it is stolen from him, he should at once notify the secretary of the treasury. A stoppage will be entered against the bond, and, if it should be presented for transfer, the department will hold possession of the bond until the ownership is clearly established. If a lost or stolen bond is not recovered within six months, the department will issue a duplicate bond upon proof of loss and a bond of indemnity being furnished.

The interest on registered bonds is paid by the government by means of checks. In order that no mistake may be made in the payment of interest, the books of the department are "closed" for a period, varying according to the importance of the loan. The books of the four per cent. loan of 1907 are closed for the whole month preceding the payment of a quarter's interest. On other loans the books are closed for fifteen days preceding the interest payment. During this period no transfers are made, and the time is devoted to preparing "schedules" which contain the names of the owners, the amount of bonds each one holds, and the amount of interest due each one. When these schedules have been prepared and proved, they are sent to the treasurer of the United States, who immediately has checks and envelopes addressed, and in due time each check is mailed to the address of its owner. The checks for the more distant points are first mailed. Interest checks are obligations of the United States, and, of course, are good everywhere.

Coupon bonds are issued in denominations of $20, $100, $500, and $1,000. Registered bonds are issued in denominations of $20, $100, $500, $1,000, $5,000, $10,000.

How to Subscribe for the New Bonds.—The war loan which is now being offered will be sold to subscribers at par during the period of subscription, which ends July 14, 1898. The method of subscription has been made as simple as possible. Blank forms may be obtained at every money-order post office, and at most of the banks and express offices, and on these forms is clearly indicated all that it is necessary for the subscriber to fill out. The subscriber may himself mail to the treasury department at Washington the blank form filled out, together with his remittance covering the par value of the amount of bonds for which he wishes to subscribe. That remittance may be in whatever form best suits the subscriber's convenience—in currency, bank draft, check, post-office money order, or express money order. The day the currency is received, or the day the proceeds are received from the checks, drafts, or money orders, the subscription will be entered and will immediately begin drawing interest. When the bonds are delivered, a check will accompany each delivery covering the interest at three per cent. from the day the subscription is entered to the 1st of August, the date of the bonds, and from which date the bonds will carry their own interest.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A CLINICAL SYNOPSIS OF THE DIAGNOSIS AND TREATMENT OF CHRONIC RENAL DISEASES.

BY WILLIAM H. McENROE, M.D.,

NEW YORK.

THE primary cause of every form of renal disorder is the inability of the kidneys to perform their normal function of elimination, and, as a result of this inaction, there is an absorption of the excrementitious and poisonous products of the urine into the circulation.

This produces a number of very definite symptoms, and is a common complication of a large number of morbid conditions in which renal suppression takes place. This is notably so in the various forms of the acute fevers, following operations on the genito-urinary tract, in tuberculous and cancerous disease of the kidneys, and, finally, complicating every form of Bright's disease.

Many attempts have been made to classify the different conditions found in the kidneys after death, and to give to each form a definite clinical history. The result of this has been greatly to confuse the nomenclature of this very intricate subject.

I have adopted the following classification:

1st. Parenchymatous nephritis.

2d. Amyloid or lardaceous degeneration.

3d. Interstitial nephritis or renal cirrhosis.

There are three distinct anatomical portions of the kidney, in one of which every form of disease of this organ has its origin. These are, first, the uriniferous tubules; second, the walls of the blood-vessels; and last, the interstitial tissue or the renal stroma.

In some cases parenchymatous nephritis commences as an acute disease complicating many of the acute fevers. It is often caused by exposure to cold. In these cases the patient quickly passes into a condition of general anasarca, the urine containing large quantities of albumin. This may continue for some time, the patient meanwhile passing into an apparently hopeless state, when suddenly the urine becomes more copious. The nervous symptoms are greatly modified and the nausea disappears. There is an apparent recovery. The albumin, however, remains in the urine, and there are swelling and œdema along the line of the tibia and the internal malleolus. The usual course of this malady is chronic from the start. The urine at first is highly colored and diminished in quantity. Later on it becomes pale in color and more copious. Albumin is constantly present, and large hyaline and granular casts are found. The face is pale and glossy. Dropsy is constant and may become very extensive. There is a great tendency to the development of secondary inflammations and attacks of uræmia are frequent. There is a marked disturbance of vision. Total amaurosis may occur. Retinitis albuminurica is often present. The optic papilla is cloudy and swollen. The retinal veins are tortuous and white patches are found on different portions of the retina. Disturbance of vision is so common in renal disorders that it is often the first symptom to attract the patient's attention. Amaurosis dependent on neuro-retinitis may be recovered from; more often, however, it progressively increases, or it may remain stationary for an indefinite period after having reached a certain limit. Paralysis involving a single muscle may follow an attack. Hemiplegia and paraplegia often occur. In some instances after an attack of convulsions and coma there is for the time being a total disappearance of all symptoms; even the albumin is not found in the urine. Everything is held in abeyance for a greater or less period of time, when another attack is precipitated. Excessive enlargement of and valvular changes in the heart do not occur so often as they do in granular kidney. The disease may be prolonged for several years. I have known complete recovery to take place after the third year.

Amyloid or Lardaceous Degeneration.—This form of renal disease comes on slowly and is always found in persons who are debilitated by some wasting disorder. It frequently complicates syphilis, pulmonary tubercle, caries, scrofula, and many other wasting diseases. The quantity of urine passed at the beginning of this affection is very large indeed, and this symptom should excite suspicion. As the morbid condition advances, the polyuria gradually lessens and ultimately ceases. Convulsions are seldom, if ever, observed.

Interstitial Nephritis or Renal Cirrhosis.—This process is slow and insidious in its development, and may remain latent in the system for some time. It occurs more often in persons past middle life. Its principal causes are the chronic use and abuse of alcoholic spirits, a gouty diathesis, and chronic poisoning by lead. The urine at first is copious in quantity, pale in color, and contains a small quantity of albumin with hyaline and granular casts, which may be absent at times. General dropsy rarely complicates this affection. Cardio-vascular changes are constantly present and often reach an extreme degree. Cerebral hemorrhage may occur at any time, owing to the degree of arterial sclerosis present in these cases. There are a number of important symptoms in this condition that indicate impending apoplexy: a loss of memory, due to anæmia and malnutrition of the brain; vertigo, generally worse in the morning after rising; a persistent tendency to wake too early in the morning; painful cramps in the calves of the legs, just before or after getting out of bed. The patient complains of a vague sense of some impending danger. The intellectual faculties are dull and impaired. This is without doubt a frequent cause of declining health during the period of middle life, producing a condition of premature old age.

Albuminuria.—The presence of albumin in the urine is a constant pathological symptom of every form of kidney disease. Albumin has been found temporarily in the urine of apparently healthy persons, and its presence is no longer considered positive evidence of renal disease. Albuminuria may be caused by a number of conditions, of which a correct appreciation is of great importance to a proper understanding of its pathological significance. Therefore, as it is an important and common symptom, it should be carefully looked

for in every specimen of unhealthy urine. The question is often asked: How is it that albumin is not found in normal urine; what prevents it escaping with the water and other matters that are filtered off through the renal glomeruli? There is no doubt that it is kept back by the layer of epithelium which surrounds and covers the capillary tufts. At one time it was supposed that albumin was present in the transudation from the glomeruli, but was again taken up from the urine and restored to the blood by the action of the epithelial cells lining the convoluted tubules. This theory is no longer tenable. When albumin is present in the urine it undoubtedly has found its way out through the renal glomeruli, because certain nutritive changes have taken place in the epithelium covering the glomeruli, thus rendering them incapable of resisting its passage. Therefore anything that causes a change in the renal circulation may produce it. It has been demonstrated that whenever a full stream of arterial blood is not maintained in the capillary tufts, there is a marked change in their epithelium, so that they can no longer fulfil their normal function. Albuminuria is also caused by any obstruction or impediment to the outflow in the renal veins. In all these cases the epithelial cells of the glomeruli are greatly changed in appearance. Albumin has been found in the urine of apparently healthy persons. It can be temporarily produced by a cold bath, by great mental distress, and sometimes by severe exercise. Some authorities claim that its presence in the urine in these cases is due to a congenital loss of power in the epithelial cells, rendering them unfit to resist the passage of the albumin. It is claimed that the occurrence of temporary albuminuria may lead eventually to the development of chronic renal disease. If the patient is young, and the albumin is not constantly present but paroxysmal in its recurrence, and the patient has never had acute renal disease, it is quite certain that under these conditions chronic disease would not follow.

There is another pathological element in the urine that is quite as constantly present as is the albumin—the bodies known as casts. The most typical and those most frequently present are the hyaline and granular. They are partially transparent and colorless, but with well-defined outlines. They are undoubtedly caused by the coagulation of the fibrinogen forced out of the glomeruli, under the influence of some product caused by the disintegration of the leucocytes. In some cases they make their appearance in the urine a day, or even two days, before the albumin appears, but as a rule the two are found together. The number of casts in a given case is directly proportionate to the amount of albumin. It is generally supposed that the presence of casts in the urine is very significant of kidney disease: this is not always so, for they are found in albuminuria caused by temporary changes in the glomeruli, owing to acute pyrexia or as the result of obstruction in the renal veins.

Dropsy.—Dropsy or œdema is a constant symptom of all the affections of the kidney. There are two varieties. The first is very similar in all its aspects to that form found in cardiac disease and pulmonary emphysema. It is caused by some obstruction in the systemic veins and is but indirectly of renal origin, for it is caused by failure of the heart to maintain the normal circulation. This form of dropsy is more marked in the dependent portions of the body, and especially involves the legs. It is generally associated with dyspnœa, orthopnœa, and great lividity of the face; it is often found in parenchymatous and cirrhotic disease.

The second form has always been associated directly with the kidney, and is peculiar to it. It makes its appearance first in the face, and especially underneath the eyelids; it may remain in the face during the entire course of the disease. More often, however, it passes to the lower extremities and may involve the entire body. It sometimes passes over the face and obliterates the normal facial outlines. It does not occur often in the granular form of kidney disease, and it has been estimated that fully one-third of these cases run their entire course without dropsy. The degree of œdema corresponds as a rule to the quantity of urine passed, but it bears no relation to the amount of albumin present.

There are cases of œdema or dropsy presenting the same characters as those found in renal disease, but at no time is the urine albuminous and the kidneys appear to be in a healthy state. Such cases are often called essential dropsy.

Many theories have been advanced as to the origin of dropsy. It is caused by a change in the elements of the blood, and this is due to perversion of the normal functions of the kidneys. It has been found by a series of experiments that the specific gravity of the blood serum when dropsy exists is greatly reduced. It is sometimes reduced as low as 1.012, the normal density being 1.030. This change in the blood is due to a deficient excretion of water and a loss of albumin, which has escaped through the glomeruli.

The loss of albumin is never very great; rarely as high as four per cent. Cohnheim found by experiment that the injection of very large quantities of one-half-per-cent. solution of sodium chloride failed to produce the slightest degree of dropsy, even with the renal arteries ligatured. It is not known what amount of water is thrown off by the skin and the lungs. There is ample clinical evidence that even in cases of complete urinary suppression dropsy does not necessarily follow. The theory that is more generally accepted is that of Cohnheim. He says a change takes place in the walls of the renal capillaries, and as the result of this change they allow the passage of fluids that under normal conditions would be retained.

Secondary Inflammations.—Very often during the course of chronic renal affections complications occur, and in many instances they are the direct cause of death. The serous cavities are freqeuntly attacked—the pleuræ, the pericardium, and the peritoneum. The inflammatory process is generally suppurative in character; meningitis is very rare. These secondary inflammatory conditions are considered to be the result of a depraved state of the blood, owing to deficient renal excretion.

Cardio-Vascular Changes.—Enlargement of the heart is a common complication of the parenchymatous and cirrhotic forms of kidney disease. It is rarely found in the waxy or lardaceous form, unless secondary inflammation of the renal cortex has reached an advanced stage. The enlargement is generally in proportion to its duration, the greatest hypertrophy always occurring in the cirrhotic form. The enlargement is most often confined to the left side of the heart. The change that takes place in the arteries is caused by a non-suppurative inflammatory process, which begins with hyperæmia and is followed by an increase in the number of the cells of the affected tissue and fatty degeneration, and finally by a marked increase of the connective tissue. This process is called cirrhosis in the kidney and sclerosis in the arteries and the nerves. Coincident with the cirrhotic process in the various organs and tissues of the body, the walls of the arteries and capillary blood-vessels become the seat of characteristic changes, those of chronic endarteritis, with an exudation of a hyaline material on the outside of the blood-vessels. The coats of these vessels become greatly thickened and their calibre is diminished, and in the case of the smaller arteries their cavity is completely obliterated. This increase of connective tissue in the various organs of the body

never occurs without injury to the cells of the part pressed upon, and as this shrinks the process goes on and finally destroys all the cells of the inflamed part, so that there is ultimately nothing but a mass of fibrous tissue left. This condition of sclerosis of the arteries and capillaries is invariably found in renal cirrhosis. It gives the hard and incompressible pulse, so characteristic of this disease; it causes a general derangement in the blood supply to the various organs of the body; it is also the principal cause of cerebral hemorrhage or apoplexy that so often occurs in this disease. These morbid conditions are preceded by a number of very definite symptoms that are caused by imperfect circulation and malnutrition of the brain.

The consideration of the pulse, as appreciated by the examining finger, elicits the following characteristics: First, it is persistent. It cannot be obliterated during the interval between the cardiac beats. It is long and full and does not fall away. If the arm is raised the radial and even the brachial arteries are distinctly visible, full, and tortuous. The pulse is hard and incompressible, requiring considerable force to overcome it. In all these cases cardiac hypertrophy and dilatation are invariably present.

Retinitis Albuminurica. — This characteristic symptom complicates the parenchymatous and granular form of the disease. The process consists of numerous white spots situated near the optic disc and the macula lutea. They often appear as round in shape, and in some instances as large irregular patches that may subsequently coalesce. Hemorrhage often takes place into the substance of the retina. A condition of optic neuritis is usually present, or there may be great œdema or swelling of the retina, sufficient completely to hide the optic disc. The veins are distended and are tortuous. Sometimes a hemorrhage occurs, forming a streaky appearance along the new fibres. This condition, as a rule, is a late manifestation, and it is claimed by some authorities that this does not occur until enlargement of the heart takes place. The retinal arteries are extremely small in size compared with the veins, and very often a condition of endarteritis obliterans is present in them. When retinitis is once established it persists, as a rule, during the life of the patient. It is not always absolutely characteristic of chronic renal disease, for a condition exactly similar to it is caused by various lesions in the brain. It frequently changes in appearance. Old hemorrhages disappear and new bleeding points make their appearance. In some cases the white spots gradually fade away and may disappear entirely.

Uræmia.—Many efforts have been made to determine the exact identity of the poisonous agent in uræmia. It has been maintained by some authorities that this toxic state is due to the retention of urea and to its subsequent decomposition into many different poisonous products. Experiments have demonstrated, however, that this condition is due to many causes, among which may be mentioned the absorption of decomposed intestinal products, the accumulation of ammonium carbonate, the presence of potassium salts, the numerous products of degenerated tissue, and the absorption of the various secretions—bile, saliva, etc. As already stated, there is no doubt whatever that uræmia is caused by the poisonous action of these materials on the nerve centres. It is undecided, however, which one produces the actual poisoning. In many cases an attack is brought on by some disturbance of bodily function. The induction of profuse diaphoresis in a dropsical patient by a hot bath followed by hot packing has caused at once a series of uræmic convulsions. They are also caused by sudden cardiac failure, the heart being unable to maintain an active circulation through the renal vessels, so that the excretory function in an already damaged kidney is quickly suppressed.

The character of the urine in chronic cases changes materially before the development of uræmic symptoms. These changes vary greatly from each other. In most instances there is a marked diminution in the quantity of the urine passed for several days before active symptoms develop, or there may be complete suppression of the urine. In other cases the normal quantity of the urine is maintained, but there is a marked decrease in the amount of urea. In some exceptional cases the quantity of the urine is greatly increased. In all cases the specific gravity is less than normal. It is a well-known clinical fact that all the most prominent symptoms of chronic renal disorders are cerebral in character, but there is a great diversity of opinion in regard to their mode of origin, for the characters of these symptoms vary greatly in the different cases. The phenomena to which the term uræmia is applied consist of convulsive movements, defects of vision, headache, stupor, coma, and often persistent vomiting. The onset of the attack may be sudden, or in some cases it begins insidiously, with headache, stupor, vomiting, and many other symptoms. The convulsive attack itself closely resembles an epileptic fit, and may consist of a single paroxysm; more often, however, attacks follow each other at intervals of a few minutes or even hours, the patient meanwhile lying in a state of profound insensibility. The face is pale, the pupils are dilated, and the stertorous breathing is constant. The temperature is greatly elevated, in some cases as high as 104° F. The coma is usually very profound, but in some cases, if seen early, it is possible to rouse the patient. The coma follows the convulsive movements, the patient passing slowly into complete stupor during the course of a day or more. In those cases in which the onset is sudden the patient falls down and becomes quickly comatose. This state closely resembles a number of conditions with which it may be confounded. It so closely simulates an epileptic fit that the diagnosis is always difficult to make, and to determine that the attack is due to uræmia it is necessary in many cases to make an examination of the urine. The catheter can be used when necessary to obtain a specimen. In uræmia the face is deathly pale and the breathing is easy. In epilepsy the face is blue in color and has a turgid, choked appearance. In apoplexy there is inequality of the pupils, with strabismus and hemiplegia. In uræmia the pupils will not react to light, and there is a urinous odor from the surface of the body and the temperature is greatly elevated. In the coma caused by opium or morphine poisoning there is symmetrical contraction of the pupils, so much so as to be likened to a pin's head. This is a very important sign and should at once arouse suspicion of morphine poisoning. As opium is a cardiac stimulant and powerful diaphoretic, there will be profuse warm perspiration; the respirations are characteristically affected in poisoning by opium. They may be reduced as low as five or six a minute, but this is an extreme degree. In every case they are markedly diminished in frequency. The respirations are stertorous and there is a marked pause before expiration. During the first stage of opium narcosis the patient can be roused and his articulation is good, but owing to his return to complete unconsciousness he very rarely completes his answer. One of the common forms of coma is that caused by excess in the use of alcoholic spirits. In this case the pulse is increased in frequency during the first stage, becoming weaker later on. If the patient is aroused, he returns to a drunken consciousness; his answers are not rational and his articulation is bad, the first effect of intoxication causing thickness of speech. He is generally irritated by interference

and uses profane language. There is a form of coma that is caused by injuries to the head, producing a condition of concussion of the brain; and, as this is often due to criminal assault, it is very important that it should be recognized quickly. Owing to the nature of the injury, the control of the brain over the spinal cord is lost, and as a result of this the reflexes are set free, so that the least external impression leads to muscular twitching. This may be severe enough to produce active movement of the whole limb; therefore whenever there is jactitation it indicates some injury of this kind, and it should never be overlooked.

Hysterical convulsions sometimes closely simulate uræmia. These attacks are made up principally of subjective symptoms. There are embarrassed respiratory movements, a sensation of fulness in the throat (the globus hystericus), great anxiety, and vertigo. These symptoms precede the attack, which is short in duration. The patient is highly emotional when consciousness is restored. In some cases, instead of active convulsions there is a state of muscular relaxation with loss of consciousness. The abdomen is greatly distended with flatus, and following the attack a large quantity of pale urine is passed. There seems to be every degree of consciousness at the beginning. The patient places herself in a position where little or no harm can possibly come to her during the attack.

Treatment.—Hygienic measures are of great importance. The patient should wear flannel next to the skin, and a certain amount of outdoor exercise should be taken. Disorders of digestion should be remedied. Salol and bismuth are often very useful for this purpose; milk as an article of diet is of great value. There are several preparations of milk which answer this purpose admirably. Some patients prefer buttermilk.

Diuretics are remedies which have the property of increasing the amount of urine excreted by the kidneys. They act as follows: first, by increasing the general blood pressure; second, by causing dilatation of the renal blood-vessels; third, by directly irritating the renal structure. In the treatment of chronic renal diseases the specific gravity of the urine is the index of its course. During the early stages of the disease the specific gravity of the urine falls to about 1.010 and remains there for a long time, and falls again near the end of the disease. When it reaches 1.006, great danger is imminent. No remedy equals calomel as a diuretic. It increases the watery constituents of the urine but not the solids. Calomel, gr. i.; pulverized scilla, gr. i.; and pulverized digitalis, gr. i., make an excellent diuretic pill. If the pulse becomes intermittent the digitalis must be left out. Digitalis acts as a diuretic by increasing the force of the cardiac systole and raising general arterial pressure. It causes a full flow of pale urine of low specific gravity. When once the action of digitalis is secured it is often continued for several days, producing a condition of great prostration, and this should never be forgotten. When there are idiosyncrasies its action cannot always be depended on. It should not be given if arterial degeneration is present, as there is great danger from the rupture of a blood-vessel, owing to the increased arterial tension produced by this drug. I have overcome this difficulty, however, by using nitroglycerin with the digitalis. Nitroglycerin, gr. $\frac{1}{100}$, and pulverized digitalis, gr. i., make a good diuretic pill. Nitroglycerin dilates the heart and the whole arterial system, and aids digitalis in its action on the kidneys, as it is a diuretic itself. Pilocarpine can be used if the heart is strong but not otherwise, as it is a powerful cardiac depressor. The dose is one-eighth grain by hypodermatic injection.

Hydragogue cathartics are far more reliable than diuretics, for in some cases the kidneys will not respond; but I have found diuretics efficient in many cases. The employment of diaphoretics, however, as eliminatives is of great value, especially if the œdema is very great or the patient is comatose. It should not be forgotten that the skin is an eliminative organ to a small extent only, and will not act as such except when the natural organs of elimination fail. Whenever, therefore, the skin is to be used for this purpose, it should always be prepared for this vicarious action. The first indication is to remove any tension that may exist, for, when the skin has been dry for any length of time, the epithelial layers are brought closely together; the mouths of the glands are thus closed, and in this way the discharge of the secretions is prevented. This condition of the skin is almost invariably found in dropsy. The dryness of the skin is due to the subcutaneous effusion acting as a mechanical obstacle to the capillary circulation, and thus arresting the secretion of the sebaceous glands by diminishing their blood supply. Inunctions of olive oil are valuable adjuvants to the diaphoretics in these cases, as they open up the glands and separate the epithelial layers. After the inunction the patient should be wrapped in a hot wet pack. It is well known that diaphoretics will not act when the other eliminative organs are in abnormal activity; therefore diaphoresis should not be attempted when the bowels are under the influence of a cathartic. I have found that small doses of antimonial wine are very useful in producing a moderate diaphoresis. The dose should not exceed ten drops. Spirit of mindererus or the liquor ammoniæ acetatis is also useful; the dose is one teaspoonful and more if needed, repeated several times through the day. The best method of acting on the skin is by the use of the hot bath. The patient should be placed in a bath of the temperature of 100° F., and hot water should be gradually added until the temperature reaches 104° or even 106° F. He should remain in the bath for at least half an hour, and in some extreme cases even an hour. He should then be closely packed in warm woollen blankets for at least three hours, during which time profuse sweating occurs. The hot-air bath is another means. A lamp can be placed in the bed near to the patient's body, while the clothes can be raised around him in the form of a tent; this procedure can be repeated every day. I have seen a number of cases of general anasarca promptly relieved by these measures. The hot bath is not indicated in cases of great prostration and marked dyspnœa; in these cases pilocarpine can be tried, combined with nitroglycerin. The first effect of pilocarpine is to cause flushing of the neck, which quickly passes to the face and is following by vertigo; this passes away suddenly. If the dose is too large, salivation will occur. The dose is from $\frac{1}{8}$ gr. to $\frac{1}{3}$ gr., with $\frac{1}{100}$ gr. of nitroglycerin. It is well to administer a full dose of brandy immediately before giving the pilocarpine. In severe cases when it was impossible to use this by the stomach or bowels, the application of infusion of digitalis, ℥ i. to ℥ xvi. of water, to the abdomen on spongiopiline or hot cloths, has been followed by good results.

In the more acute forms of convulsions venesection or the abstraction of blood is often of great value. From ten to twenty ounces of blood may be drawn. Inhalation of chloroform will often check the violence of the convulsive movements.

Acupuncture is sometimes necessary. This is done with a needle, which is plunged into the subcutaneous tissue in the thigh or the leg. The needle should be turned from side to side so as to leave an opening for the fluid to escape. Small incisions are sometimes made to accomplish the same result. Before the needle or knife is used the skin should be well oiled to prevent any maceration of the cuticle. The fluid should be

collected by using woollen blankets, which should be wrapped around the limb. These should be changed often and the open surface washed with a solution of creolin or carbolic acid.

Anæmia is a prominent and persistent symptom of all forms of chronic renal diseases. I greatly prefer the muriated tincture of iron combined with the sweet spirit of nitre for these cases: it is remarkable to see what improvement follows.

It is well known that a large number of the most prominent symptoms of renal disease are cerebral in origin. The pathology has been explained already. This pathological state of arterial sclerosis is a constant companion of the granular kidney. It is a common cause of declining health in middle life, producing premature old age. This is illustrated by examination of the urine. Albumin and casts are found, but a far more serious symptom is also found: low specific gravity, even as low as 1.010. The urine is very light in color.

Against this very frequent cause of declining health in middle life there is fortunately a constitutional remedy of the highest value. I refer to mercuric chloride or corrosive sublimate. The first effect of this remedy is to bring back the natural color of the urine. The specific gravity also rises and may reach 1.018. There is no other remedy known to the science of medicine that in its action is so nearly a specific for these conditions as corrosive sublimate. This fact is not generally known by physicians. I have seen a large number of patients suffering from granular disease of the kidneys, in whom this remedy brought about a cure. I have found by practical experience that almost every case of granular kidney is complicated with chronic meningitis or chronic pachymeningitis, caused by the universal sclerosis present. During the early stages of this disease, where there is throbbing of the arteries of the neck and head, the combination of ergot with the bichloride is of great value. Each and every symptom of this protean disease is promptly checked, the memory is improved, the pulse becomes soft and compressible, the headache and vertigo disappear, the painful cramps in the calves of the legs are no longer felt, the intellect becomes clear. For prolonged treatment I employ the following prescription:

℞ Hydrargyri corrosovi chloridi . . . . . gr. i.
Tinct. ferri chloridi . . . . . ʒ ij.
Spiritus ætheris nitrosi . . . . . ʒ i.
Aquæ . . . . . ʒ i
Elix. simplicis . . . . . ad ʒ iv.
M. S. One teaspoonful in water after meals

The mortality in the various forms of chronic renal disorders is very large, and they usually terminate in death sooner or later, unless the patient succumbs to some one of the numerous intercurrent complications. They vary considerably in duration, and, as they are slow and very insidious in their development, they may have existed for a long time before there were any manifestations of active symptoms. In many cases the progress of the disease is checked, and may remain stationary for an indefinite time, the patient having apparently recovered. In these cases the albumin and casts may disappear from the urine for a time.

An important element in the prognosis is the persistence of the albumin in the urine. If the quantity is large and there is marked œdema with great pallor of the face, the prognosis is unfavorable.

Melancholy. There is nothing which cheers up your spirits like a dose of Epsom salts. They have gone out of vogue, but a tacit compliment is, notwithstanding, constantly being paid to them, for people still find the efficacy of the more expensive bottled waters which contain the salt.—Charles J. Hare.

THE BLOOD COUNT IN ANÆMIA AND CERTAIN NERVOUS AFFECTIONS.

By Mary Putnam Jacobi, M.D.,

New York.

A few months ago, upon making the blood count in a patient affected with an hysterical vasomotor neurosis, I was astonished to find that the red cells numbered 8,084,444, and the white 102,222. On previous occasions the results of a similar examination had been very different. Thus, on October 18th, the red cells were 2,680,000; on November 12th, 3,892,000; on December 16th, 3,393,000—white, 60,000; on January 6th, 3,215,555—white, 22,222; on January 20th, 5,480,000—white, 51,000. The abnormally high count was taken on December 11th, thus midway between counts of three million plus.

On consulting the records of other apparently anæmic and certainly nervous patients, I found that the microscopic proofs of anæmia upon which we have become accustomed to rely were lacking in a number of cases. Thus:

a. W. November 4th, 5,109,077.

b. A. S. November 11th, 5,948,800; anæmia, dysmenorrhœa without endometritis, chronic mucous colitis.

c. H. November 18th, 5,704,400—white, 37,000: hysterical ovaralgia.

d. D. March 13th, 6,660,000—white, 37,777; exhausted school teacher, great pallor.

e. H. March 3d, 5,100,000—white, 8,400; neurasthenic college student.

In other cases, and after a brief period of medication with iron or other drugs, the red corpuscles increased with great rapidity, and quite out of proportion to improvement in the conscious well-being of the patient, even when this was observed to some extent. Thus:

a. W. November 4th, 5,109,077, placed upon a beef preparation without other treatment. December 2d, red cells were 6,128,888.

f. B. December 9th, the red cells were 4,424,000—a number which corresponded with the signs of anæmia presented by the patient. On February 2d, the red cells were 5,695,500, yet the patient was only moderately improved, the treatment prescribed having been carried on very irregularly.

g. E. A case of profound and constitutional anæmia from childhood. On October 21st, red cells, 2,974,000. October 28th, a day or two before menstruation, and after a week of peptomangan, the cells had gone up to 4,898,000. On December 2d and 30th, the counts were over 5,100,000 each time, but the condition of the patient had changed very little. On January 6th, when she had been suffering rather more than usual from headache, drowsiness, and sense of fatigue, the red cells numbered 5,151,100.

This discrepancy between the clinical symptoms of anæmia and the results of the test with which the brilliant invention of Malassez has enriched the resources of the physician, has attracted the attention of several observers, but has been variously interpreted.

Dr. Robert Edes, in a paper on the nutrition of neurasthenics, published in the last volume of the Transactions of the Association of American Physicians, observes that "the nerve centres have a nutrition of their own, and receive according to their own requirements a larger or smaller share of the nutriment offered by the general circulation. . . . The nervous substance can select and utilize from a solution bearing the appropriate pabulum, in quite widely varying degrees of dilution, enough to carry on its ordinary functions without exhaustion." And conversely, according to Dr. Edes' estimates, neurasthenics

may gain in weight, while nevertheless their nervous symptoms remain quite unimproved—a statement which runs counter to the doctrine at the basis of Dr. Mitchell's celebrated essay on fat and blood.

Dr. Edes' paper records no blood counts, but contains a table of estimates of hæmoglobin, which would seem to show that a fair degree of health was compatible with a much lower percentage of hæmoglobin than is usually supposed. It is regrettable that, in pursuing this special line of thought, Dr. Edes had not investigated the apparent richness of the blood of his neurasthenic patients, in regard to the red and white corpuscles. As he has not done so, his paper touches upon the subject of the present note only by the single suggestion that the nutrition of the nerve centres does not necessarily proceed on parallel lines with that of the somatic tissues, including the blood, but may be fairly active when the latter is imperfect, or depressed when the blood is rich and other tissue than nervous is well-nourished.

Dr. J. K. Mitchell, in an essay in the *American Journal of the Medical Sciences* in 1894, notes that many neurasthenic cases presented a full normal or even a supranormal corpuscular count, together with a good percentage of hæmoglobin, and nevertheless showed every external sign of poverty of the blood; namely, pallor of the skin and mucous membranes, cold extremities, anorexia, indigestion, dyspnœa on trifling exertion. The interpretation of this paradox offered by Mitchell is either that the total volume of the blood in the body is reduced, or, in some hitherto inexplicable way, the usefulness of the corpuscles is impaired. On the current view that the function of the corpuscles is unique, that, namely, of carrying oxygen to the tissues, it is difficult to suppose that their "usefulness was impaired," while their amount of hæmoglobin—as shown by the color index—remained normal. The capacity of tissue elements—especially of the neurons of the nerve centres to appropriate oxygen—probably varies within wide limits, but such variation does not necessarily imply incapacity in the oxygen-carrying elements themselves. The suggestion that the total volume of blood may be reduced, while the corpuscular richness of each cubic millimetre is yet maintained, seems to me interesting and fruitful, however difficult to prove.

It is, however, rather surprising that Dr. Mitchell's attention has not been attracted to an element in the problem which his own experiments should serve to emphasize rather pointedly—I mean the degree of concentration of the blood drop at the moment of observation.

In thirty-five persons, some healthy but most neurasthenics, Dr. Mitchell examined the blood before and immediately after an hour's general massage. The uniform result of the massage was to cause a very marked increase in the number of red corpuscles—sometimes also in the white—the hæmoglobin suffering little change.

MITCHELL.

	Before Massage.		After Massage.	
	Red.	Hæmoglobin.	Red.	Hæmoglobin
Healthy	5,675,000	110	7,950,000	120
Neurasthenia	5,150,000	75	5,600,000	72
Simple anæmia	4,275,000	....	5,450,000	
Hysterical torticollis (appallingly anæmic)	5,900,000	...	6,750,000	
Neurasthenia (dysmenorrhœa)	3,637,500	55	6,025,000	60
Toxic anæmia (chronic lead poisoning)	5,000,000	100	5,925,000	
Neurasthenia following dysmenorrhœa	5,612,500	....	8,062,500	

Oliver, in a Croomian lecture for 1896, comments upon Mitchell's observations, and remarks rather slyly that it is natural that physicians who have used massage a great deal should want to interpret such phenomena at once as a proof of therapeutic improvement, which they are not, although indicating changes which may result in improvement. For massage, like several other agencies whose effects have also been carefully studied, does not directly affect the composition of the blood, but the tension of the walls of the blood-vessel. As the lumen of the latter diminishes the pressure of the intravascular fluids increases, with the consequent force of transudation of the latter into the intervascular spaces. With the rise of tension in the arterioles, the transudation of the fluid portion of the blood through the capillaries increases, the capillary blood becomes therefore more concentrated, the proportion of corpuscles to the cubic millimetre rises, although their absolute number is by no means increased.

Text-books like Cabot's lay stress on the necessity of correcting a blood count, under circumstances which should cause a general depletion of the watery parts of the blood, such as a profuse diarrhœa or a Turkish bath. Cabot maintains with less emphasis the agencies which cause an apparent concentration of the blood by constricting the small blood-vessels, as cold, pain, the suprarenal extract. Winternitz[1] has demonstrated after cold baths a special increase of the white cells, which rise from a proportion of 1–400 to 2–3, with the same amount of red. Oliver observed a marked increase in the proportion of the red blood corpuscles in any limb in which vigorous muscular contractions had been effected, either through volition or by the faradic electricity, and attributes the polycythæmia to the stimulation of the lymphatic circulation, with augmented exchange of fluid from the blood to the tissues and consequent concentration of the blood.

Cheron[2] similarly interprets the marked effects of massage, dry friction, and static electricity, which within ten minutes, he says, caused in one case a rise of red corpuscles from 2,430,000 to 4,080,000. Long ago Vigoroux described a similar result of static electricity, and adduced it as a proof of the rapid effect on nutrition of this agent. It is evident that justly to estimate such effect, the observation must be made at least twenty-four hours after the static electricity shall have been applied. In fact, in all cases in which high vascular tension is known to exist, a high proportion of blood corpuscles to a given cubic millimetre of blood cannot be accepted as satisfactory evidence of the composition of the blood. Polycythæmia is frequently observed in chronic interstitial nephritis, as also in chronic gout; and to this same high arterial tension is probably to be attributed the apparent corpuscular richness of the blood of many neurasthenics, especially the so-called lithæmic neurasthenics. Possibly the leucocytosis assigned to gout is similarly apparent rather than real.

Oliver marks the improvement of patients, not by the absolute rise or percentage of the blood corpuscles, but by the rise of the blood decimal or color index. This is found by dividing the percentage of the red cells, calculated on a basis of 5,000,000 as normal, into the percentage of hæmoglobin, as calculated on the Fleischl or Gowers scale:

	August 3d.	August 7th.	August 13th.	August 23d.
Corpuscles	110	98	90	87
Hæmoglobin	105	96	91	96
Blood decimal	0.95	0.98	1.0	1.09

The prompt influence of any vasoconstricting agency in causing an apparent increase of blood cells is shown

[1] Centralblatt für klinische Medicin, 1893, p. 177.
[2] Comptes Rendus de l'Académie des Sciences, vol. ii., 1895

by a pretty experiment of Cheron's. Having made the blood count of a fairly anæmic patient, he injected hypodermically five cubic centimetres of a one-per-cent. solution of common salt. The blood count taken immediately after showed a rise from 2,480,000 red cells to 4,080,000. Simultaneously the arterial pressure rose from eleven centimetres to sixteen centimetres. "Every stimulation of a large sensitive surface determines," says Cheron, "the same phenomenon in anæmic subjects. Thus in the ascension of mountains or under the prolonged influence of high altitudes, in consequence of the immediate stimulus of the central nervous system, the entire vascular system reacts, the muscular coat of the vessels contracts, the total capacity of the circulatory system diminishes; the liquid part of the blood, forcibly compressed, escapes into the perivascular tissues, and the red corpuscles, bathing in a less quantity of liquid, appear much more numerous in a given space. There is not then a sudden hyperglobulia, but the result of the concentration of the blood. Probably many anæmias, if not all, are really hydræmias, consecutive to a sort of vascular paresis or neurasthenia." I repeated Cheron's experiment on a patient whose blood count gave 4,433,333 red corpuscles and 6,222 white, the hæmoglobin being seventy-five per cent. After the salt injection the count was 5,620,000 red cells, 57,777 white.

With these data I return to my patient with the amazingly high blood count, both in red and white cells, and note that the prominent symptom in her case at the time of observation had been an extreme vasomotor irritability manifested by frequent chills; also hysterical nervous attacks which seemed attributable to vasomotor spasm of the cerebral blood-vessels. There was marked contraction of the visual field. These symptoms had been particularly marked at the time the blood counts in question had been taken. I inferred that the richness of blood was only apparent, and due to its concentration through narrowing of the lumen of the superficial blood-vessels by increased vasomotor tonicity or spasm. A count was made, but only of the white cells. After two weeks' sojourn at Altantic City, and when the patient was feeling perfectly well, all the vasomotor symptoms having for the time disappeared, the white cells then numbered 4,400.

The possibility of such an occurrence considerably confuses the estimate of the state of the blood which can be made clinically in neurasthenics. In them vasomotor irritability is so common that, in view of the above considerations, it must remain difficult to decide whether a given neurasthenic be or be not anæmic.

Observation of the contemporaneous sphygmogram may serve to correct the blood count, for if the sphygmogram show a high pulse tension in a person with clinical signs of anæmia, yet a high blood count—precisely such cases as are commented upon by Mitchell with surprise—the phenomena may be attributed to vasomotor irritability, which is itself an expression of a marked anæmia. This combination of conditions is to be anticipated in the numerous cases of neurasthenia associated with or dependent upon lithæmia. On the other hand, the rapid improvement in the blood count that is sometimes observed, even in a few days after the use of certain remedies, may depend not on any real increase in the number of blood cells, but on an increased tonicity of the small blood-vessels.

When the blood is locally concentrated through vasomotor spasm, the white cells must be affected together with the red, and in the cases I have cited an apparent leucocytosis did indeed coincide with the apparent polycythæmia. One of these patients, a woman aged thirty-nine years, showed symptoms of a premature menopause, and in her blood the proportion of white cells always remained very high, even when, apparently together with vasomotor relaxation, the proportion of red cells fell. It has occurred to me that leucocytes may always tend to accumulate in the blood when their normal periodical derivation through the adenoid tissue of the endometrium is interrupted, and that in some way such a leucocytosis would help to explain the nervous phenomena which are so common at the menopause, especially if, spontaneously or through surgical interference, this be prematurely induced. But this, as Mr. Kipling would say, is another story.

BACTERIOLOGICAL DIAGNOSIS OF TYPHOID FEVER.

By JAMES H. REILLY, M.D.,

MEMPHIS, TENN.

When Stillé and Gebhart, of Philadelphia, and Louis, of Paris, differentiated between typhoid and typhus fever, and gave, as a more correct term for typhoid, enteric fever, it was thought there was little else if anything to learn as to its pathological anatomy; but since the advent of bacteriological research, we have been confronted with so many conditions foreign to our idea of enteric or typhoid fever, that the question might well arise, What is typhoid fever? Certainly our ideas of typhoid fever will have to undergo a change, in the light of modern bacteriological research.

Heretofore we have always associated with typhoid or enteric fever an ulcerated condition of the patches of Peyer, more or less diarrhœa and elevation of temperature, and other symptoms, such as epistaxis, gurgling in the right iliac fossa, characteristic tongue, and rose spots. Very true, that a great many cases were not of the classical type: very true, that a great many cases coming under the observation of intelligent physicians did not have all the so-called classical symptoms; some of the minor ones might be absent, but the course they pursued justified the diagnosis of typhoid fever.

What are the conditions that confront the clinician to-day? He is practically told by the bacteriologist that the symptoms he elicits from a patient, in the absence of bacteriological examination of the blood or some of the secretions, are of little value. In some cases this might be very true, but, so far as it refers to cases of so-called typhoid fever, it has not a tendency to give him that confidence which is essential to true research.

It would appear to the honest investigator that clinical symptoms should not be ignored in connection with bacteriological examination, but such is the case very often, and as a result we have the so-called peculiar cases of enteric fever reported, and by men eminent in the profession.

My purpose in writing this paper is not to discourage bacteriological investigation—far from it, I am a thorough believer in the germ cause of disease; but I do not think that the present tendency of some observers, in reporting cases of so-called enteric fever with no bowel lesion, as typhoid fever, merely on the finding of the bacillus typhosus, gives the clinician that confidence that is essential to honest and careful research. I do not mean to imply that we may not have other lesions than that of the intestines in typhoid fever. I appreciate how often we have to contend with a secondary infection of the respiratory tract and of the kidney; but I do contend that it is just as inconsistent to say that one may have typhoid or enteric fever according to the accepted pathology of this disease without any bowel lesion, as to say one might have meningitis with no involvement of the meninges.

Either the pathology of enteric fever will have to be

rewritten, or we shall have to enlarge our knowledge on the bacillus typhosus.

In 1890 Valliard, of Paris, in a paper before the Society of Hospital Physicians, reported a case of infectious disease in which he discovered the presence of the bacillus typhosus and the streptococcus, without there being any intestinal lesion. The history of the case was as follows:

"A young soldier, convalescent from slight grippe, presents successively great lumbar pain and cerebral excitation, with high temperature and abundant epistaxis. There soon follows coma vigil, with complete anæsthesia, contraction of the nape of the neck and of the muscles of the pharynx, and obstinate constipation, death occurring on the tenth day after a brief warning of cerebral symptoms. The autopsy revealed general congestion and localized œdema of the cerebral and spinal meninges. The lungs were congested, the spleen was swollen and softened, and weighed ten ounces; there were no alterations of the intestine. Cultures on different media were made with the splenic pulp, blood from the lungs, and part of the spinal marrow; they revealed a bacillus morphologically like the typhoid bacillus described by Eberth, Gaffky, Chantemesse, and Widal. Valliard claims that in this case typhoid fever ran its course without any enteric lesion, and asks why typhoid infection should not be able to exist without manifesting the usual intestinal lesions. Besides there was found in the spleen and meningeal exudates the streptococcus which has been described in cases of fatal grippe. The patient therefore succumbed to a mixed infection of the streptococcus and typhoid bacillus."[1]

Banti has reported a case of typhoid fever without any intestinal lesion, but in which the typhoid bacillus was found in the spleen and mesenteric glands.

Adnot cites a case of meningitis without any intestinal lesion, in which he identified (proof not positive) the bacillus typhosus.[2]

The deduction made from the cases reported by these distinguished observers is that typhoid fever is not a fever with the lesions confined to the intestines, but one of systemic infection primarily, with any of the serous membranes or organs of the body involved, and not alone the patches of Peyer, as has been taught since 1829.

Of all the unusual cases of typhoid fever that have come under my observation, in which the diagnosis was made on the discovery of the bacillus typhosus microscopically, not a single case did I find in which a biological test was made to differentiate it from the bacillus coli communis; and when we recall the fact that they cannot be differentiated morphologically, it seems strange that, in cases in which lesions were found so far remote from our understanding of typhoid lesions, the observers did not pursue their investigations further, and demonstrate without a doubt that the bacillus isolated was the typhoid and not the coli communis.

That the bacillus coli communis has pathogenic properties has been demonstrated without a doubt. In a paper read by Dr. Welch before the Maryland Medico-Chirurgical Faculty in 1891, and published in the MEDICAL RECORD the same year (vol. xl., page 720), he states that he found this bacillus in thirty-three of two hundred and fifty autopsies which he performed, and that all the subjects had dysentery, a diphtheritic condition of the mucous membrane, hemorrhages, ecchymoses, and typhoid ulceration.

In the MEDICAL RECORD (vol. xlv.) a case is reported by Dr. Hermann Biggs, demonstrating the pathogenic property of this bacillus also. The case is one of acute purulent pachymeningitis following a case of typhoid fever. At about the seventh or eighth week the meningitis suddenly developed and caused death.

Bacteriological examination of the exudate revealed pure culture of the bacillus coli communis. Valliard, in his unusual case of typhoid fever, a report of which I have given above, states that he finds the bacillus typhosus in the meninges, but does not state whether or not any means were taken to differentiate the bacillus found from the coli communis. The inference to be drawn is that this was not done. In Dr. Biggs' case we are not left in doubt as to the bacillus found, and in the future study of this bacillus this case will be of interest, while in the case reported by Valliard, as well as in about all of the so-called atypical cases of typhoid fever reported, no positive deduction can be drawn, and consequently they will not help in the study of this disease.

The method most generally used to differentiate the bacillus typhosus from the coli communis is known as the Ellsner method. This consists in the preparation of a culture medium upon which no species of micro-organism can grow, except the typhoid bacillus and the bacillus coli communis. Such a medium is prepared as follows: To half a kilogram of chopped potatoes add one litre of water and boil for one and one-half hours; strain through a cloth, and add ten per cent. of glycerin; the degree of acidity of this mixture must be such that each 10 c.c. shall require 2.5 c.c. of a decinormal soda solution to neutralize it; one per cent. of potassium iodide is finally added, and the medium is completed; the potassium iodide should not be added until shortly before use. Upon this medium nearly all micro-organisms, except the bacillus coli communis and the typhoid bacillus, either do not grow at all or are greatly inhibited. At the end of twenty-four hours the colonies of the colon bacilli can be easily found with the aid of a low-power objective, while those of the typhoid bacilli are scarcely visible. At the end of the forty-eight hours the colonies of the typhoid bacillus appear as small, very finely granular points, while those of the colon bacillus are larger, coarser, and more highly colored.

As this is apparently a simple procedure, one might think that there should be no trouble in differentiating the bacillus typhosus and the colon bacillus, and the fact is that there would not be if the character and growth of the colonies in apparently the same media were not subject to variations; to overcome this objection, and in an attempt to establish a broad and practical differentiation between these two forms of organisms, based on their growth peculiarities in semisolid media, especially media becoming semisolid between 30° and 40° C., Dr. Philip Hansen His, assistant bacteriologist to the New York City health department, after a series of experiments, has devised the following method for their differentiation by the culture method:

An agar-gelatin mixture of 0.5 per cent. agar and 8 per cent. gelatin was adopted as a stiffening-basis. The first medium of this kind tried contained 0.5 per cent. meat extract, 0.5 per cent. common salt, 2 per cent. peptones, and 1 per cent. glucose, and showed a reaction of 1.5 per cent. acid to phenolphthalein.

The inoculated tubes were allowed to remain in the incubator at 37° C. for twenty-four hours; the cultures of bacillus typhosus showed a uniform clouding of the medium, extending completely across the tube and downward to an even base to a varying extent depending upon the time and depth of the puncture, but generally becoming completely clouded in twenty-four hours. The growth along the line of puncture was hardly more dense than throughout the rest of the medium.

The colon culture, on the other hand, developed a growth only along the lines of inoculation, at times

[1] MEDICAL RECORD, vol. xxxviii., p. 179.
[2] *Ibid.*, p. 180.

with some outspreading of isolated colonies. Later, in some parts of the medium, a local clouding sometimes developed. Gas was formed, and in the wake of ascending bubbles streaks and patches of growth occurred, giving in twenty-four to forty-eight hours a medium generally clear with a varying number of these patches scattered throughout it.

Dr. His has also demonstrated a method of plate culture and various differential tests for the identification of the bacillus typhosus, and those who would like to investigate this subject I would refer to his original article in the *Journal of Experimental Medicine*, vol. ii., No. 6. I would also state that the His test is now used in connection with the Widal test, by the health department of the city of New York.

As to the Widal test for diagnosing typhoid fever, I will say that we have heard its merits discussed from various standpoints during the past year; we have also observed, from the reports of many observers during the past year, that their success was varied. I think no fairer value can be accorded the test than that given it by Dr. Gilman Thompson,[1] who draws the following conclusion from the study of five hundred cases in which the Widal test was applied:

1st. While the test is positive in the large majority of cases of enteric fever, and negative in the greater number of other diseases, there is a margin of error of eleven or twelve per cent. on each side of what might be termed the normal line between cases in which the test fails when it ought to succeed, and those in which it succeeds when it ought to fail, in order to make it of real clinical value.

2d. This total of twenty-three per cent. possible error unfortunately includes just those cases in which there is a greater doubt upon the purely clinical side.

3d. As a genuine diagnostic aid, the test has about the value of the diazo reaction in typhoid fever or the study of leucocytosis in pneumonia; that is, it is confirmatory in connection with the appropriate symptoms, but misleading if positive reliance be placed upon it.

4th. The fact that an expert bacteriologist is required to make the test is offset by the ease of transportation of dry blood, which long retains the power of reaction, and it is greatly to be hoped that further possible improvement in technique may place this most ingenious test upon a firmer practicable basis than can at present be claimed for it.

Vaughan states that there are reasons for believing that too much reliance has been placed upon the Widal test, and that normal blood serum will often have a similar effect upon the typhoid bacillus, and that the difference in behavior between the typhoid and colon germs toward the blood serum of typhoid patients is not so marked as has been generally believed.[2]

It has been claimed by Rodet and Roux, of Lyons, that the bacillus coli communis and the typhoid bacillus are varieties of the same species. If this be true, the pollution of drinking-water with normal fæces may cause typhoid fever; it is therefore evident that a positive decision on this point is of great importance.

Attempts to reach such a decision were first made by rendering animals immune to one of these germs, and then ascertaining whether or not this immunity held good against the other. The results reached by experiments of this kind were contradictory. Sanarelli and Demell and Orlandi found that animals immunized against the typhoid bacillus were also immune to the colon bacterium, and those protected in like manner to the latter became immune to the former.

These investigators reached the conclusion that the products of these germs are biologically equivalent. On the other hand, Neusser found that animals protected against from twelve to twenty times the ordinarily fatal dose of the typhoid bacillus died when treated with from two to three times the usual fatal quantity of the colon bacillus, and that those immunized against from ten to twelve times the fatal dose of the colon germ succumbed to three times the fatal quantity of the typhoid bacillus.

A second method of studying this question is founded upon the discovery of Pfeiffer, that the blood serum of the animals immunized against the typhoid or cholera bacillus protects other animals against the germ used in securing immunity, and not against others; *i.e.*, that the immunity is specific. The typhoid bacillus has been compared with the colon germ by the application of this test. Experiments of this kind have been made by Pfeiffer, Loeffler and Navel, Dunbar, Frank, and others. All have reached similar results.

The blood serum of animals rendered immune to one of these germs does not give equal immunity against the other. In other words, judged by this test, the typhoid bacillus cannot be regarded as a variety of this germ.

It is a well-known fact that the typhoid bacillus has not met all the requirements of Koch's law (the fulfilment of which he considered as necessary in order to identify an organism as the etiological factor in a given disease), which are as follows: The constant presence of the organism in the affected tissue of the diseased animal, its isolation from the pathological lesions, and its continuous cultivation in pure cultures under artificial conditions through many generations, the power of such cultures to reproduce the disease when inoculated into susceptible animals, and the detection of the organism in the lesions found in the animal thus inoculated.

Notwithstanding the fact that the bacillus of Eberth has not fulfilled this one essential requirement of the Koch law, it has been generally accepted as the particular micro-organism which produces the disease. But when we find this bacillus associated with lesions so far remote from our general understanding of enteric fever, a doubt might well arise whether we have in the Eberth bacillus the bacillus typhosus. On the other hand, considering the element of uncertainty which there has been in the Ellsner method of differentiating between the bacillus of Eberth and the coli communis, the question might still arise, "Was the bacillus isolated, in the cases reported of enteric fever without any bowel lesion, the bacillus of Eberth or the coli communis?"

The Treatment of Hemorrhoids, Dittel's Method.—Dr. Zuckerkandl (*Wiener medizinische Presse*) recommends Dittel's elastic ligature, after employing it with good result in two hundred and sixty-nine cases, as a simple and radical means. General anæsthesia is not necessary; the Schleich infiltration anæsthesia suffices to deaden the pain. The operation is applicable only for internal hemorrhoids with prolapse of the mucous membrane. By pressing, the patient forces the masses as far out as possible: then with a polyp forceps curved on the flat and directed by the index finger of the left hand the pedicle is grasped and the forceps are twisted to an angle of ninety degrees. This procedure develops the hemorrhoid, which is then tied off with tensely stretched elastic ligatures. Three or four such ligatures are sufficient. After from eight to ten days the ligated masses necrose and fall off, leaving a clean granulating wound, which heals in as many more days.

THE ADVANTAGES OF VAGINAL SECTION FOR PELVIC SUPPURATION AND CIRCUMSCRIBED HEMORRHAGE.[1]

By EDWARD NICHOLAS LIELL, M.D.,

JACKSONVILLE, FLA.,

LATE LECTURER ON GYNÆCOLOGY, NEW YORK POLYCLINIC, AND GYNÆCOLOGICAL SURGEON TO ST. ELIZABETH'S HOSPITAL, NEW YORK.

An acceptance of the invitation conveyed through our worthy president to prepare a paper on abdominal surgery, with the object of creating a general discussion to be participated in by the surgeons from the many regiments in camp, would have placed me in the position of practically duplicating my paper recently read before the Florida State Medical Association, many of the members of this society being present at the time.

I have chosen instead, as a suitable theme this evening, a branch of operative gynæcological work comparatively new, demonstrating, through individual clinical work, the advantages of vaginal incision under limited conditions, and also as an exploratory measure for the purpose of differential diagnosis. To decide always upon the proper operative procedure to adopt and which will be for the good of the patient, at the same time accomplishing the best results, is not always an easy matter. To follow blindly also in the train of any group of enthusiasts is at all times injudicious. From a personal experience of thirty-four cases, and having assisted other operators at fully as many more in New York City, the advantage is given me of surveying an area far beyond the horizon of my own individual efforts.

No department of surgery has progressed more rapidly than pelvic surgery by vaginal section, for but a few years ago nothing short of an abdominal section could be entertained when pelvic suppuration and hemorrhage, whether tubal or otherwise, existed. It is true that when Péan, Jacobs, Segond, and other French surgeons entered into the treatment of suppurating appendages by removal of the uterus in connection with pus tubes, by vaginal section, they met with greater success in the more serious cases than by abdominal section. Their argument was that as the appendages were diseased beyond recall the uterus was of little if any service by itself, it being considered in the nature of a foreign body demanding removal. A reaction has since set in, it being the experience of surgeons more conservative that, in many cases of suppurating appendages or pelvic suppuration, the condition can practically be eradicated and the patient cured by a measure much less formidable—vaginal incision and drainage. In some instances, when the minor operation is but a relief measure and not a cure, the local conditions may be so changed that a subsequent operation for removal of the appendages and uterus would not be relatively dangerous. It is needless to open the peritoneal cavity, and there is much less danger in operating per vaginam, if success can be attained as well by so doing.

Vaginal section, having for its object the breaking up of adhesions and thus the removal of vague pelvic pains, was done by me eight times, complete success attending in six instances with disappearance of the pain, adhesions with consequent pain recurring in two.

As an exploratory measure and as a means of differential diagnosis—the character of the neoplasms with accompanying adhesions making the diagnosis otherwise uncertain—vaginal section was performed six times. In two instances the neoplasm was diagnosed as of malignant character.

Operation by the inexperienced is little to be preferred to expectant measures of treatment. It is to be remembered that the condition present is often one that requires a sharp eye and a delicate touch—an educated index finger, in fact—and that success is attendant upon skill obtained by practice.

We will assume that the general aseptic principles governing the preparation for any operation have been taken preliminary to operation. The uterus being drawn down by a double tenaculum or volsellum, a longitudinal or semicircular incision is made through the vaginal tissue into the posterior cul-de-sac by means of a scalpel, the forefinger carried within the incision with a boring motion, the abscess or hemorrhagic sac entered by means of sharp-pointed scissors, and the contents are then removed. A protective wall of lymph, which nature has built up, protects the abdominal cavity in almost every instance from more serious complications. If multiple in character, all pockets must be felt for and freely opened. If a pus sac be the case, either tubal or ovarian, and adhesions to the uterus or rectum be present, the adhesions must often be broken up to anticipate the remote as well as the immediate good effects of the operation. The cavity, after evacuation of the contents, may be thoroughly swabbed out or irrigated, as the case may demand, followed by the introduction of strips of iodoform gauze, which should be packed not too firmly, the vagina retaining the excess of gauze. After remaining in place from two to four days, the dressings may be renewed once or twice, as the case may be, and if the contents have been thoroughly removed and good drainage has been secured, convalescence is usually rapid. The instances are not many, comparatively speaking, which require entering of the abdominal cavity, though the fear of this should not deter one in the least in his efforts to do a thorough operation, ideal drainage being the requirement and the danger of infection correspondingly diminished. The incision should be large and free, thus avoiding probable premature closing and the necessity for a second operation. Ligatures are usually unnecessary, forceps and torsion being the chief dependence.

The adoption of the Trendelenburg position in operating by the vagina has facilitated and rendered possible results in cases in which otherwise such would not have been.

Though a pus tube or ovarian abscess may be successfully treated by vaginal incision and thorough drainage, it is not to be expected that all cases are entirely cured by this method, improvement usually more or less marked merely following in some instances.

The chief advantage of vaginal incision and drainage is that it lessens the seriousness of operation by abdominal section, and when the indications are such that the operation can be done thoroughly there is no question that it is much to be preferred to the abdominal route.

In this connection I desire to report the two following cases as examples of the two conditions referred to in the paper:

Mrs. J——, aged twenty-six years. Diagnosis of pelvic abscess, retro-uterine; bulging inward of vault of vagina, posteriorly and laterally; exquisitely tender to the touch. Fixation of uterus considerable. Temperature, 103.2° F. History of gonorrhœal vaginitis and endometritis. Free incision through posterior vaginal wall into abscess sac, and contents evacuated; cavity gently curetted, irrigated with hydrogen-peroxide solution, and packed with iodoform gauze; subsequent drainage excellent, and closure of the wound at end of second week.

Mrs. X——, aged twenty-one years, married two years. Encysted hæmatocele, attended with suppuration, the result of ruptured ectopic gestation ten days previous to operation. Patient gave a history of sharp

[1] Read at a meeting of the Duval County Medical Society, Jacksonville, Fla., June 7, 1898.

pain in the left side of the pelvis some ten days previous to my being called into consultation. No history of pregnancy obtained, patient having menstruated regularly, though her last menstruation had been intermittent and prolonged, but not increased as to quantity. Temperature, 102.6° F.; pulse, 130. Upon examination a diagnosis of pelvic abscess, the size of a grapefruit, was made, although a suspicion of ruptured tubal pregnancy was entertained. Advised immediate operation. Incision into the sac let out a quantity of grumous liquid, blood clots, and broken-down tissue, which, when subsequently examined with the microscope, proved to be decidual tissue. Hemorrhage was considerable, to check which three serre-fine forceps were used, which remained on the sac wells for forty-eight hours. The patient made an excellent and uneventful recovery.

Ectopic or tubal gestation is of more or less general interest, inasmuch as one may at any time be confronted with this condition, and if rupture takes place and such remains unrecognized or unoperated upon, the result may be an untoward one. The hemorrhage may be into the folds of the broad ligament, or into a space formed by pre-existing adhesions—extraperitoneal and circumscribed in character; or free into the peritoneal cavity — intraperitoneal type, which does not concern us in this paper, except to state that it is almost invariably fatal if surgical interference by abdominal section be not immediately resorted to.

GONORRHŒAL PYELITIS AND PYELONEPHRITIS.[1]

By J. HENRY DOWD, M.D.,

GENITO-URINARY SURGEON TO THE BUFFALO HOSPITAL AND TO THE HOSPITAL OF THE SISTERS OF CHARITY, ETC.

Pyelitis or pyelonephritis, when secondary to gonorrhœa, and especially in the subacute or chronic stage, seems not to be recognized as readily as it should. The only excuse that can be offered is that authors say so little about it, some almost questioning such a malady being due to gonorrhœa in any stage.

Finger says: "This rare complication of gonorrhœa is also the least known;" but, on the other hand, Morris says: "Pyelonephritis, when secondary to disease of the bladder, is too often unrecognized until found at the post-mortem examination." Stimson[2] says: "In certain forms the affection may exist for months or even years, without giving rise to symptoms that attract much attention and without seriously affecting the health of the patient." The above statement is indisputable, and explains why such a condition can complicate a gonorrhœa without giving evidences of its existence. An individual is rendered a chronic incurable invalid, liable at any time to the serious complication of pyelonephritis, ending in the loss of one of the most important organs of the body. The misleading point has been in assuming that an inflammation of the bladder must precede an involvement of the kidney pelvis. I have in a number of cases found the bladder free from any involvement, the cystoscope showing only one or two reddish streaks, apparently under the mucous membrane, extending from the urethral to the ureteral openings. The condition appeared to be simple extension by the lymphatics, and not by continuity. As regards the symptoms, there seem to be two extremes—one where the onset is scarcely noticeable by the patient or his attendant, and the other where severe local and constitutional disturbances manifest themselves.

A daily visual, or possibly microscopical, examination of the urine from a gonorrhœal case is an absolute necessity. The microscope, however, is the only positive means of determining the involvement of the pelvis when the process is unaccompanied by severe constitutional symptoms. A chill, high fever, and full, bounding pulse, with excruciating pain in the back, may or may not be the first symptom present. There is frequency of urination, and if the secreting portion of the organ is involved the urine may be decreased in quantity to twelve or fourteen ounces in twenty-four hours. The face at times shows the effects of the involvement of these important organs. Great pallor, most anxious expression, twitching of the lips, and, in one case lately seen, purpura hæmorrhagica almost covering the entire upper part of the face are the symptoms noted. There is great prostration, the patient at times, owing to this and the pain, having to take to his bed. The urine is the only positive means of diagnosis, but the examination of it must be thorough. Blood is usually present, but at times in such small quantities that only a three-minute centrifugalization or the microscope will reveal its presence. Casts will generally be found—if not tubular, mucous cylinders showing kidney congestion. The pelvic epithelium, especially if in shingle-like form with clumping of the pus cells, is the most positive indication of pelvic involvement. Hyperacidity, with albumin in excess of that due to pus, is a constant condition. As the inflammation becomes chronic, anæmia, flabbiness of the muscles, nervousness, constant brooding about one's self, nightly calls to urinate, and a long train of other symptoms arise. It is not my purpose to speak of any but the acute condition, for it is only in this that a permanent cure can be hoped for. These patients can be cured if they are discovered early and heroic measures are used. Confinement to bed with milk diet is indispensable.

As a routine measure it is advisable to place several dry cups over each loin, and the bowels should be made to move every day. The main indications sought for with drugs are to lower arterial tension, increase the quantity of urine, rendering the same as unirritating as possible, and act on the pelvic and renal mucous membrane with an astringent. The above are carried out nicely and effectively by the administration of aconite, lithium citrate, and hamamelis, in large doses every three or four hours in a glass of water, preferably distilled. If the case is discovered early, recovery is prompt, even though the tubules have been extensively involved.

The urine should be watched for some time thereafter, as an indiscretion in diet or malt beverages may bring on a relapse; in fact, all food rich in the oxalate of calcium and liquors, except possibly a little light wine, should be avoided for months. A brief history of two cases will show the extremes to which the symptoms may manifest themselves.

Case I.—E. C——, referred to me in March, 1898, with a first gonorrhœa of two months' duration. Examination showed a free discharge; right epididymis swollen; both glasses of urine containing pus; no albumin, sugar, blood, or casts; no history of Bright's or any disease that would favor such a condition. Under appropriate treatment the discharge quieted down at once and the urine cleared. On the fifth day I noticed the upper part of the face and forehead covered with dark red blotches (purpura). The urine was very red, and upon examination I found an immense quantity of tubular casts, blood corpuscles, renal and pelvic epithelium. There was no doubt of the diagnosis of ascending pyelonephritis, and without a symptom noticeable to the patient, except possibly the dark red spots already referred to. When I closely questioned him as to the amount of urine passed, he said that for half a day he had made but very little water. It must be remembered that I saw this patient only twenty-four

[1] Read before the surgical section of the Buffalo Academy of Medicine, 1898.

[2] Morrow's "System of Genito-Urinary Disease."

hours before the examination that revealed the casts, etc. The before-mentioned treatment was at once ordered and examinations of the urine were made daily; not a cast or pelvic cell could be found on the fifth day. It is now about three months since the attack, and frequent examinations have failed to show any change.

Case II. will show the most aggravated symptoms. M. S——, gonorrhœa in 1886, no cystitis or epididymitis. Second attack in 1891; cystitis, but after a long siege entire recovery. Third attack in 1893. For two years there was blood following urination, when he was suddenly seized with severe pain in the left groin; the urine was thoroughly mixed with blood, and the patient had to pass the same every hour or so. As I did not see this case until about a year later, it is impossible to speak as to involvement of the secreting portion of the kidney, but on my first examination I found clumping of the pus cells and pelvic epithelium in shingle-like formation, the urine being cider-like in appearance, due to the pus. Deep pressure over the left loin caused slight pain, and cystoscopic examination showed a free discharge of pus from that side (left kidney). His mother having died of phthisis, a careful examination was made for tubercle bacilli several times, but none could be found. This case is incurable on account of its chronicity.

Of four or five cases lately seen by me, this is the only one that had any symptoms of cystitis and in which the cystoscope showed any bladder involvement. Several other cases showing symptoms even less pronounced than the first might be cited, but I think the above will suffice to show that it is always well to be on the lookout for serious conditions which can arise during the course of a gonorrhœa.

124 Franklin Street.

Progress of Medical Science.

Tuberculosis of the Kidney.—Speaking of the disease generally, Dickinson states that both kidneys are affected as often as one kidney alone, and only one case in seven occurs in which the disease does not affect other organs. Aldibert has collected twelve cases of children in whom nephrectomy was performed. Of these nine recovered and four died, two of the deaths not being traceable to the operation or to the original disease. No recurrence had taken place in one at the end of eight years, and none in another after three. Gross' tables give twenty instances of removal of the kidney at all ages for scrofulous disease; twelve patients recovered; eight, or forty per cent., died. Tubercle was limited to one kidney in only sixty-five per cent. In eight cases of preliminary nephrotomy relief was not afforded, so that this proceeding is not recommended. Morris, on the contrary, recommends that nephrotomy should first be tried in cases that are not advanced, in the hope that it may check progress by opening and draining the abscess cavity. Nephrectomy may be performed later if strength improves or if lardaceous disease threatens. He adds: "It is in the scrofulous kidney especially that we so much need the means of ascertaining the working-capacity of the other kidney, and it is in these cases also that the difficulty of doing so is almost insuperable." Gross, from this point of view, recommends the operation in an early stage by means of a ventral incision, by which both kidneys can be examined, and of which he states the mortality to be 14.28 per cent. against 53.84 per cent. by lumbar method. Newman's tables, published in 1888, record two cases of nephrotomy for this condition in children, both of whom ultimately recovered, though one (Morrant Baker's) subsequently had the kidney successfully removed; and five cases of nephrectomy, four of which ended in recovery. To these may be added a case of Wright's, in which at intervals nephrotomy, cystotomy, and nephrectomy were performed, the child dying with much ulceration of the bladder; and a case of Eve's, in which, in a child aged three years and nine months, nephrotomy was first performed, and seventeen days later the kidney was removed through a prolonged incision. The child recovered and was in perfect health seven months later. In the light of these results, it would seem that when abscess is large nephrotomy and drainage should first be tried, and later nephrectomy; but when indications of an early state of disease are tolerably certain, the two kidneys should be examined by means of a ventral incision, and if one be found healthy and the other extensively diseased, the latter should be at once removed.—John H. Morgan, The Lettsomian Lectures on "Affections of the Urinary Apparatus in Children," *British Medical Journal*, February 12th.

On the Concurrence of Enuresis Nocturna and Adenoid Vegetations of the Nasopharynx.—Dr. A. C. Groenbeck (*Jahrbuch fur Kinderheilkunde*, 1897) in the year 1892 observed twenty-two cases of enuresis among one hundred and ninety-two cases of adenoid growth in the nasopharynx. He operated in thirty cases of adenoids associated with enuresis, with the following results: Twelve patients were completely cured; in two of these enuresis recurred simultaneously with a new growth of adenoid tissue; fifteen were improved, two only partially; three were unimproved.

Surgical Suggestions.

Alexander's Operation.—The ligament is drawn out as far as possible, and while it is kept on a stretch two sutures of fine catgut are passed through it and the pillar of the external ring on either side. Then sutures are passed on both sides through the aponeurosis, then through either half of the ligament parallel with its long axis, or out through the aponeurosis again near the point of entrance. When tied, these unite the ligament firmly to the aponeurosis without constricting the former. The operation is completed in the usual way.—Calmann.

To Extract the Intubation Tube.—With the child in position, thrust the left index finger past the epiglottis, hook this up, rest the tip of the finger upon the two arytenoid cartilages, and carry the extractor point to the end of the left index finger at the pulpy portion generally regarded the most delicately tactile. The finger tips upon the arytenoids mark the posterior boundary of the glottis in the median line. Now, if the extractor point be carried along the median line to the end of the finger and the handle be elevated, the point will naturally be pried forward, from the end of the left index finger on the arytenoids into the aperture of the tube.—Northrup.

Stricture of the Urethra.—A tapering metallic instrument presents many advantages in the treatment by dilatation: (1) It enables the surgeon rapidly to pass several sizes of dilators at one sitting; (2) the flexible beak is serviceable in changing the direction of the point, which is a little manœuvre often of great advantage in penetrating a tortuous stricture; (3) the bulbous extremity assists the operator in determining that penetration has been successfully accomplished. —John Ward Cousins, *British Medical Journal*, January 8th.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 25, 1898.

SUNSTROKE AND ITS VARIED CAUSES.

SUNSTROKE, though known since early times, is even yet not well understood. The belief that to produce it the body, and particularly the head, must be exposed to the direct rays of the sun, has long since passed away, and it is now a matter of common knowledge that, although heat is the principal exciting cause, there are several other predisposing causes besides heat. Probably the foremost authorities on sunstroke are those surgeons in the British army who live or have lived in India, for the simple reason that they have there the best opportunities for observing the disease on a large scale. Sir Joseph Fayrer, one of the most eminent of these, in his monograph on the subject, says: "Under the designation of sunstroke, heat stroke, insolation, thermic fever, calentura, heat apoplexy, heat asphyxia, ictus solis, etc., a variety of morbid conditions from the simplest to the gravest are included. However these conditions may be modified by personal susceptibility, local surroundings, and climatic influences, they are all essentially due to heat, and are the result of a direct exposure to the rays of the sun or to a high atmospheric temperature in the shade." It may be said that the foregoing words express the universal opinion on the matter, but Dr. L. Sambon has quite recently promulgated a new theory as to the cause of thermic fever, in which the ever-active microbe plays the chief part. According to the distinguished Italian physician, thermic fever, or siriasis as he prefers to term it, is not heat fever at all, but a distinct infectious disease. He says: "I believe heat exhaustion to be nothing more than syncope and siriasis, a specific infectious disease." Again: "The idea that siriasis is due to excessive heat is greatly derived from the fact that it occurs during the hottest season of the year, but such an argument is manifestly illogical. Although siriasis be intimately connected with the hot season, it exhibits remarkable endemic characters. In one locality it is extremely prevalent, in another it is totally absent, though the region may be quite adjacent and under precisely similar climatic influences."

On the whole, Dr. Sambon makes out a strong if unconvincing case for the germ theory, and at any rate, be he right or wrong, his opinion must necessarily carry great weight. In the present state of things, however, interesting as the etiology of heatstroke naturally is, we are not so much concerned with the theoretical as with the practical side of the question. A large number of our troops will shortly be in the islands of Cuba and of the Philippines, countries in which the conditions are peculiarly favorable to the accident of heatstroke in one or other of its forms, and therefore it may not be out of place to cull from the writings of experienced men some precautions that should be taken to prevent its occurrence, as well as its treatment. Fayrer wisely remarks that "the principal object should be prevention. The clothing should be light and loose, and woollen material should be worn next the skin, as cotton or linen is decidedly harmful. The head and spine should be protected from the direct rays of the sun out of doors by a pith hat and a cotton pad let into the coat over the back of the neck and spine. The accoutrements should be as light as possible. Moderation in diet is especially to be enjoined; very little animal food should be taken, and the food, while sufficiently nutritious, should be light and unstimulating. Iced water, when procurable, should be drunk freely and frequently, and the greatest moderation in the use of stimulants should be observed; and finally strict attention should be paid to the bowels."

The treatment recommended in ordinary heat exhaustion is cold water dashed on the head and rest. For thermic fever, cold bath, cold affusions; quinine to be given internally, and, if quinine is not effective, phenacetin or some drug of a like nature. When insomnia is distressing hypnotics may be useful, but must be given with great caution, and opium avoided, if possible. But, although our soldiers in Cuba and the Philippines have our sympathy and have good reason to dread the heat, we must not forget that those on board a ship of war—and especially the engineers and firemen—are in this respect in a still worse plight. Of the fifty-nine cases of heatstroke that occurred in the United States navy in 1896, no less than forty of these were caused by heat in fire and engine rooms. Probably little can be done to ameliorate their condition to any extent or in the way of prevention, but a suggestion made by Dr. John D. Thomson might, if carried into effect in times of peace, be of benefit in treating cases of sunstroke. His idea is to have a room connected with the refrigerator, where the temperature could be gradually lowered and the atmosphere kept fresh and cool. We may, however, rest assured that, so far as the present war is concerned, the care of both our soldiers and sailors is in good hands, and that every necessary step will be taken to keep them in good health and to treat them efficiently when attacked by disease.

THE EARLIEST RECORDED DISCOVERY OF THERMAL SPRINGS.

THE science, or pseudo-science, as some hard-headed sceptics allege, of balneology is of comparatively modern development, although the empirical use of natural waters in the treatment of disease is of great antiquity. In former times, and even yet in certain places, the therapeutic efficacy of the waters was attributed to divine intervention. The curative action could not be explained logically by the temperature, the more or less nauseous taste, or the extraordinary

purity of the water; and so the cures obtained were regarded as miraculous, that being always an easy and perfectly satisfactory explanation of anything otherwise inexplicable. It is natural, therefore, that the first mention of thermal springs should be found in the religious records of the human race, and indeed this mention is made in the first book of the Bible, as we learn from a scholarly article by Dr. Prosser James, of London, which appeared some months back in the *Journal of Balneology and Climatology*.

Dr. Prosser James shows that the discovery was hidden from English biblical students through an amusing mistranslation in the King James version of the Old Testament. In the revised version (Gen. xxxvi. 24) we read: "This is Anah who found the hot springs in the wilderness as he fed the asses of Zibeon, his father." The Douai Bible has it, "hot waters," but the authorized version of the English Bible says that this was the Anah that found the "mules" in the wilderness, though why such a find of livestock should be regarded as so extraordinary as to entitle Anah to special mention among his fellows has never been apparent. We can readily understand, however, that the discovery of healing waters in a desert place should have been looked upon as an event of sufficient importance to serve as a distinguishing mark between this particular Anah and his uncle of the same name. There is some question as to the sex of this first of balneologists, but Dr. Prosser James proves quite satisfactorily that Anah was a man and one of the fathers-in-law of Esau. That the glory of having discovered a thermal spring, and not a few mules, properly belongs to Anah, is rendered still more probable by the fact that his second name and the one by which he was subsequently known was Beeri, derived from a word meaning well of water.

Having thus secured for Anah-Beeri the recognition of priority in this discovery, the author discusses the probable location of these springs, and comes to the conclusion that they were within the border of Edom, among the mountains of Seir. This range extends from near the head of the Gulf of Akaba to within about eight miles of the Dead Sea. In the chain of Seir there are many fertile valleys as well as uncultivated and uninhabited tracts, to one of which the word translated "wilderness" might well refer. Now "in this rugged mountain range," he says, "which has evidently been convulsed by the vast forces of nature, 'hot springs' would be likely to issue; and perhaps it was in one of these mountain valleys that Anah-Beeri first discovered the thermal spring,' as he fed the asses of Zibeon his father.'"

It seems more than probable that these waters were utilized medicinally, since in all ages springs of unusual character have been resorted to for the treatment of disease. The mere fact that these particular springs were warm would soon have lost its novelty, and the impression of surprise or awe created by their discovery would have faded, had not their reputation been sustained by the miraculous cures wrought through their saving power. We are entitled to conclude therefore, Dr. Prosser James thinks, that these thermal waters enjoyed a reputation for efficacy in the alleviation of suffering at the time the book of Genesis was written; "and that therefore the name of Anah-Beeri had been handed down with honor, and his great discovery distinguished him from his uncle Anah mentioned in this record, as well as from any one else of the same name."

The writer of this most interesting paper has proved himself to be a biblical student of rare acumen as well as a critical Hebrew scholar, and his article bears evidence also of the historian's talent for deducing broad facts from very slender clews. Such talents, so profitably cultivated, are rare to find in the members of our busy and practical profession—too rare, indeed, for a physician is none the worse for occasional excursions in fields other than medical.

INHUMAN WEAPONS OF WAR.

The above was the title of a paper read by Professor von Bruns at the German Surgical Congress recently held in Wiesbaden. The author refers to the dum-dum bullets, and asserts that he made a number of experiments upon dead bodies or portions of them, with these bullets supplied to the British troops during the recent campaign on the Indian frontier, and states that the results of their contact are fearful and cannot be exaggerated. The *British Medical Journal*, in answer to this charge, says: "The question of the special effects produced by the dum-dum, it will be remembered, was raised a short time ago in the House of Commons, and the reply of the government was to the effect that the reports as to the mutilating properties were erroneous, and that its effects were not those of an explosive bullet." Since the publication of the *British Medical Journal* containing the above report, two prominent surgeons in the British Indian army have given their views on the subject. Both agree that the dum-dum bullet is not explosive, but that its effects are much more harmful than those of an ordinary small-bore bullet; but they at the same time assert that a bullet wound from the old time Snider was much more destructive, and that under the regulations of the Geneva convention the dum-dum bullet can hardly be objected to as an inhuman weapon of war. However, an unofficial reply was made by the British government, that the dum-dum or expanding bullet would not be used against civilized troops. The fear has been expressed that the Spanish Mauser bullet may be transformed into a dum-dum; indeed, it is thought that such transformed bullets were employed by the Spaniards who harried our marines at Guantanamo Bay, for the mutilation of the dead was frightful, and according to the surgeon's report this was the result of the bullets and not of machete wounds inflicted on the dead by Spanish savages, as was at first believed.

"Annals of Gynæcology and Pediatry."—Dr. B. Sherwood Dunn, formerly of Paris, has become associated with Dr. E. W. Cushing in the editorial management and publication of the *Annals of Gynæcology and Pediatry*. Dr. Dunn is a graduate of Bellevue Hospital Medical College in 1884, and of the medical department of the University of Paris in 1888.

THE SPANISH MILITARY AND NAVAL MEDICAL ORGANIZATION IN CUBA.

According to the report of Dr. Angel de Larro Cerezo, surgeon-general of the Spanish troops in Cuba, the Spanish army and navy would appear to be remarkably well equipped and organized, from a medical standpoint. It is most probable, however, that the medical, like the military, equipment is chiefly on paper. In 1895, the surgeon-general says, hospitals were built in every province of the island. This work was carried on during 1896–97, until at the latter date the beds for the reception of patients numbered more than 45,000. It is stated that there are 11 hospitals containing more than 1,000 beds, while there are 8 with 1,000 beds each. The larger ones are the Royal, 5,000 beds; Alfonso XIII., 3,000; Manzanillo, 3,000; Beneficienza, 2,100; Santiago, 2,000; Sancti Spiritus, 2,000; Ciego, 1,700: Cienfuegos, 1,450; Remedios, 1,400; Holguin, 1,300; Mudera, 1,100; all these are well supplied with instruments and necessaries of every description, and each has also a perfectly equipped laboratory. In addition to the ordinary sanitary ambulance corps, a service of carriages is provided for the rapid conveyance of the wounded to the base hospitals in Havana, Santiago, Matanzas, Santa Clara, Manzanillo, Sagua la Grande, Trinidad, and Cienfuegos.

The Spanish navy is also amply provided with hospital ships; in fact, in this respect it would seem to be in advance of our navy, always assuming, of course, that the surgeon-general is not drawing on his imagination, after the example of his superior officers. Three of the best steamers of the Compañia Transatlantica Española, the *Alicante*, the *Montserrat*, and the *Sant' Ignacio Loyola*, were especially fitted up as hospital ships, and contain four large wards of ninety-six beds each, four smaller wards with seventy-six beds, four small isolation wards, and surgical wards for operations. The ships are lighted all over with electricity. To insure a supply of fresh air the portholes are kept open when weather permits, and there are as well a number of large air pumps. Each vessel carries a large quantity of drugs; baths are also provided, while for the convalescent there is a large and comfortably furnished saloon. On the three ships accommodation is found for fifteen hundred patients. During the first two years after the erection of the hospital of Alfonso XIII., eighty thousand patients were admitted into its wards, and more than a thousand operations were performed. In 1897, the third year of its existence, fewer patients were treated, and at the same time the rate of mortality decreased. The cause of this diminished death rate is ascribed to increased hospital space for each patient, which is secured by the early removal of convalescents to the annex and hospital ships.

The report states that the medical staff in Cuba has suffered severely within the past three years. The total number of deaths among physicians in the service of the army and navy since the beginning of the rebellion has been fifty, of which number more than two-thirds have been the victims of yellow fever.

News of the Week.

The Otto Vahlbruch Prize Awarded to Roentgen.—The University of Gottingen has awarded the Otto Vahlbruch prize for the greatest advance in science during the past two years to Professor Roentgen, of Würzburg. The prize is of the value of 9,200 marks ($2,250).

The American Academy of Medicine.—At the annual meeting of this society, held in Denver on June 6th, under the presidency of Dr. L. Duncan Bulkley, of New York, the following officers were elected for the coming year: *President*, Dr. Edward Jackson, Denver; *First Vice-President*, Dr. W. L. Estes, South Bethlehem, Pa.; *Second Vice-President*, Dr. J. T. Searcey, Tuscaloosa, Ala.; *Third Vice-President*, Dr. William Elmer, Trenton, N. J.; *Fourth Vice-President*, Dr. Robert H. Babcock, Chicago; *Secretary* and *Treasurer*, Dr. Charles McIntyre, Easton, Pa.; *Assistant Secretary*, Dr. W. L. Pyle, Philadelphia.

The Hospitality of Idaho Springs.—The American Medical Association may well feel proud of the welcome accorded it in the West, and of the unstinted hospitality displayed by the people of the various localities visited by its members. It was generally agreed that one of the most remarkable of the striking features of the memorable excursion around "The Loop" was the manner in which the people of Idaho Springs received and entertained upward of two thousand visitors. The whole town turned out—ladies, children, and all—and made the occasion one huge lawn party, in which all were individually welcomed and made happy; yet it was done with such an absence of apparent effort that the guests became possessed with the notion that such wholesale entertainment must be a part of the every-day life of that town. It was one link in a chain of many pleasant recollections which the visiting members carried home with them.

The Hospital Ship "Relief" was inspected on last Sunday by Surgeon-General Sternberg, who found everything in good order and ready for service. A large quantity of medical stores has been put aboard, and it is expected that the ship will have sailed by the time this appears. It is intended to station the *Relief* off Santiago for the present.

A Red Cross Supply Boat.—The relief committee of the American National Red Cross has purchased the steam yacht *Admiral* for use as a medical supply boat. The vessel is 134 feet 6 inches over all, 117 feet on the water line, and 20 feet beam. She draws eight feet and has a very high freeboard. The bottom is copper-sheathed, adapting the boat for cruising in Southern waters. The *Admiral* has stateroom accommodations for twenty-five persons, and is equipped with an electric-light plant, including a very powerful searchlight. Besides the usual complement of boats, she carries a naphtha launch. As soon as the supplies are on board the boat will be sent to Jacksonville, where she will take in tow the relief launch *Moynier*.

The launch will be taken to Key West, where both boats will await instructions from Miss Clara Barton, who is on the way to Cuba, having followed the transports on the relief ship *State of Texas*.

A Hospital on Jekyl Island.—Mr. David H. King, Jr., of this city has offered the use of his summer home on Jekyl Island as a hospital for sick and wounded sailors, and has offered to defray all expenses incurred in fitting the place up and maintaining it as a hospital. Jekyl Island is off the southern coast of Georgia and a short distance from Brunswick. There is some doubt, however, concerning the establishment of the hospital, as objections have been raised by other and less patriotic members of the club owning Jekyl Island.

A Massachusetts State Hospital Ship.—The Massachusetts Volunteer Aid Association has obtained on appropriation of $50,000 from the State legislature toward the equipment and maintenance of a hospital ship. A vessel has already been purchased and is now being fitted out. The name of the boat will be the *Bay State*, and she will sail under the Red Cross flag. She will be well stored with medical supplies, and will have on board surgeons and trained nurses ready for any emergency of battle or disease. She will also serve as a transport to bring back sick or wounded soldiers, either from Cuban battlefields or from Southern camps, to hospitals or places of refuge nearer their homes in the invigorating climate of Massachusetts.

The Sanitary Service at Camp Alger.—Some green newspaper correspondents having reported that the sanitary condition at Camp Alger was bad, an inquiry was instituted, with the result of disproving the assertion. General Graham reported that the chief surgeon of the second army corps, Lieut.-Col. A. C. Girard, "is a most competent and efficient officer professionally. His administration is entirely satisfactory. The friends of the soldiers may rely upon his ability to administer the affairs of the medical department with sound judgment and conscientious attention to their wants."

The Post-Graduate Hospital.—A special committee of the State board of charities appointed to investigate the affairs of the New York Post-Graduate Hospital held a session at the rooms of the board, in this city, on Monday afternoon of this week. The committee consists of Messrs. T. G. Bergen and J. V. Dahlgren, and Dr. Stephen Smith. The investigation grows out of the charges made last winter, by a former director of the hospital and professor of surgery in the medical school, that $85,000 of endowment funds had been used to pay the current expenses of the hospital and also that the directors were overcharging the city in the matter of free patients.

The Health of the Pope is again reported to be precarious. Dr. Lapponi asserts, however, that his illustrious patient is suffering merely from slight muscular rheumatism in the shoulder and that he has resumed his usual audiences.

Obituary Notes.—Dr. Richard C. M. Page, of this city, died in Philadelphia on Sunday last, after a brief illness. Dr. Page was born in Virginia in 1840, and was graduated in arts from the University of Virginia. He served during the civil war in the Confederate army, and upon the conclusion of peace came to New York to study medicine, being graduated from the University Medical College in the class of 1868. He was specially interested in diseases of the thoracic organs and filled a chair on these subjects in the New York Polyclinic, besides having published a number of monographs on cardiac and pulmonary affections. He was a member of many medical, historical, and social organizations.—Dr. Eben Jackson, of Somerville, Mass., died at his home in that place on June 22d, at the age of seventy-three years. He was born in Boston, and received his medical degree from the Castleton Medical College, Vermont, in 1856. He served as a surgeon in the Union army under Grant, and had charge at different times of many hospitals at Memphis, Vicksburg, and elsewhere. Owing to a belligerent impulse, which he had inherited from a line of fighting ancestors, he took an active part in several battles, filling the place of some fallen combatant, and earned thereby the sobriquet of the "fighting doctor." After the close of the war he retired to civil life, and had practised for many years in Somerville.

The Late Dr. John Blair Gibbs.—At a meeting of the Society of the Alumni of Lebanon Hospital held on Tuesday, June 14th, the following resolutions were passed:

"*Whereas*, We have learned with profound sorrow and regret of the death of Dr. John Blair Gibbs at Guantanamo, Cuba, we feel that we should express ourselves in a manner whereby his memory may be honored. Not only has a vacancy been made among ourselves which can never be filled, but the medical profession has lost a true brother and the nation a son whose manliness, noble character, and zeal can never be questioned; and

"*Whereas*, We have constantly been indebted to him, while acting in the capacity of assistant attending surgeon at Lebanon Hospital, for valuable council and unfailing courtesy: we therefore

"*Resolve*, In order to perpetuate his name for his heroic conduct and as a token of our esteem and love, to erect a tablet in the operating-room of Lebanon Hospital, and to enter these resolutions in full in the minutes of the meeting."

[Signed] M. L. Maduro, M.D., *Secretary*.

In Memory of Dr. Gibbs.—Services in memory of Dr. John Blair Gibbs, who was killed at Camp McCalla, Cuba, on June 12th, were held in Trinity Church on Thursday afternoon of this week. Very many of Dr. Gibbs' social and professional friends, members of the Delta Kappa Epsilon Fraternity, and others were present to do honor to the memory of the first American surgeon killed in this righteous war.

A Civil Service Examination for a Bacteriologist will be held in the new criminal court building, corner of White and Centre streets, on Wednesday,

June 29th. The examination will be conducted to determine both technical knowledge and experience. Candidates desiring further information should address Lee Phillips, Esq., secretary of the municipal civil service commission.

Laryngological Section of the American Medical Association.—At the meeting of the section on laryngology and otology of the American Medical Association, held at Denver, June 7th to 10th, the following were elected as officers for the ensuing year: *Chairman*, Dr. Emil Mayer, of New York City; *Secretary*, Dr. C. R. Holmes, of Cincinnati, Ohio.

The First Nathan Lewis Hatfield Prize.—The College of Physicians of Philadelphia announces through its committee that the sum of $500 will be awarded to the author of the best essay in competition for the above prize, on "A Pathological and Clinical Study of the Thymus Gland and its Relations." The essays must be submitted on or before January 1, 1900. The treatment of the subject must, in accordance with the conditions of the trust, embody original observations or researches or original deductions. The competition shall be open to members of the medical profession and men of science in the United States. Further information may be obtained by addressing Dr. J. C. Wilson, M.D., 219 South Thirteenth Street, Philadelphia, Pa.

The Texas State Medical Association.—The war spirit has apparently taken possession of some of our scientific bodies. We referred recently to the disgraceful scene enacted at the meeting of the California State Medical Society, and now we learn from the *Texas Medical Journal* that "the thirtieth annual session of the Texas State Medical Association at Houston, April 28th, 29th, and 30th, was enlivened by a fist fight on the rostrum. A big burly fellow from Galveston sought to whip the secretary (as we are informed), for calling him a liar out loud in meeting, when he had risen to a point of personal privilege and complained, as we learn, of having been dropped from the roll of membership for non-payment of dues (in accordance with the bylaws)."

Harlem Medical Association.—The following officers were elected at the ninth regular meeting of this society, June 13th: *President*, Dr. Philip Arthur Malleson; *Vice-President*, Dr. Henry W. Mooney; *Secretary*, Dr. Joseph E. Lumbard; *Treasurer*, Dr. Charles A. Clinton; *Trustees*, Dr. David Franklin, Dr. Samuel E. Gibbs, Dr. Henry J. Wolf.

The Chicago Society of Internal Medicine is the name of a society recently organized by a number of physicians in Chicago. In the circular of invitation for charter members it is stated that charter membership will be limited to gentlemen of reputation in internal medicine, and future admissions will be by approved thesis, the object being to lay the foundation for a society of the highest grade. It is thought that eventually the society will become the section of internal medicine of the Chicago Medical Society, but with autonomy in the management of its internal affairs. The officers for the first year are the following: *President*, Dr. John A. Robison, *Vice-President*, Dr. John H. Hollister; *Secretary*, Dr. Edward F. Wells; *Treasurer*, Dr. Lester Curtis; *Censors*, Drs. Henry M. Lyman, Henry B. Favill, and Arthur R. Edwards.

"Illustrirte Rundschau der medicinisch-chirurgischen Technik."—This is the title of a new quarterly publication devoted to descriptions of new instruments and apparatus of all kinds for use in medicine or surgery. It is published in Berne by K. J. Wyss, under the editorial management of Dr. Gustav Beck, assisted by a number of Swiss, French, and German practitioners.

Hospital Improvements.—Plans have been filed at the department of buildings for new buildings of the New York and the Roosevelt Hospitals. At the latter there will be erected a two-story structure, to be known as the accident building. At the New York Hospital there are to be three new buildings. Two of these, a large annex to the main hospital building and a two-story structure for the use of the governors of the hospital, will be on Sixteenth Street, and the other, for the accident service and the laundry, will be on Fifteenth Street. The estimated expenditure for the three buildings will be $500,000.

The Caleb Fiske Prize of the Rhode Island Medical Society, of the value of $350, has been awarded to Dr. David A. Wolfstein, of Cincinnati, Ohio, for the best essay on the subject, "The Neuron Theory as Related to Nerve and Brain Disease in the Light of the Most Recent Investigations." The subject for the next essay is "The Etiology of Gout."

Training-School of the Manhattan Hospital.—The first annual graduation exercises of the training-school for nurses of the Manhattan State Hospital for the Insane were held on Ward's Island on the afternoon of Monday, June 20th. An address was made by Bishop Potter, of New York.

Contract Medical Practice.—The following is the text of the resolutions adopted by the Connecticut State Medical Society at its one hundred and sixth annual meeting, in New Haven, on May 26th:

"*Resolved*, That the Connecticut Medical Society declares it to be derogatory to the dignity of its members to render professional services at a stipulated fee per capita per annum, to the members of any lodge, society, association, or organization, or to enter into any contract for such services with any lodge, society, association, or organization, provided that professional services rendered any hospital, dispensary, orphan asylum, town poor, or other public charity, shall not be prohibited by this act.

"*Resolved*, That any member of this society violating the above resolution is guilty of a breach of professional etiquette, and is subject to the rules and regulations governing the same."

At this meeting the following officers were elected for the ensuing year: *President*, Dr. H. P. Stearns, of Hartford; *Vice-President*, Dr. C. S. Rodman, of Waterbury; *Secretary*, Dr. N. F. Wordin, of Bridgeport; *Treasurer*, Dr. W. W. Knight, of Hartford.

Dr. Edward G. Janeway, of this city, president of the Academy of Medicine, received the degree of LL.D. from Rutgers College on June 21st.

An Accident to the Surgeon-General.—According to a report in *The Sun*, while Surgeon-General Sternberg was riding along the beach at Hillsborough Bay, one evening recently, his horse stumbled and fell into the water, carrying the rider with him. The surgeon-general could not withdraw his feet from the stirrups, and might have been drowned or trampled to death had it not been for the prompt assistance of Private Bronk, of the New York volunteers, who jumped into the water and disentangled the officer.

The Johns Hopkins Medical School.—Twenty-two medical students were graduated from the Johns Hopkins Medical School this year. Four of these were women. Dr. Osler will be dean of the school in place of Dr. Welch. Drs. T. C. Gilchrist and J. W. Lord have been made clinical professors of dermatology, and Dr. Louis E. Livingood has been made associate in pathology.

Association of American Medical Colleges.—At the annual meeting of this association held in Denver, June 6th, the following officers were elected: *President*, H. O. Walker, of Detroit: *Senior Vice-President*, Dr. H. Bert Ellis, Los Angeles; *Junior Vice-President*, Dr. G. E. Woody, Louisville; *Secretary* and *Treasurer*, Bayard Holmes, Chicago.

Canadian Medical Association.—The thirty-first annual meeting of this society will be held at Laval University, Quebec, on August 17, 18, and 19, 1898. Those members who purpose reading papers are requested to send the title of the same to the secretary on or before July 20th. The president of the association is Dr. J. M. Beausoleil, and the secretary, Dr. F. N. G. Starr, 471 College Street, Toronto. The society has a membership of between six hundred and seven hundred.

A Chinese Plague Hospital.—The sanitary board of Hong Kong has given permission to the Tung Wah Hospital to establish a branch for the reception of plague sufferers, in which the patient will have the option of being treated according to Western medical methods or those of the Chinese physicians. This action was taken, despite the protests of the medical members of the board, in the desire to humor the prejudices of the native population. The results may be of educational value to the Chinese, since the mortality of plague under native methods of treatment is nearly double that of the disease under European management.

A "Non-Combatant."—Surgeon-Captain Hopton Scott, of the British army, is happily recovering, at St. Thomas' Home, from the effects of severe wounds received during the recent expedition in West Africa. We read concerning him in the *British Medical Journal* that, like his distinguished brother officer at Majuba Hill, although his left femur was smashed by a heavy slug, and another missile of a like formidable kind had torn his chest without actual penetration, he stuck to his duty, and, while prostrate on a stretcher and severely tortured by his wounds, he continued to give surgical aid to his wounded comrades.

The Pasteur Monument.—The *British Medical Journal* says that the monument to Pasteur, which is to be erected in Paris in the space in front of the Pantheon, is now almost completed. M. Falguière, the sculptor, has introduced certain modifications into his original design, in which Pasteur was simply represented as overcoming death, which was in the act of flight. Now a group of a mother with her child, thanking Pasteur, has been added on the right, while behind the central figure Fame is shown crowning him with laurels. The international subscription to the memorial now amounts to nearly $65,000.

Dr. Senn Ordered to Cuba.—Col. Nicholas Senn, M.D., of Chicago, chief surgeon of the volunteer forces at Chickamauga, has been ordered to Newport News to embark for Santiago. He will be chief surgeon of the reinforcements to be sent to General Shafter from Camp Alger.

The Yellow Fever Quarantine against most of the Gulf towns has been raised by the Mobile board of health. The disease has shown no tendency to spread from McHenry.

Infantile Syphilis.—Dr. John T. Nagle, chief of the bureau of municipal statistics of New York, writes that at the forthcoming meeting of the Royal Society of Public Medicine of the Kingdom of Belgium, in July next, in Brussels, there will be a discussion on infantile syphilis, and strenuous efforts are being made to obtain as accurate and complete information on this subject as possible. The results of this investigation that the society is making, Dr. Nagle thinks, will be of interest to the medical profession in general, and he would be thankful if those who have devoted much time to this subject would furnish him immediately with any facts that they possess which bear on the inquiries that are made by the society. The questions are as follows: 1. Do you meet with cases of infantile syphilis in your practice: if so, how frequently? 2. In what year did your observations begin? 3. In the cases which you have been able to follow, was the disease slight in degree or was it so severe as to produce pronounced cachexia? Please state, if you remember them, the lesions present. 4. What age, approximately, were the children? 5. What was the result of the disease? 6. Were you ever able to trace it to its source, heredity or contagion, from parents, nurses, etc.? 7. Is syphilis rare or frequent in the locality where these infantile cases have been observed? 8. Do you often see children, born of syphilitic women, who present no characteristic lesions of the disease during their early years? 9. If you have collected any special observations on the placenta in syphilitic women or those who have been cured of the disease, kindly mention them. The answers to these questions may be sent to Dr. Nagle, 346 Broadway, New York City, who is a corresponding foreign member of the society.

Reviews and Notices.

Air, Food, and Exercises. An Essay on the Predisposing Causes of Disease. By A. Rabagliati, M.A., M.D., F.R.C.S. *Ed.*; Honorary Gynæcologist and late Senior Honorary Surgeon, Bradford Royal Infirmary; Consulting Medical Officer, Bradford Children's Hospital. Second Edition. New York: William Wood and Company. 1898.

This is a thoughtful essay on the question of improper feeding as a cause of disease. The author regards the excessive consumption of carbohydrates as the cause of most of the minor, and some of the major, ills of humanity. Since a generic name is necessary for the condition resulting from the retention of waste products in the economy, Dr. Rabagliati gives us "triphthæmia," the commonest species of which, he thinks, is "triphthæmia carbonifera" due to overeating of starchy foods, especially bread. His theory of the cause of all our woes appears to be just the opposite of Haig's, and his arguments in support of his theory are just as little convincing. But though one may not accept the author's views in their entirety, the reading of the book is interesting and gives food for reflection. And this is praise enough for any book.

Therapeutics of Infancy and Childhood. By A. Jacobi, M.D. Philadelphia: J. B. Lippincott Company. 1898.

The second edition has just been received; it is modelled on the lines laid out in the first one. While this last edition contains fifteen chapters, the first one contained fifteen chapters plus an appendix. The arrangement has been slightly altered, the wording is exactly the same. The author states in the preface to this new edition that "the criticisms of reviewers and correspondents have been carefully considered." We had hoped that this would at least apply to the review in the Medical Record, March 21, 1896, which the author has possibly overlooked.

While the author constantly thunders against the propriety of using patent foods, we find this distinguished gentleman recommending a patent food on page 43, the same food on page 57, and finally he regards it as so valuable that on pages 57 and 58 he believes it useful per rectum. *Deus!*

The value of the book would certainly be enhanced if the author would eliminate personalities. This book is certainly a personal one, for Jacobi insists on all his former hobbies. So, for example, he dwells in great detail on the excellent value of mercury in diphtheria, stating that some physicians refused antitoxin when offered the same, owing to "success with mercury and intubation." The work may truly be called up to date and contains many valuable points, all of which are not to be found in the first edition. The author gives many therapeutic suggestions of value. In the section dealing with the treatment (surgical) of empyema, all details from a modern aseptic standpoint are carefully considered.

We note with extreme regret that but a few lines are devoted to intubation of the larynx, and that the author has omitted to give the careful details of this most valuable method of relieving laryngeal stenosis. It certainly deserves a place in the therapeutics of infancy and childhood.

Mammalian Anatomy. A Preparation for Human and Comparative Anatomy. By Horace Jayne, M.D., Ph.D., Director of the Wistar Institute of Anatomy and Biology, Professor of Zoology in the University of Pennsylvania, etc. Part I. The Skeleton of the Cat: Its Muscular Attachments, Growth, and Variations compared with the Skeleton of Man. With over 500 original illustrations. Philadelphia: J. B. Lippincott Company. 1898.

In taking up this ponderous tome of over eight hundred pages one might ask, as in primer days, "What is this?" to receive the laconic reply, "This is a cat." But in truth it is not the whole cat; it is upon his bones alone that the author has published this immense volume, the value of which any one interested in comparative osteology cannot fail to appreciate.

It is a very thorough, careful, and exhaustive study, ranking with Ecker's "Frog," Mivart's "Dog," and other classics in comparative zoology. The illustrations are numerous and excellent, and the typography and bookwork all that could be desired.

It is by such studies that advanced work in anatomy may be accomplished, and it is a pleasure to know that work of such high grade is coming from one of our universities.

The Nervous System and its Diseases. A Practical Treatise on Neurology for the Use of Physicians and Students. By Charles K. Mills, M.D., Professor of Mental Diseases and of Medical Jurisprudence in the University of Pennsylvania, Clinical Professor of Neurology in the Woman's College of Philadelphia, etc. Diseases of the Brain and Cranial Nerves, with a General Introduction on the Study and Treatment of Nervous Diseases. Philadelphia: J. B. Lippincott Company. 1898.

This volume, constituting but a partial accomplishment of the author's ambition in the way of a treatise on the diseases of the nervous system, is one of the most promising works along this line that have been published in this country or abroad. In fact, when compared with the only works along similar lines, Gowers' or von Monakow's, the advantages are, we believe, with Dr. Mills. In one thousand and fifty well-used pages there is to be found an ample, clear, and thoroughly scientific treatment of the anatomy of the nervous system; the general pathology, symptomatology, and methods of examination; diseases of the membranes, veins, and sinuses; histology of the cortex and physiology of the cerebrum with reference to focal diseases of the brain; vascular lesions and disturbances in the brain, and their following degenerations; lesions of the special nerves of sense and their affections; disturbances of the ocular apparatus due to nuclear or peripheral lesions; diseases of the facial and the fifth; lesions of the pons and preoblongata; diseases of the glosso-pharyngeal, pneumogastric, spinal accessory, and hypoglossal nerves; and lesions of the postoblongata and bulbar regions.

The book throughout bears the impress of ripe and careful scholarship, and moreover it represents modern neurology in its present garb. It would be impossible in the space at our disposal to mention all of the commendable features of the book, but a few have impressed themselves upon the reviewer's notice as of especial service to the general practitioner. The chapter upon the general means that the physician has at hand for the treatment of diseases of the nervous system is one of great value; the discussion on the actions of the chief drugs used in neurological work, what they can do in ordinary use and what results from overdoses, are facts worth having in the shape in which they are presented. The chapter upon the minute anatomy of the cortex and the discussion on cerebral localization is very valuable—the latter part perhaps more than the former, where the author makes little use of the newer cytological work bearing upon the structure of the nerve cells. The discussion of the affections of the ocular and auditory apparatus is masterly, from the neurological standpoint at least, and cannot fail to be of value to the specialist in these fields. We are not in thorough sympathy with nomenclatural cataclysms, and feel that frequently the old and familiar is clothed in new terms for the sake of lending an air of novelty and an apparent gloss of "science." Still in the biological sciences nomenclature forms one of the most important landmarks of progress, especially when by it newer and wider conceptions are gained. We believe, however, that in the adoption of the "Wilder" terminology the author has departed from a healthy historical conservatism, but this is perhaps but an academic matter after all.

All in all, the work is to be most heartily commended and deserves a generous recognition of its many estimable qualities.

Celluloid Bandages.—Celluloid has been suggested as a substitute for plaster of Paris, its weight being less than one-fourth that of the former. It is readily cleaned, has a smooth surface, and is impervious to urine and discharges. Cut into small pieces, celluloid is dissolved in acetone. This solution is rubbed into each layer of gauze bandage or jacket, a kid glove being worn to avoid the celluloid drying on the skin. Ten layers are necessary. Three or four hours are required in drying. Small holes may be punctured for ventilation.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—CYSTS OF THE URACHUS—CANCER OF THE UTERUS—INJURY TO THE URETERS IN OPERATIONS—DEATHS OF THREE VETERANS.

LONDON, June 3, 1898.

THE session of the Medical Council closed on Tuesday. A good deal of routine business was got through, in which your readers would take no interest. The register was purged by the exclusion of some found guilty of infamous conduct. One of these had associated himself with a "Professor Munyon," a notorious advertiser of quack medicines, whose advertisements have disfigured the newspapers which disgrace the press by accepting his pay.

Mr. Horsley is by no means satisfied with the manner in which it was determined to obstruct members in their investigations into the history of the council, and we shall doubtless hear more on the subject.

The promoters of the midwives registration bill were allowed to state their case, but the council cannot depart from the position it has taken.

A second interim report of the medical-aid-associations committee was presented, but does not advance the settlement of this burning question. Conciliation is recommended and consideration of local circumstances. The great friendly societies express a wish to meet the views of the council, and are certain to receive every consideration from the profession, but the tooting of societies got up to trade on practitioners will have to be put down.

The council appointed a deputation to urge on the government to insert in the companies act now before Parliament a clause to prevent medical, surgical, and dental practice being carried on by companies.

The case of unqualified assistants was brought forward, but, though hardship to certain individuals is unavoidable, the council was unable to alter the decision, of which notice has been given, that it cannot sanction unqualified practice.

The dental curriculum and examinations received a large share of attention.

The president was requested to communicate with the privy council as to the practicability of amending the laws, so as more effectually to prevent the holder of a medical diploma from using it after his name has been removed from the register.

At the Medico-Chirurgical Society Mr. Doran read a paper on a case of cyst of the urachus, with notes on urachal and so-called allantoic cysts. He remarked that a good deal had been written on these cysts, both in America and in Germany, but the term had been applied too freely to various tumors and collections of fluid closely related to the abdominal walls below the umbilicus. He mentioned some of the explanations which have been put forward and the difficulties attending them. Many of the older cases reported as "urachal" are more than doubtful. They really read like cases of encysted dropsy. It may even be doubted whether Tait's cases are certainly of allantoic origin. Other cysts may very closely resemble urachal cysts, as may collections of fluid in tuberculous peritonitis.

As to the surgery of true urachal cysts, Mr. Doran thinks that when they can be dissected out the peritoneum detached from behind should be trimmed away, as it is apt to slough. When they cannot be enucleated, they should be incised and drained. The relations to the peritoneum, bladder, and viscera must be most carefully determined. If the cyst communicates with the bladder, the principles of plastic surgery must be applied. Every case must be carefully watched, as after operation the bladder may give way through the forcing open of the vesical orifice of the urachus or through yielding of its walls from damage during operation or the presence of a drainage tube.

The president, Mr. Bryant, mentioned two cases which puzzled him when he operated some years ago, but which Mr. Doran's paper convinced him had really been urachal.

The unreliability of microscopical examination for determining malignancy was well shown at the Harveian Society's meeting on the 12th ult., when Dr. Handfield-Jones read a paper on cancer of the body of the uterus, and admitted that diagnosis at an early stage was so difficult that he asked whether benign growths, after remaining stationary for long periods, might ultimately take on malignancy and rapidly destroy the patient. Uterine scrapings obtained by curettage and carefully examined by the microscope could not be trusted to settle the diagnosis. Dr. Jones admitted that the microscope might sometimes confirm the diagnosis from clinical signs and symptoms, and so far afford some satisfaction; but the gravity of the case and the need for operation must be estimated from the clinical aspects. He laid stress on the early symptoms, and especially on rapid increase in the size of the uterus.

In the discussion that followed all the speakers agreed that the microscopical examination is very unreliable. The president, Dr. Goodhart, said that a growth at the menopause is more likely to be malignant than benign, and he was convinced that simple growths may eventually become cancerous. On the other hand, the growth of cancer sometimes is delayed for months or even years. In hepatic cancer it may even shrivel up and practically disappear. This makes it difficult to decide whether extirpation of the uterus should be performed as soon as malignancy is manifest. As to this, the mortality of vaginal hysterectomy is a point for consideration.

Dr. Gow said that if a soft, well-defined growth is found inside the uterus with hemorrhage after the menopause, it is safe to regard it as malignant and act accordingly.

Dr. Amand Routh advocated the removal of any uterus after the menopause when there is recurrence of metrorrhagia after curettage, with definite enlargement of the body of the uterus, although surface scrapings give a negative result. Ordinary senile or fungous endometritis does not cause progressive enlargement; it may occasionally recur, but it can be cured by a second curetting.

Mr. Parker Young said he had found, in undoubted malignant disease of both the uterus and the breast, that the microscope failed to detect it. As to the time the patients might live, he said that in one case pronounced to be malignant by leading gynæcologists the patient has survived over ten years without operation.

One of the dangers of hysterectomy is the risk of injuring the ureters. This was discussed by the Gynæcological Society apropos of a case related by Mr. Purcell. The operation was followed by anuria. Falling temperature and vomiting denoted the approach of uræmia, and the abdominal wound was reopened and the ureters were examined. They were ballooned. The ligatures of the uterine arteries were removed; no blood followed, but the ureters diminished and catheterism obtained urine from the bladder. It was proved that both ureters were pervious; neither had been tied, but both were kinked by the gathering up of the tissues in the ligatures. Dr. Purcell was congratulated on the case, especially on having avoided tying the ureters, and on the decision to

reopen the wound and determine the cause of the anuria.

The president (Dr. Macnaughton-Jones) remarked that the two chief risks of hysterectomy were injury to ureters and hemorrhage. The parts were often so altered that anatomy alone did not afford sufficient assistance. He had written to several operators and obtained statistics as to damage to the ureters, and laid the letters before the society. They comprise interesting experiences from Martin, Landau (Berlin), Doyen (Paris), and Kufforath (Brussels).

The death is announced of Dr. Melson, aged eighty-seven. He was a Cambridge man of great culture, who practised for many years in Birmingham, was one of the original physicians to the Queen's Hospital, and professor at the college. When in full practice he also preached for the Wesleyan Church in many parts of the country, and his able sermons never failed to attract large congregations.

Dr. Thomas G. Wright—a nonagenerian, born in February, 1808—died on the 27th ult. He was for sixty-seven years consulting physician to the Wakefield Asylum. He was also physician to the Clayton Hospital and other institutions. He wrote on the blood and on cholera, and took great interest in the progress of various sciences.

Another veteran, Dr. Heckscher, died on the 29th ult., aged seventy-four. He practised for many years in Manchester, where he was greatly esteemed by his German compatriots. He was M.D. of Berlin, 1847; of St. Andrews, 1858; and M.R.C.P. Lond., 1860; and retired about two years ago.

OUR PARIS LETTER.

(From our Special Correspondent.)

BICYCLING AND FEMALE EDUCATION—THEIR INFLUENCE FROM A SOCIAL AND MATRIMONIAL STANDPOINT—INJURIOUS EFFECTS OF BICYCLING ON THE PELVIC ORGANS IN YOUNG WOMEN—DISORDERS AT THE ÉCOLE DE MÉDECINE—PROFESSOR BROUARDEL—BICARBONATE OF SODIUM IN HYPERCHLORHYDRIA—ANTIPYRIN AND THE ALKALIES IN DIABETES, ETC.

PARIS, June 5, 1898.

THE danger of bicycling to health, especially in young women attaining the age of puberty, and young married women as well, is so great that leading members of the profession in Paris are quite outspoken against its use, and many go so far as to interdict it altogether. I refer to danger only in the medical and pathological signification of the term, leaving to one side the danger from accident, which is obvious, the production of vulvo-vaginal and uterine disease, external bruises, abrasions, and contusions, menorrhagia, metrorrhagia, vulvitis, displacements, cellulitis, and a variey of pelvic and abdominal troubles, cases of which have been reported as directly due to bicycling; to say nothing of aggravation of morbid conditions already existing, whether it be the heart, kidneys, or other organs that are affected. There is an evil, social and matrimonial in its bearing, that is springing up in France, and which is beginning to tell upon the decrease in its male population, affecting thereby the numerical strength of the large army that European armed peace obliges her to maintain. The education of young girls to-day comprises not only studies hitherto regarded as more suitable to the male sex, but athletics and out-of-door exercises as well, and sports generally, of which the bicycle forms a prominent part. Becoming wedded to these, especially the latter, they have little desire for matrimony, which they come to regard as a chain or kind of bondage—certainly a restriction and check upon liberty. Consequently they prefer to remain spinsters, and a quasi third sex is formed—young horsewomen, wheelwomen, tennis and golf champions, fisherwomen, hunting-women, yacht-women, and "all-around sport" women. The sex masculinizes itself. Womanhood in its physiological and motherly sense is sacrificed to narrow hips, atrophied breasts with retracted nipples, and a development of brachial, leg, and abdominal muscles that would do credit to a "light weight."

This production of a third sex is a bit of practical philosophy, evolved from the manners and customs of the century that is just ending.

Another of those boisterous, and it may be said, scandalous demonstrations to which professional Paris is accustomed, has just occurred at the Faculty of Medicine. It was at the recent competition of "*agrégation*" in anatomy. The medical students, blaming energetically the conduct of Prof. Raphael Blanchard with reference to Dr. Heim, who is professeur agrégé, went *en masse* to the hall where the competition was taking place under the presidency of Professor Blanchard, and became so uproarious by their stamps, shouts, groans, and hisses, intermingled with cries of "*Démission!*" (resignation), that the jury had to adjourn the sitting to a room in another part of the building, where the competition was continued with closed doors, which I am informed were in danger of being forced by the pressure of the *manifestants*, against whom they were shut. It is stated that Professor Brouardel, dean of the faculty, does not possess the moral authority necessary to maintain order among the students and insure harmony among his colleagues, and so another dean in his place is being spoken of.

It would seem that alkalies of which bicarbonate of sodium is the type are not innocent, especially when used in the large doses that are indicated in the treatment of some dyspeptic states. Bicarbonate of sodium in excessive doses may neutralize to a certain extent the muriatic acid contained in the stomach in hyperchlorhydria, but does not possess sufficient power over the glandular system to diminish notably the secretion. Moreover, its long-continued use in massive doses may produce the very hyperchlorhydria it is intended to cure. This is the opinion of Professor Hayem, an opinion which is strongly contested by perhaps the majority of practitioners. Personally, I have never found the least inconvenience from giving bicarbonate of sodium in such cases for a long-continued period, either in small or large doses. A very good way of administering it is to mix it with magnesia. This should be given at the time of or just before the usual attack of gastric pain or burning caused by HCl, irritating the mucous membrane of the stomach.

While on the subject of the alkalies, let me draw attention to their utility in the treatment of diabetes—fat diabetes as distinguished from thin or pancreatic diabetes. Of all the alkalies, Dr. Lemoine, professor of clinical medicine at the Faculty of Lille, makes choice of lithia, which he combines with antipyrin in equal doses of ten grains each three times a day—morning, noon, and evening—in a glass of alkaline water. This he prescribes when the case presents symptoms of intoxication and hepatic insufficiency, with diminished urinary secretion and scanty elimination of urea; in other words, when there is warning that diabetic coma may supervene. Whatever the case, the use of antipyrin is continued for two weeks, either as above prescribed or separately, and going as high as two and one-half or three grams a day divided into three doses, the patient drinking at the same time one gram of the carbonate or benzoate of lithia in a glass of some alkaline water at eleven in the morning and another gram in a like quantity of water in the evening at five o'clock. At the end of a week the quantity of antipyrin is diminished in accordance

with the amelioration obtained to one and one-half grams a day. If at the end of two weeks the glycosuria and concomitant symptoms, such as neuralgia, migraine, polyuria, and polydipsia, are alleviated or disappear, the antipyrin is stopped for one week, when a fresh period of two weeks is begun, at the end of which time the glycosuria usually disappears completely.

When there is no sugar in the urine, Dr. Lemoine gives the alkalies, pure and simple, as, for instance, benzoate of lithium and carbonate of lithium, each 50 cgm. (gr. viiss.), for one wafer. One wafer is given in the morning half an hour before breakfast and a second about five or six o'clock in the evening, each with a glass of alkaline water; for, he adds, diabetics are usually arthritics. This treatment, which is to be repeated as necessary two weeks at a time, during several consecutive months, usually causes the final disappearance of glycosuria.

If the nervous element predominates in the case, with disturbed rest at night, he supplements the treatment with bromide of potassium in a mixture with the phosphate of sodium as a tonic for the nervous system, as follows:

℞ Bromide of potassium..... 40 gm.
Phosphate of sodium ..... 10 "
Water ..... 300 "
M. Sig. Take one tablespoonful in a cup of milk or any infusion without sugar one hour before bedtime.

The use of the bromide should be continued about a month after the nights become calmer. The alkaline treatment of diabetes has been a favorite one in France for some years, and is based on its well-known favorable action upon the nutrition.

ELECTRICITY IN EXTRA-UTERINE PREGNANCY.

To the Editor of the Medical Record.

Sir: Dr. Boldt will pardon me if in this way I endeavor to correct a misapprehension in regard to the electrical treatment of ectopic gestation. In his paper entitled "A Clinical Contribution to Tubal Pregnancy," an abstract of which appears in the Medical Record of June 11th, he reports an interesting case of extra-uterine pregnancy in which a successful operation was performed during profound shock, and speaks of it as "serving to emphasize once more the utter unreliability of the electric current in the treatment of this condition."

I do not purpose to offer here any arguments in support of this method of treatment. We all know that it has been successfully attempted in many cases, and there are not a few who, if the conditions warranted, would much prefer this simple and easy process to the knife, if the patient was one of their own.

But the surgeons have decided against it, and it looks very much as if it had to go. If, unfortunately—as it seems to me—this must be, it is only fair that it should not be aided or hastened by a misunderstanding of the *modus operandi*. In this case of Dr. Boldt, previous to the final diagnosis there was supposed to be some endometritis, and to relieve this an intra-uterine application of fifty milliamperes was given; and, according to the report, the "embryo was not killed or the rupture would not have taken place."

Now fifty milliamperes is perhaps quite sufficient to destroy the embryo, if employed properly and with a definite purpose to that end; but used as in Dr. Boldt's case—an intra-uterine application without interruption for the relief of an endometritis—it was quite powerless. If the galvanic current is used, it is the shock produced by the interruptions that renders it effective, and it is altogether probable that if these fifty milliamperes had been thus used and the internal electrode properly placed for this result, the embryo would have been killed. If so, then, as Dr. Boldt acknowledges, the rupture would not have taken place. At all events it must be admitted that the case, as reported, does not by any means prove the unreliability of the electric current in tubal pregnancy.

A. D. Rockwell, M.D.

New York, June 11, 1898.

MAMMARY-GLAND THERAPEUTICS FOR FIBROIDS OF THE UTERUS.

To the Editor of the Medical Record.

Sir: In the report of the American Gynæcological Association in the Medical Record of June 4th, my remarks upon the extract of mammary gland in the treatment of fibroid tumors of the uterus were misquoted. I was speaking of the thyroid gland and not the mammary gland when I said that it acted as a powerful heart depressant, and that it should not be given in doses much exceeding three to six grains daily of the desiccated powder. The mammary gland, on the other hand, has, in my limited experience with it, given rise to no untoward systemic effects. I give of the desiccated powder or extract the equivalent of from thirty-six to seventy-two grains of the fresh gland daily (*i.e.*, six to twelve grains of the desiccated powder of Armour & Co.), and find that it causes the menstrual periods to become regular and normal, reducing the menorrhagia and metrorrhagia in a marked degree, and that the tumors slowly diminish in size. When the dose is pushed to seventy-two grains or over, marked cramps and contracting pains occur in the tumor. Without the aid of other forms of treatment the general health of the patients improves.

John B. Shober, M.D.

Philadelphia, Pa.

FOREIGN BODIES IN THE NOSE.

To the Editor of the Medical Record.

Sir: To the very practical directions of Dr. Barret's paper in the Medical Record of June 11, 1898, I would add that in many cases a foreign body in the nostril may be expelled by closing the other nostril and blowing suddenly and strongly into the child's mouth. It is the work of an instant, requires no restraint, and does not scare the child. John Winslow, M.D.

Ithaca, N. Y.

Cycling and Traumatic Urethritis. — Dr. De Keersmäcker, in *Le Scapel*, October 3, 1897, reports an absolutely characteristic case of purulent traumatic urethritis caused by the friction of a hard saddle on the perineum. The victim was a young man who, four days after a ride of about one hundred kilometres on a saddle without elasticity and of the ordinary shape, which exercised a constant friction, was attacked with a discharge not containing gonococci. This disappeared at the end of fourteen or fifteen days, during which the patient used astringent injections of sulphate of zinc. Dr. De Keersmäcker insists on the advisability of a saddle so constructed as not to come in contact with the perineum. This contact can be avoided by a saddle so planned that a metal frame will support two cushions, which will come in contact with the ischiatic tuberosities, a wide deep groove being left between them. The writer thinks that in all cases of diseases of the urethra, testicles, prostate, or bladder, however mild they may be, it is prudent to advise abstinence from the bicycle. Sudden relapses, inexplicable in any other way, during treatment for chronic urethritis, he has attributed to this form of exercise.

Medical Items.

Contagious Diseases Weekly Statement.—Report of cases and deaths from contagious diseases reported to the department of health, borough of Manhattan, for the week ending June 18, 1898:

	Cases.	Deaths.
Tuberculosis	217	158
Typhoid fever	25	2
Scarlet fever	142	17
Measles	334	22
Diphtheria	162	22
Laryngeal diphtheria (croup)	13	9
Chicken-pox	19	0
Cerebro-spinal meningitis	0	7

Immunity of Arabs to Typhoid Fever.—M. Vincent (Val-de-Grace) stated, at a meeting of the Academy of Medicine held in Paris on May 10th, that he has found that French soldiers are on the average a hundred times more subject to typhoid fever than native soldiers; a singular observation, because this disease is in general serious when it attacks Arabs. The comparative exemption of the Arabs depends, in his opinion, neither on a previous attack nor on a slow acclimatization consequent on residence in towns, but on a natural immunity comparable to the immunity of negroes against yellow fever or of Algerian sheep against anthrax. M. Vincent endeavored to discover if the blood obtained from Arabs caused agglutination of typhoid bacilli. The blood of twenty-three natives was used for that purpose, but it presented no distinct serum reaction, the phenomena being exactly the same as those yielded by the blood of persons susceptible to typhoid fever. This constitutes a new proof that the agglutinating power of blood is not necessarily connected with immunity, whether natural or acquired, and that the serum reaction is a reaction of infection and perhaps of defence, but not a reaction of immunity. —*The Lancet.*

Typhus Bacillus to Replace the Cat Corps in the German Army.—"We always study with pleasure any new points in the present *régime* of the German empire," says *The Bookman*, "for there is always sure to be found on every side a delightful blend of scientific thoroughness with a most fascinating lack of humor. One item of news recently wafted across the ocean has greatly tickled our fancy. It appears that the Kaiser's military establishment has for some time included a regularly organized corps of cats, whose function it is to protect the military stores from mice. These cats are trained in their duties by the inevitable drill-sergeant, they wear badges, receive rations and medical attendance, and draw annual pay, amounting to the sum of eighteen marks per cat. Now the announcement is officially made that this corps is to be disbanded, inasmuch as Professor Loeffler has discovered a species of typhus bacillus which is fatal to mice and whose services will in consequence be substituted for those of the cats. Probably no German sees anything comical in this bulletin, but to the American mind the whole thing is simply delicious. One involuntarily finds himself dwelling upon the little incidents that are implied in it. We love to picture the military cat, after passing the physical examination and being mustered in, donning his badge and reporting for duty. We joyfully imagine the same cat drawing his daily rations of milk and cat's meat; of the cat gravely saluting the 'schneidig' officer in the barrack yard; of the cat lining up at the paymaster's for his quarterly wages; of the cat applying for a few hours' leave of absence and riotously squandering his pay on unlimited catsup, and then failing to return to the caserne at roll call; of the cat inebriated and uttering seditious yowls opposite the officers' club; and of the cat, bedraggled, headachy, and repentant, being haled at last before a court martial for constructive desertion and 'Majestäts Beleidigung.' It is all fine, wonderfully fine. But what we really want is some official information as to how much pay the typhus bacillus is going to draw and also whether it will wear a badge."

Health Reports.—The following statistics concerning small-pox, yellow fever, cholera, and plague have been received in the office of the supervising surgeon-general of the Marine Hospital service during the week ending June 18, 1898:

		Cases.	Deaths.
Small-Pox—United States.			
Texas, El Paso	June 11th	3	
West Virginia, Benwood	June 4th	1	
Wisconsin, Wausau	May 19th	1	
North Carolina, Statesville	June 11th	11	
Small-Pox—Foreign.			
Brazil, Pernambuco	April 15th to 23d	1	
China, Hoog Kong	April 23d to 30th	4	1
Germany, Hamburg	May 21st to 28th	1	
India, Bombay	May 10th to 17th	..	2
Calcutta	April 30th to May 7th	..	7
India, Madras	May 7th to 13th	..	5
Japan, Akita	April 29th to May 19th	2	
Awomori	April 29th to May 19th	27	8
Fukuoka	April 29th to May 19th	1	
Fukushima	April 29th to May 19th	22	8
Hiogo	April 29th to May 19th	1	
Ishikawa	April 29th to May 19th	2	
Iwate	April 29th to May 19th	5	
Miyazaki	April 29th to May 19th	24	7
Nagano	April 29th to May 19th	1	
Nagasaki	April 29th to May 19th	1	
Nara	April 29th to May 19th	1	
Shidzuoka	April 29th to May 19th	2	
Tokushima	April 29th to May 19th	2	
Yamagata	April 29th to May 19th	2	1
Yehime	April 29th to May 19th	3	
The Hokkaido	April 29th to May 19th	11	3
Russia, Moscow	May 7th to 14th	2	3
Odessa	May 21st to 28th	7	
St. Petersburg	May 21st to 28th	14	3
Yellow Fever—United States.			
Mississipi, McHenry	May 20th to June 13th	15	
Yellow Fever—Foreign.			
Brazil, Rio de Janeiro	April 30th to May 6th	78	54
Cholera.			
India, Bombay	May 10th to 17th	..	4
Calcutta	April 30th to May 7th	..	16
Japan, Kanagawa	April 29th to May 19th	6	5
Okayama	April 29th to May 19th	1	
Tokyo	April 29th to May 19th	1	
Plague.			
India, Bombay	May 10th to 17th	.	107
Calcutta	April 30th to May 7th	..	16
Japan, Taiwan (Formosa)	April 29th to May 19th	2,223	1,421

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DISEASES OF THE STOMACH. Second Revised Edition. By Dr. Max Einhorn. 8vo, 480 pages. Illustrated. William Wood and Company, New York.

METHODIST EPISCOPAL HOSPITAL REPORTS. Vol. I. Edited by Dr. L. S. Pilcher and Dr. G. R. Butler. 8vo, 563 pages. Illustrated.

APHASIA AND OTHER SPEECH DEFECTS. By Dr. H. C. Bastian. 8vo, 366 pages. Illustrated. D. Appleton and Company, New York.

DISEASES OF THE LARYNX. By Dr. L. Grünwald. Edited by Dr. C. P. Grayson. 8vo. Illustrated. W. B. Saunders, Philadelphia. Price, $3.50 net.

RHEUMATOID ARTHRITIS. By Dr. G. A. Bannatyne. Second Edition. 8vo, 182 pages. Illustrated. J. Wright & Co., Bristol. Price, 7s. 6d. net.

YELLOW FEVER. By Dr. Just Touatre. Translated by Dr. C. Chassaignac 8vo, 206 pages. New Orleans Medical and Surgical Journal, New Orleans.

ATLAS OF LEGAL MEDICINE. By Dr. E. Von Hofmann. Edited by Dr. F. Peterson, assisted by Dr. A. O. J. Kelly. 8vo. Illustrated. W. B. Saunders, Philadelphia.

PROCEEDINGS OF THE DEDICATION OF THE HUNT MEMORIAL BUILDING. 8vo, 48 pages. Illustrated.

INDEX.

A

Abbe, Robert, new plastic operation for the relief of deformity due to double harelip, 477.
Abbott, A. C., notice of book by, 244.
Abdomen, abscess containing a gallon and a half in the—laparotomy—recovery, 310; stab wound of the, 744; unusual anatomical conditions in the, disclosed by section, 531.
Abdominal cavity, foreign bodies removed from the, 497; section as a medical measure, 460; section, statistics of, in America, 69, 142; surgery, golden rules of, 104.
Abortion, syphilis as a cause of, 284.
Abrahams, R., clinical miscellany, 316.
Acclimatization in the tropics, 737.
Accouchement forcé in the light of modern experience, 471.
Accountability of the physician, 576.
Acne, application for, 250.
Acromegaly, a case of, 570.
Actinomycosis, 171.
Adenoids, pharyngeal, 817; anæsthesia in operating on, 589; forceps and curette for the removal of, 575.
Adirondacks, 760.
Adolescence, albuminuria of, 170.
Adulteration of food in Connecticut, 58.
Age, influence of, in surgical affections, 892.
Albany Medical College Alumni of Greater New York, 32; dinner of the, 163.
Albumin, eclamptic, 180; oxyphenylsulphonic acid as a test for, 483.
Albuminuria, diabetic, treatment of, 771; in dyspeptics, 138; significance of, in otherwise healthy persons, 173.
Albumose in the urine, test for, 628.
Albumose, spontaneous precipitation of, 790.
Alcohol as a hypnotic, 502; consumption of, in the United States, 106; effect of excess in the use of, on occupational mortality, 503; injections of, in carcinoma, 105; medical use of, 33.
Aldersmith, H., notice of book by, 491.
Alexander operation, some points in the technique of, 170.
Alger, Ellice M., on cutaneous burns, 766.
Alimentary canal, relation of bacteria to the normal, 169.
Alkalies, dangers of, 949.
Allen, Charles W., electrolysis in dermatology, 927.
Allbutt, Thomas Clifford, notice of book edited by, 59, 420.
Allport, Frank, a new aseptic ear syringe, 540.
Almshouses in Massachusetts, 521.
Alopecia areata, treatment of, 248; see also *Baldness*.
Amaurosis, alcoholic, from wood alcohol, 776.
Amazia, congenital, 282.
Ambulance service, ups and downs of the, 288.
Ambulance ship *Solace*, 698.
American Academy of Medicine, 943,
American Dermatological Society, 848.
American Gastro-Enterological Association, 740.
American Gynecological Society, 819, 852.
American Laryngological Association, 813,
American Medical Association, 849, 889, 943; Section on Practice of Medicine, 913; Section on Obstetrics and Diseases of Women, 904; Section on Surgery and Anatomy, 892.
American Pediatric Society, 849.
Amidon, Royal W., the cheat of charity, 34.
Amputation at the shoulder-joint for sarcoma of the humerus, 616; interscapulo-thoracic, 606.
Anæmia, 167.
Anæsthesia, antiquity of surgical, 236; "gas and ether," 296; local, 104, 501, 677; nitrous oxide and ether for, 456; Obersts' method of local, 412; prevention of vomiting after, 138; Schleich's method of general, 62, 205, 214, 358, 500, 504, 816, 823, 843; Schleich's method of local, indications and contraindications for, 340.
Anæsthetics in the London hospitals in 1897, 503; use of, 518.
Anæsthetist, relation of the operator to the, 230.
Anastomosis, intestinal, 232, 541, 566, 678, 895, 897; *The Lancet* on, 127.
Anatomical data, method of recording, by the card catalogue system, 749.
Anders, James M., notice of book by, 242.
Andrews, Gwendolin Foulke, notice of book by, 244.
Aneurism, dissecting, 498; gelatin injections for, 624; of the arch of the aorta, 747, 750; of the arch of the aorta, ligation of the right carotid and subclavian arteries for, 895; of the basilar artery, 567; rupture of an aortic, into the bronchus, 484.
Anger a disease, 610.
Angina pectoris, 49.
Animal diseases communicable to man, 302, 413; extracts, rational therapeutics of some of the, 784.
Anthrax in Pennsylvania, 58; pulmonary, 180; spores, vitality of, 412.
Antipyrin as a local anæsthetic, 501.
Antiseptic or germicidal treatment of disease, 741.
Antiseptics, new, 538.
Antistreptococcic serum, 774; in obstetrics, 853.
Antrum, fracture and depression of the anterior wall of the maxillary, 815.
Anus, operations on the, 855; painful fissure of the, 123.
Aorta, aneurism of the ascending arch of the, 747; rupture of, in anger, 36.
Aphasia, treatment of, 79.
Aphonia, hysterical, 313.
Aphtha, Bednar's, 52.
Apoplexy, operation for, 567.
Appendicectomy, 478.
Appendicitis, 171, 582; a modified incision at the outer border of the rectus muscle for, 321, 359; and localized tuberculous peritonitis, 350; correspondence between a layman and a surgeon on the subject of, 728; early views of, 359; fæcal fistula following operation for, 349, 744; in pregnancy and the puerperium, 888; origin of, 478; perforating, in an infant, 600; spurious, 273; treatment of, 898; volvulus simulating, 531.
Appendix, abscess of the, 498; condition of the, in intervals of inflammation, 856; intestinal parasites in the, 350; morbid conditions found in the, 195; perforation of the, in typhoid fever, 924; removal of the, cœliotomy for secondary pelvic abscess followed by fæcal fistula, intestinal resection in the same patient, 806; specimens showing disease of, prior to the onset of grave attacks, 100.
Appetite, to stimulate the, 16.
Archibald, Dr., death of, 776.
Arm, amputation of, for evulsion of forearm, 349.
Army, appointment of acting assistant surgeons in the, 488; medical service, British, 250, 605, 790; sanitary condition of the, 90, 847; surgeons, volunteer, 667.
Arrhythmia, rare cases of, 918.
Arsenic, neuritis and atrophy following acute poisoning by, 99.
Arteries of the forearm, unusual condition of the, 879.
Arthritis deformans, 495; deformans, the syndrome of chronic, 88; surgical treatment of acute rheumatic, 268.
Arthropathy, treatment of, by hot air, 746.
Ascites, formula for, 16.
Association of American Anatomists, 417.
Association of American Medical Colleges, 946.
Association of American Physicians, 709.
Asthma associated with emphysema, treatment of, 426; dyspeptic, 589; theories of, 605; treatment of, 425, 426, 643, 644.
Astoria Hospital, closure of the, 489, 573.
Atkinson, Thomas H., death of, 271, 272.
Atlantic City, N. J., 759.
Atlantic City (N. J.) Academy of Medicine, officers of the, 416.
Atlantic County (N. J.) Medical Society, officers of the, 416.
Atwater, W. O., notice of book by, 243.
Augur, F. A., forward dislocation of both bones of the forearm, 314.
Australia, heat in, 504.
Autoscope, Kirstein's, 814.
Axilla, primary carcinoma of the, 895.
Axillary artery, incised wound of the, 282.

B

Babcock, Warren L., hemilingual atrophy with coexisting bulbar symptoms associated with insanity other than general paralysis, 446.
Baby incubators in England, 415.
Bacillus aerogenes capsulatus, recovery after pure infection with the, 205; aerogenes found in various affections, 351; relation of a new anaerobic, to botulism, 661.
Bacteria of the vagina and their significance, 824.
Bacterial infection, 712.
Bailey, Thomas B., death of, 344.
Bailey, W. O., vaginal cœliotomy considered as an approach for the removal of multiple uterine myomata, 41.
Baldness in women, 792; the microbe of, 738.
Ball, James B., notice of book by, 634.
Ball, M. V., notice of book by, 61.
Baltimore, quarantine physician for, 453.
Bar Harbor, 765.
Barber surgeon, story of a, 503.
Barlow, C., notice of book by, 919.
Barnes, Albert C., symptomatology and treatment of the common clinical forms of lithæmia, 439.
Barnet, S. Amelia, death of, 20.
Barret, R. D., foreign bodies in the ear or nose, 841.
Bashore, Harvey B., how to prevent typhoid fever in rural districts, 87; notice of book by, 383.
Baths, 143; fever patients, simple mode of giving, 71; importance of public, 647; public, in European and American cities, 784.
Battleship, some of the disadvantages of a modern, 197.
Beaussenat, Dr., notice of book by, 242.
Bednar's aphtha, 52.
Bees, poison of, 591.
Behla, Robert, notice of book by, 244.
Bellevue Hospital, early history of, 107.
Bellevue Hospital Medical College, resignations from the faculty of, 845.
Benedict, F. G., notice of book by, 243
Bennett, Thomas L., anæsthesia—"gas and ether," 296.
Berg, Henry W., the serum exanthemata observed in the antitoxin treatment of diphtheria; their pathogenesis and probable prevention, 865, 885.

Berkshire Hills, 764.
Berlin, letters from, 33, 141, 357, 461, 682; life-saving society in, 33; municipal board of health for, 668.
Bernay sponge in the nose and nasopharynx as a hæmostatic, 814.
Bernays, A. C., my recent work in appendicectomy, 478.
Bernhardt, Sara, operation upon, 307.
Berry, Charles White, placenta prævia, 599.
Berry, Jane L., an epidemic of diphtheria, demonstrating in a marked degree its contagious nature and the value of immunization, 217.
Bertine, Louis E., death of, 888.
Besnier, Ernest, notice of book by, 382.
Bevan, Charles F., extragenital lesions of syphilis, 364.
Bicêtre, proposed sale of the, 56.
Bickham, Dr., death of, 271.
Bicycle, see *Cycle*.
Bile pigment, delicate test for, 628; tracts, surgical anatomy of the, 893.
Billings, John H., healthy offspring of syphilitic parents, 532.
Bitter drug, to disguise the taste of a, 643.
Black book, a physician's, in Paris, 107.
Black Hills Medical Society, 740.
Bladder, apparatus for irrigation of the, 786; comparative frequency of stone in the, in the white and negro races, 18; tuberculosis of the, 827
Blauberg, Magnus, notice of book by, 95.
Bleeding, therapeutical action of, 103.
Blood, chloride-of-ammonium process for the detection of uric acid in the, 536; count of the cells of the, in anæmia and certain nervous affections, 933; free leucocytic granules in the, 746, method of counting the cells of the, 209; method of obtaining, for bacteriological examinations, 747; pathological physiology of coagulation of the, 135, practical hints for examination of the, 208, quantity of ammonia in human, under physiological and pathological conditions, 88; results of bacteriological examination of the, 592.
Board of Health, changes in the 487.
Boas, I., notice of book by, 920.
Bogert, E. S., the naval ambulance ship *Solace*—her purpose and construction, 698.
Boils, treatment of, 642.
Boldt, H. J., a reply to Dr. Vineberg—abdominal hysterectomy—acute puerperal sepsis, 571.
Bollinger, O., notice of book by, 919.
Bonds, United States, 927.
Bone-setting in rural England, 570.
Book Notices:
Acromegalia nei suoi rapporti coll' organo visivo, per F. Denti, 61.
Air, food, and exercises, by A. Rabagliati, 947.
Alkohols, therapeutischer Wert des, bei acuten Krankheiten, von B. Kantorowiez, 922.

Scarification by Vidal's instrument, 642.
Scarlet fever a local disease, 86; nursing directions for, 213.
Schäfer, E. A., notice of book edited by, 919.
Schleich method of general anæsthesia, 504, 607, 816, 823, 843; of local anæsthesia, 340.
Schneller, E. W., congenital amazia, 282.
Schools, medical inspection of, 783; medical inspection of, in Germany, 141; physical training in the public, 414.
Schott, Theodor, treatment of chronic diseases of the heart in the light of Roentgen rays, 436.
v. Schroeder, Waldemar, death of, 451.
Schürmayer, B., notice of book by, 492, 561.
Schwimmer, Ernest, death of, 487.
Sciatica, treatment of, 212, 644.
Science, progress of, in the future, 324.
Scleroderma, diffuse symmetrical, with marked muscular atrophy, 880; salol for, 643.
Scripture, E. W., notice of book by, 59; reaction time in abnormal conditions of the nervous system, 196.
Scudder, Charles L., middle meningeal hemorrhage in a woman, sixty-nine years old; operation; recovery, 876.
Scurvy, Captain Cook's contribution to the prevention of, 611; infantile, 532, 853.
Sea water, electrolyzed, as a disinfectant, 323; intravenous injections of, 214.
Seborrhœa capitis, treatment of, 425.
Seguin, Edward Constant, obituary of, 309; resolutions on the death of, 452; the will of, 343.
Semilunar cartilage, dislocation of the, 105
Seminal emissions, thuja for, 644.
Senn, N., notice of book by, 60.
Senn prize medal, 238.
Sepsis, puerperal, 824; puerperal, abdominal hysterectomy for, 387, 463, 571, 886; puerperal, gonorrhœa as a factor in, 912; puerperal, serum therapy of, 313, 462, 853.
Septicæmia following an injection of antistreptococcus serum, 500.
Septum, cartilaginous nasal, Asch operation for deviations of the, 190, 206.
Serpent venom, cholesterin and biliary salts as chemical vaccines against, 660; suprarenal bodies antidotal to, 681.
Serum, antistreptococcic, 774, 853; concentration of therapeutic, by freezing, 36; exanthemata following the use of, in diphtheria, 865, 885; therapeutic, testing, 19; therapy, the possibilities and limitations of, 839.
Sewage, disposal of, 784.
Sex and population, 468; determination of, 199, 357, 667; influence of, in surgical affections, 892.
Shaffer, Newton M., notice of book by, 922.
Sharon Springs, 761.
Shattuck, Frederick C., some remarks on hospital abuse, 649.
Sheffield, Herman B., pyæmia in a boy thirteen years old, 375.
Shepherd, W. G., death of, 716.
Sherow, Edward J., death of, 58.
Shober, John B., mammary-gland therapeutics for fibroids of the uterus, 950.
Shock, operation during, 857; pathology of, 449; prognostic significance of rapid pulse in, 106.
Shoemaker, J. V., notice of book by, 382.
Shoes for the troops, 882.
Shoulder, congenital backward dislocation of the, 172; examination of the, for injury, 540.
Sigmoid flexure, local examination and treatment of diseases of the, 525; resection of, for carcinoma, 347.
Sigmoidostomy, 606.
Simmons, Dr., painful accident to, 882.
Simon, Charles E., notice of book by, 61.
Simon, Saling, the relation of the operator to the anæsthetist, 230.
Singers, hoarseness of, 816.
Sinus, frontal, operative treatment of inflammation of the, 818.
Skaguay Hospital, 632.
Skin, burns of the, 766; changes in the, in acute rheumatism, 734; disorders of sensation in the, in visceral disease, 675; electrolysis in the treatment of diseases of the, 798; grafting after removal of lupus of the face, 203; grafting, new method of, 877; removal of pigment blemishes of the, 426.
Skin and Cancer Hospital, opening of the new building of the, 380, 524.
Skirts, sanitary, 396.
Skull, fractures of the base of the, 105; osteoplastic resection of the, 802.
Slander of a physician, 812.
Slater, D. J., death of, 428.
Sleep, 127; observations on, 431.
Sleeping-sickness, bacteriology of, 592; in Africa, 828.
Small-pox in Cuba, 163; in England, 391, 460, 682; in the South, 56, 240, 488.
Smegma bacillus, 854; culture media for, 736.
Smith, George W., a liver with sixteen lobes, 791.
Smith, Noble, notice of book by, 418.
Smoking among women in England, 609; early writers on, 199.
Snakes as domestic pets, 144.

Tarnier, Professor, death of, 22; tribute to the memory of, 103.
Taxing medical men, 669.
Taylor, Alfred S., notice of book by, 96.
Taylor, Robert Hibbert, death of, 251.
Taylor, Robert W., notice of book by, 420.
Telephones for hospital patients, 165.
Temperature, causes of subnormal, 483; long-continued abnormally low, 640.
Tendon suture, preparation and use of, 901.
Test, Frederick Cleveland, floating kidney, 878.
Testicles and prostate, relationship between, 483; epididymectomy in tuberculosis of the, 136.
Testifying against each other, 449.
Tetanus, antitoxic properties of the normal central nervous system in, 376; serum therapy in, 539.
Tetany in childhood, 482; treatment of infantile, 248.
Texas State Medical Association, 945.
Thayer, W. S., mixed typhoid and malarial infections, 632; notice of book by, 490.
Therapeutics, some modern outlooks in, 665.
Thermal springs, earliest recorded discovery of, 941.
Thermometry, 107.
Thermometers, the first, 502.
Thiersch's solution, 248.
Thin, George, notice of book by, 418.
Thompson, Lloyd O., the conditions of medical practice in France, 130.
Thompson, W. Gilman, immunity: recent theories viewed from the clinical standpoint, 37, 99; notice of book edited by, 635.
Thomson, W. H., a case of acute leukæmia, 333.
Thought, rapidity of, 612.
Throat, use of Schleich's solutions for anæsthesia in operations on the, 816.
Thrombosis of the femoral vein following pneumonia, 340; pathological physiology of, 135.
Thyroid, 809; congestion in young men, 628; extract, indications for, 250; extract in the treatment of uterine fibroids, 826; feeding in insanity, 267; gland, functions of the, 157; gland, syphilis of the, 706; treatment of sporadic cretinism, 493.
Thyroidectomy for calcified cyst, 603.
Tic rotatoire, 482.
Tinnitus aurium from quinine, prevention of, 16.
Tollemer, Dr., notice of book by, 492.
Tongue, coating of the, 627; dry, chewing gum for, 643; hemiatrophy of the, with coexisting bulbar symptoms associated with insanity other than general paralysis, 446.
Tonic, a general, 212.
Tonsil, enlargement of the lingual, as a cause of cough, 814; pharyngeal, importance of the early recognition of enlargements of the, 745; tuberculosis of the, 827; tumor of the, 105.
Tonsillitis, follicular, gargle for, 212.
Tooth, supernumerary, in the palatine vault, 313.
Torticollis, spasmodic, treatment of, 225.
Tourniquet, a new field, 609.
Trachea, injections into the, for diseases of the bronchial tubes and lungs, 207.
Transports, disinfection of, 883.
Treatment, non-medicinal methods of, 648.
Tri-State Medical Society, 669.
Tropics, acclimatization in the, 737.
Truax, John Gilbert, death of, 272; resolutions on the death of, 344, 380.
Trudeau, E. L., the tuberculin test, 926.
Tubercle bacilli in butter, 482.
Tuberculin, as a test of cure, 724, 926; Auclair's experiments with, 137; in dermatology, 268; report on, 358.
Tuberculosis and chronic syphilitic fever, error in diagnosis between, 710; antitubercle serum in, 529; cinnamic acid for, 643; climatic treatment of, 707; commission and congress for the study of, 489; communicable from animals to man, 302; control of, in Denmark, 812; creosote in, 70; curability of, 924; heredity alone not a sufficient cause of, 924; immunity against, in high latitudes, 915; in children, treatment of, 249; inoculation, 348; laryngo-tracheal, 813; meningeal, simulating opium poisoning, 591; miliary, 461; notification of, 163; nursing in, 201; of the uterine adnexa, 556; of the uterus and tubes, treatment of, 742; peritoneal, surgery of, 475, 863; personal observations in pulmonary, 688; report of the royal commission on, 751; serum treatment of, 715; spread of, by meat and milk, 180; state sanatoria for, 743; the blood in, 854; tonsillar, 827; turpentine in, 130; vesical, 827.
Turkey, practice of medicine in, 610.
Turkish losses in the Greek war, 739.
Turner, Dawson, notice of book by, 634.
Typhoid and malarial infections, mixed, 632.
Typhoid fever, abortive treatment of, 147, 277; atypical case of, 600; bacteriological diagnosis of, 935; clinical value of the Widal test for, 519; cold-water treatment of, in private practice, 168; endemic, 90; epidemics of, in England, 33, 68, 93, 102, 140, 176, 286, 288; hydrotherapy in the treatment of, 314; intestinal features of, 304; in the aged, 289; perforation of the appendix in, 924; prevention of, 164, 177; prevention of, in rural districts, 87; relation of sewerage to the mortality from, 791; serum diagnosis of, 304; treatment of, 665; treatment of hemorrhage in, 644; waterborne, 592; Widal test for, 101, 138.
Typhus fever in London, 645.

U

Uchermann, V., notice of book by, 61.
Ulcer, gastric, 104, 535; gastric, enterostomy for, 661; indolent, application for, 32; of the leg, treatment of chronic, 592.
University Medical College, trouble in the, 560, 704, 775.
Uræmia in childbearing, 855; treatment of, 213; washing the blood in acute, 300.
Urachus, cysts of the, 948.
Uranalysis of the six-day bicycle racers, 156.
Ureters, catheterization of the male, 271; hemorrhage in catheterization of the 571; separation of urine coming from each, 805, 896, stricture of the right and early tuberculosis of the kidney, nephrectomy for, 193.
Urethra, apparatus for irrigation of the, 736; indications for resection of the, 776; stone impacted in the, from childhood, 204; stricture of the, electrolysis in the treatment of, 554; stricture of the, in a young boy, 778; treatment of rupture of the posterior, 539; treatment of stricture of the, 483; treatment of stricture of the, by continuous elastic dilatation, 169.
Urethrectomies, 662.
Uric acid, chloride-of-ammonium process for the detection of, in the blood, 536; diathesis, 713; new, rapid, and accurate method of estimating, 373, 633.
Urinary infections, bacteriological study of, 745.
Urine, bacterium coli commune in the, and its significance, 53; carbon dioxide in the, 694; effect of sulphur in the, 108; from the two kidneys, separate collection of the, 805, 896; gas in the, 902, 912; in pneumonia, 676; spontaneous precipitation of albumose in, 790; test for hæmatoporphyrin in the, 287.
Urino-glucosometer, 753.
Uropoiesis and faradization of the liver, 736.
Urotic acid, 674.
Urticaria, application for, 213.
Uterine appendages, conservative operations on the, 826.
Uterus, acute inversion of the, 887; aluminium acetate in hemorrhage of the, 426; an unusual case of sarcoma of the, 670; blood casts of the, 386; curettage of the, in acute infection with adherent placenta, 911; curettage of the, in tubal disease, 911; displacements of, not pathological, 638, 793; duplex, pregnancy in a woman with, 388; early operation for lacerated cervix, 855; enucleation of a large interstitial fibroid of the, without hysterectomy, 26; epithelioma lymphangiomatodes of the cervix, 853; fibroids of the, 562; fibroids of, simulating pregnancy, 533; incarcerated pregnant, operation for the relief of, 823; inertia of the, during labor, use of ergot to overcome, 782; needle for operations on the cervix, 106, 431; operative treatment of cancer of the, 855; pregnancy following ventro-fixation of, 820; remote consequences of extensive hemorrhage from the, 170; rupture of the, bacillus aerogenes in, 351; spontaneous rupture of the, before term, 303; treatment of adherent, through the posterior vaginal cul-de-sac, 820; treatment of fibroids of the 743, 825, 950; treatment of hemorrhage from fibroids, 212; treatment of retrodisplacements of the, 904; treatment of tuberculosis of the, 742; tuberculosis of the adnexa, 556; vaginal cœliotomy considered as an approach for the removal of multiple myomata, 41.

V

Vaccination, compulsory, 22; glycerinated lymph for, 177; in Japan, 108; necessity of repeated, 783; parliamentary bill regarding, 828; shield, 684.
Vagina, antisepsis of the, 249; bacteria of the, and their significance, 824; instrument for establishing drainage of the, 26; irrigation of the, 808.
Valentine, Ferd. C., several new genito-urinary instruments, 572.
Van Duyn, S. W., death of, 200.
Van Santvoord, R., some interesting cases of brain injury, etc., 613.
Van Sawn, John D., death of, 560.
Van Vleck, William J., death of, 129.
Varicosities, 447.
Variot, G., notice of book by, 492.
Vasectomy for some forms of vesical fistulæ associated with enlarged prostate, 539.
